Series Foreword

With the rapid evolution of highly sophisticated computers, communications, service, and manufacturing systems, a major shift has occurred in the way people use and work with technology. The objective of this series on human factors and ergonomics is to provide researchers and practitioners alike with a platform through which to address a succession of human factors disciplines associated with advancing technologies, by reviewing seminal works in the field, discussing the current status of major topics, and providing a starting point to focus future research in these ever evolving disciplines. The guiding vision behind this series is that human factors and ergonomics should play a preeminent role in ensuring that emerging technologies provide increased productivity, quality, satisfaction, safety, and health in the context of the “Information Society.”

The present volume is published at a very opportune time. Now more than ever technology is becoming pervasive in every aspect of the Information Society, both in the workplace and in everyday life activities. The field of virtual environments (VEs) emerged some 40 years ago as a very exotic, extremely expensive technology whose use was difficult to justify. The discipline has matured, and the cost of VE technology has decreased by over 100-fold, while computer speed has increased by over 1,000 fold, which makes it a very effective and viable technology to use in a broad spectrum of applications, from personnel training to task design. With this viability and broad potential application come numerous issues and opportunities, and a responsibility on the part of researchers, practitioners, designers, and users of this powerful technology to ensure that it is deployed appropriately.

The *Handbook of Virtual Environments* was guided by a distinguished advisory board of scholars and practitioners, who assisted the editor in ensuring a balanced coverage of the entire spectrum of issues related to VE technology, from fundamental science and technology to VE applications. This was achieved in a thorough and stimulating presentation, covered in 56 chapters, authored by 121 individuals from academia, industry, and government laboratories from Europe, Asia and the United States on topics of system requirements (including hardware and software), design and evaluation methods, and an extensive discussion of applications. All this was presented, after careful peer reviews, to the publisher in 1,911 manuscript pages, including 3,012 references for further in-depth reading, 255 figures, and 76 tables to illustrate concepts, methods, and applications. Thus, this handbook provides a most comprehensive account of the state of the art in virtual environments, which will serve as an invaluable source of reference for practitioners, researchers, and students in this rapidly evolving discipline.

This could not have been achieved without the diligence and insightful work of the editor and cooperative efforts of the chapter authors who have made it all possible. For this, my sincere thanks and appreciation go to all of you.

—Gavriel Salvendy
Series Editor

Foreword

An explosion has occurred in recent years in our understanding of virtual environments (VEs) and in the technologies required to produce them. Virtual environments, as a way for humans to interact with machines and with complex information sets, will become commonplace in our increasingly technological world. In order for this to be practical, multimodal system requirements must be developed and design approaches must be addressed. Potential health and safety risks associated with VE systems must be fully understood and taken into account. Finally, ergonomic and psychological concerns must be investigated so people will enjoy using VE technology, be comfortable using it, and seek out its application.

This book provides an up-to-date discussion of the current research on virtual environments. It describes the current VE state of the art and points out the many areas where there is still work to be done. The *Handbook of Virtual Environments* provides an invaluable comprehensive reference for experts in the field, as well as for students and VE researchers. Both the theoretical and the practical side of VE technologies are explored.

The National Aeronautics and Space Administration (NASA) has long been interested in virtual environments. This interest arises from the need for humans to efficiently interact with complex spacecraft systems and to work with very large data sets generated by satellites. In the future, when humans travel beyond low Earth orbit to explore the universe, the relationship between the space-faring crew and the technologies they bring with them must be extremely intimate. The need for a small number of people to be able to work with a huge number of different technologies will be unprecedented. Virtual environment trainers, for example, are particularly attractive as a means of conducting just-in-time training before a crew member conducts a maintenance procedure not practiced for many months. In terrestrial applications, the complete life cycle for the design of complex systems such as aerospace vehicles will be completed virtually, before a single piece of metal is cut.

NASA's needs are unique in some respects but share much in common with other endeavors in today's world. Virtual environment technologies will also find military, medical, and commercial (e.g., in manufacturing and in entertainment) applications. As the science and technology of VEs progress, full-immersion technologies will likely become a standard interface between humans and machines. This book will help to make that vision a "real" reality.

Perspective

We read that we are in a new economy and that the pace of technological change is accelerating. This seems true because there are so many revolutionary innovations popping up. However, from the vantage of a given field, the picture can seem very different. It is over 35 years since Ivan Sutherland gave his address, “The Ultimate Display,” at the National Computer Conference. Part of the delay is explained by the observation that problems that are not worked on do not get solved. Only a few years ago, I could argue that progress in the field was being held back because the enabling devices being used—the Polhemus magnetic tracker, the DataGlove, and the screens from handheld consumer television sets—were invented decades earlier. No one ever disagreed with those assertions. Today, it is different. In the best “divide and conquer” tradition, researchers have deployed themselves around every possible research problem. All of the easy problems have been run over and very smart people are working on most of the hard problems. In this book, those same people are reporting where things stand.

In fact, at least one hard problem has been solved, at least in preliminary form. Thirty years ago, I considered head-mounted displays (HMDs), but reasoned that they would be unacceptable unless they were wireless and permitted natural ambulation around a large area. I rejected the approach—not because I thought it was too hard but because I felt that the encumbering paraphernalia would be too awkward. I did not then appreciate how fast and how accurate the tracking would have to be and understood little about multipath transmission problems and diversity receivers. After 20 years of effort, the University of North Carolina recently demonstrated a wide-area tracking system with the needed performance and reported that its impact on the user’s experience was every bit as powerful as one would hope it would be. Finally, it is possible to show what an HMD can do that no other display can.

A host of applications have been attempted in visualization, training, and entertainment. Even once unlikely opportunities have been gaining traction. In 1970, I received what I suspect was the first job offer in virtual reality. Dr. Arnold Ludwig came into my interactive installation and was so impressed with its impact on people’s behavior that he wanted me to join him in the Department of Psychiatry at the University of Kentucky and to focus my interactions on psychotherapy. Today, virtual therapy is a thriving field with nothing to fear but the running out of phobias.

However, many of these “applications” have been motivated by the desire to do research rather than the expectation that the results would be immediately practical. Some of these systems are being used to do real work within the organizations that created them. An even smaller number have been sold to early adopters. But virtual environment (VE) applications are

not yet being sucked into the marketplace by irresistible demand. Thus, while VE technology may be able to do a job, it is not yet recognized as the best or most cost effective way to do any job.

On the other hand, virtual environments have been unusually successful at spinning off its technology into adjacent fields even before it has gotten under way itself. Techniques for tracking human motion developed for VEs are now standard procedure in the film industry. Haptic devices are working their way into desktop and automotive systems. Virtual surgery, once a wild speculation, then a Defense Advanced Research Projects Agency (DARPA) program managed by Richard Satava, and now a nascent industry with publicly traded companies, is selling robotic surgical systems and surgical simulations to hospitals. Finally, the HMD has been incorporated into eyeglasses and has to be considered a competitor for the mobile display of the future.

In the background, Moore's law has continued to operate, assuring the increase in computer power and the advance of computer graphics. However, it is important to note that while the film industry routinely spends an hour computing a single frame of graphic animation, a VE system has only $\frac{1}{30}$ or $\frac{1}{60}$ of a second to create its necessarily simpler image. This is a 100,000:1 difference in time, or 16 doublings, or a 24-year lag between the time a state-of-the-art image appears in film and when a similarly complex image can be used in virtual environments. Mere doublings do not guarantee subjective improvement; only orders of magnitude are discernible. Nevertheless, we can be confident that ultimately the needed processing and graphics capacity will be readily affordable.

At that point, all that remains to be developed is the VE technology itself: the tracking, the displays, and an answer to the question that I posed well over a decade ago: Would you use it if it was free? Whatever you are willing to pay for a technology, once you own it, it is free. How much you choose to use it at this point determines its future as much as the economics of its purchase or the efficacy of its performance. If it is a pleasure to use, you will try to use it for everything you can think of. If it is awkward and uncomfortable, you will not use it for any task where it is not absolutely required. In fact, you will be looking for an alternative way to perform the tasks for which it is suited.

The question is: How good does it have to be? Not so long ago, I attended a conference at which the keynote speaker declared computer graphics to be the key to VE technology and that more realistic images would assure its success. I asked him, "If we turned out the lights, would we still be here?" The point was that graphic realism does not appear to be necessary or sufficient. It would seem simple to depict a dark, cloudy night—or just a dark room—with current graphic technology, but instinct suggests that the experience would not be convincing. There is still a long distance between depiction and illusion.

In visualization applications, believability is not so important. Training can be useful even if the experience is not totally persuasive. A game or a story can be entertaining even if the participant never suspends disbelief, but in each case, there is a threshold at which a technology goes beyond serviceable and becomes compelling. When this threshold is crossed, the technology is poised to go from being a niche solution to becoming a way of life.

It is not clear where critical mass will be reached first. Will one of the immersion applications take hold? Will a VE entertainment system supplant traditional video games? Or will the desire for portable wearable devices lead to the routine wearing of HMDs unobtrusively integrated with eyeglasses? At the moment, I would bet on the latter because the standards for success are so low. Text is easy to display. The screens on cell phones and handheld computers are too small. And while speech may be ideal for answering questions, it is too slow for presenting options. Only an eyeglass-mounted display can provide the full screen of information that we take for granted at the desktop. If popular, such limited devices would inevitably be used for gaming, just as cell phones are today. Head tracking would make those games more interactive,

if not more convincing, and augmented reality applications could be implemented in specific locations like grocery stores. More immersive displays could then evolve over a period of time, always assured of this installed base.

Starting from the other direction, real breakthroughs are needed in HMD design to provide immersive experiences that are guaranteed to work. A wide field of view and minimal weight are required before we can be confident that the HMD wearer will forget the apparatus and embrace the virtual world.

Whatever the path or pace of the technology and its deployment, virtual reality will maintain its proper role as the best metaphor for the world that is evolving around us. It will continue to be depicted in films and incorporated into everyday thought to the point that it is so familiar as a concept that by the time the real thing seeps into our daily lives, we may barely notice.

—Myron Krueger
President
Artificial Reality Corporation

Preface

When computers first permeated the public domain, thoughts of the Turing Test arose yet were quickly extinguished, as users labored over perplexing interfaces, which often left them bewildered and thoroughly frustrated. There had to be a better way, and so began the field of human-computer interaction (HCI). HCI efforts have substantially improved computer interaction, yet barriers to user friendliness still exist due to the abstract concepts that must be conquered to successfully use a computer. A user must work through an interface (e.g., window, menu, icon, or some other mechanism) to achieve desired goals. They cannot access these goals directly, but only through their interface surrogates. Until now.

Virtual environments (VEs) allow users to be immersed into three-dimensional digital worlds, surrounding them with tangible objects to be manipulated and venues to be traversed, which they experience from an egocentric perspective. Through the concrete and familiar, users can enact known perceptual and cognitive skills to interact with a virtual world; there is no need to learn contrived conventions. Virtual environments also extend the realm of computer interaction, from the purely visual to multimodal communication that more closely parallels human-human exchanges. VE users not only see visual representations, they can also reach out and grab objects, “feel” their size, rotate them in any given axis, hear their movement, and even smell associated aromas. Such experiences do not have to be in solitude, as VE users can take along artificial autonomous agents or collaborate with other users who also have representations within the virtual world. Taken together, this multisensory experience affords natural and intuitive interaction.

The paragraph above describes an ideal, but not, unfortunately, the current state of the art. In today’s virtual environments, users are immersed into an experience with suboptimal visual resolution, inadequate spatialization of sound, encumbering interactive devices, and misregistration of tracking information. These issues are among the scientific and technological challenges that must be resolved to realize the full potential of VE technology, which were well defined by Nathaniel Durlach and Anne Mavor in their seminal work, *Virtual Reality: Scientific and Technological Challenges*. Chapter 1 of this handbook furthers this definitional effort by reviewing the recommendations set forth by Durlach and Mavor and identifying the current status of those objectives, the sine qua non being that VE technology, both hardware and software, has realized substantial gains in the past decade and is posed to support the next generation of highly sophisticated VE systems. However, psychological considerations and VE usability evaluation require additional study to identify how best to design and use VE technology. In addition, Durlach and Mavor (1995, p. 2) mentioned in their work the

“inadequate terminology being used” to describe and communicate progress in VE technology. Chapter 2 thus presents definitions for many of the key terms used throughout this handbook, thereby providing users with a common understanding of concepts discussed.

After providing an introduction to VE technology, the handbook organizes the body of knowledge into five main sections and three subsections. In the first of these sections, “System Requirements,” multimodal system requirements are addressed, including physiological characteristics that affect VE system design. This section is subdivided into hardware, software, and application requirements. The hardware subsection addresses visual, auditory, haptic, vestibular, motion and eye tracking, gesture, and locomotion interface design, specifying the state of the art and how it compares to user and application requirements. The software requirements subsection discusses virtual world modeling, design of interaction techniques, multimodal design considerations, autonomous agents design, and Internet-based VE design. The application requirements subsection covers structured development approaches and transfer-of-training issues.

“Design Approaches and Implementation Strategies” is the next main section. While conventional HCI design approaches can be used to some extent to develop VE system designs, their multimodal nature mandates that new approaches be developed that augment existing techniques. This section addresses cognitive design strategies, identifies perceptual illusions that can be leveraged in VE design, discusses navigational issues such as becoming lost within a virtual world, and provides insights into structured approaches to content design. This section also reviews technology management techniques and user acceptance concerns, uncovers means of addressing potential products liability issues related to the risks associated with VE exposure, and provides sales and market modeling strategies.

“Health and Safety Issues” is the next section. While repetitive use of conventional computer systems has led to a number of associated afflictions (e.g., carpal tunnel syndrome), VE technology brings its own set of additional physiological and psychological risks. This section covers the direct physiological effects of VE exposure, such as biological effects, trauma, and injury. It tackles issues associated with motion sickness, including signs and symptoms, as well as neurophysiology and physiological correlates, and provides potential approaches to treatment. The advantages and risks of perceptual and perceptual-motor adaptation are also discussed, including the ability of humans to overcome the deleterious effects and aftereffects frequently associated with current VE devices. This section also addresses social concerns, which have received far too little attention in the field, discussing both the antisocial and prosocial impact of VE exposure.

Evaluation approaches are presented in the next section. While VE system design can leverage existing usability engineering techniques, the novel aspects of human–VE interaction require these techniques to be modified and extended to better address VE evaluation. This section provides the state of the art in VE usability engineering, addresses human performance measurement in VEs, identifies usage protocols that can be used to manage the use of VE technology, and provides means of measuring and managing visual, proprioceptive, and vestibular aftereffects associated with VE exposure. Approaches to measuring and engendering sense of presence, which is often considered to be essential to VE usability, are discussed. Ergonomic concerns of fit and comfort are also addressed in this section.

The final main section, “Selected Applications of Virtual Environments,” provides a compendium of VE applications. Virtual environment applications pioneers have set the stage for an exciting future. From its military roots, VE technology has branched out into numerous domains. Developments in the area of military defense have led to substantial gains in hardware and networking. Academic efforts are leading to new approaches to experiential learning. Medical VE applications are pushing the envelope in diagnosis, therapy, and rehabilitation, resulting in truly revolutionary advances. System design efforts are allowing models to be created in a

more intuitive and natural manner, with multidisciplinary design teams communicating their ideas via the VE medium. Advances in information visualization are enabling dynamic investigation of multidimensional, highly complex data domains. Manufacturing VE applications have led to advances in the design of manufacturing activities and manufacturing facilities, execution of planning, control, and monitoring activities, and execution of physical processing activities. Likely the most popular of all VE applications, the entertainment industry is leading the way to truly innovative uses of the technology. From interactive arcades to cyber cafes, the entertainment industry has leveraged the unique characteristics of this communications medium, providing dynamic experiences to those who come along for the ride.

This handbook closes with a brief review of the history of VE technology, as we must acknowledge the pioneers whose innovativeness and courage provided the keystones for contemporary successes. The final chapter also provides information on the VE profession, providing those interested with a number of sources to further their quest for the keys to developing the ultimate virtual world.

The main objective of this handbook is to provide practitioners with a reference source to guide their development efforts. We have endeavored to provide a resource that not only addresses technology concerns but also tackles the social and business implications with which those associated with the technology are likely to grapple. While each chapter has a strong theoretical foundation, practical implications are derived and illustrated via the many tables and figures presented.

Taken together, the chapters present systematic and extensive coverage of the primary areas of research and development within VE technology. The handbook brings together a comprehensive set of contributed articles that address the principles required to define system requirements and design, build, evaluate, implement, and manage the effective use of VE applications. The scope and detail of the handbook are extensive, and no one person could possibly do justice to the breadth of coverage provided. Thus, the handbook leveraged authoritative specialists that were able to provide critical insights and principles associated with their given area of expertise. It is through the collective effort of the many contributing authors that such a broad body of knowledge was assembled.

Acknowledgments

If men will not act for themselves, what will they do when the benefit of their effort is for all?

—Elbert Hubbard, *A Message to Garcia* (p. 23)

In the case of the many contributors to this handbook, the answer to this question is that they will selflessly endeavor to provide the insights and assistance required to realize this tremendous effort. In many ways I feel the creation of this handbook is “our Message to Garcia,” one developed through altruistic dedication, the only impetus being that such a source is direly needed in the field. Many individuals openly gave of their time, energy, and knowledge in order to develop this handbook, often when they were fully loaded with their own responsibilities. The efforts of the many contributing authors and to the advisory board, which helped formulate the content coverage, are most sincerely appreciated.

To Gavriel Salvendy, who has provided me with many opportunities, including the invitation to edit this handbook, which have shaped and molded my career I am forever grateful. I have also been blessed with the finest of mentors, Robert S. Kennedy, who gives tirelessly of himself—thank you. I am greatly appreciative of the support of the National Science Foundation, Office of Naval Research, and Naval Air Warfare Center Training Systems Division, in particular Gary W. Strong, Helen M. Gigley, and Robert Breaux. The National Science Foundation CAREER Award and ONR Young Investigator Award have provided me with the opportunity to develop technical depth in human-computer interaction and virtual environment technology and fostered interchange with experts in the field, many of whom contributed chapters to this handbook.

Each chapter in the handbook was peer reviewed. I would like to thank the many advisory board members and chapter contributors who assisted with this process, as well as the following individuals who kindly gave of their time to the review process: Andi Cowell, Chuck Daniels, Nathaniel Durlach, Jason Fox, Thomas Furness, Phillip Hash, Susan Lanham, Dennis McBride, Dean Owen, Randy Pausch, Leah Reeves, Mario Rodriguez, Randy Stiles, and Mark Wiederhold.

For the persistent efforts and encouragement of Anne Duffy, our Lawrence Erlbaum senior editor, who stuck with me even as I missed deadlines and acted out of frustration, I am deeply grateful.

Much appreciation goes to Branka Wedell, who took my amorphous ideas and, through her inspired creativity, designed the striking cover art for this handbook.

The efforts of David Bush are greatly appreciated, as he assisted with many of the activities associated with the handbook and always with a smile on his face. I am also indebted to Kelly Kingdon, who assisted me with many of my personal responsibilities so that I had more time to dedicate to this effort.

To those individuals who constitute the fabric of my life, my parents who instilled the work ethic that allowed me to persevere and see this effort through to completion, my sisters and brother, my very best friends, my brother-in-law who introduced me to *A Message to Garcia* at an opportune moment, and my three sons, Sean, Ryan, and Michael, who fill my world with sunshine, I have been blessed by your encouragement and confidence.

Above all, I am deeply indebted to my husband, who not only encouraged me as I fretted that this handbook would remain a *virtual* reality, but also rolled up his sleeves and assisted with editing and proofreading. His love is my pillar and his steadfast support of my career is my forte.

About the Editor

Kay Stanney is an associate professor with the University of Central Florida's Industrial Engineering and Management Systems Department, which she joined in 1992. She is an editor of the *International Journal of Human–Computer Interaction*. She is a cofounder of the Virtual Environments Technical Group of the Human Factors and Ergonomics Society. Dr. Stanney has more than 100 scientific publications and has given numerous invited lectures and presentations. Her research into the after-effects associated with virtual environment exposure, which is funded by the National Science Foundation, Office of Naval Research, and National Aeronautics and Space Administration, has appeared on MTV Network's health show *Mega-Dose*, NBC *Nightly News*, the Canadian Broadcasting Company's *Undercurrents*, and NBC's local Orlando news, as well as receiving front-page coverage in various newspapers. Dr. Stanney received a bachelor of science in industrial engineering from the State University of New York at Buffalo in 1986, after which time she spent three years working as a manufacturing/quality engineer for Intel Corporation in Santa Clara, California. She received her master's degree and Ph.D. in industrial engineering, with a focus on human factors engineering, from Purdue University in 1990 and 1992, respectively.

1. INTRODUCTION

You see, then, that a doubt about the reality of sense is easily raised, since there may even be a doubt whether we are awake or in a dream. And as our time is equally divided between sleeping and waking, in either sphere of existence the soul contends that the thoughts which are present to our minds at the time are true; and during one half of our lives we affirm the truth of the one, and, during the other half, of the other; and are equally confident of both.

—*Theaetetus*, Plato

As Plato so eloquently stated, that which is reality emanates from that which is present to our minds. In *Theaetetus*, Plato examines perception, knowledge, truth, and subjectivity. This work suggests that Forms (i.e., circularity, squareness, and triangularity) have greater reality than objects in the physical world. This reality is derived because Forms serve as models for our perceptions. So it is that a virtual environment (i.e., a modeled world) can represent a “truth” that can educate, train, entertain, and inspire. In their ultimate form, virtual environments (VEs) immerse users in a fantastic world, one that stimulates multiple senses and provides vibrant

experiences that somehow transform those exposed (e.g., via training, educating, marketing, or entertaining).

Visions such as *The Matrix*, written and directed by Andy and Larry Wachowski, have elevated the status of VE to the level of pop iconography, and some of those associated with the technology have arguably risen to star status (e.g., Jaron Lanier). Yet, while one may speak of VE as contemporary, even in vogue, how far has the technology really come since the pioneering work of Ivan Sutherland, with his 1963 Sketchpad that provided the first interactive computer graphics, or Morton Heilig's 1956 engineering marvel Sensorama rambled through Brooklyn's streets and California's sand dunes (Rheingold, 1991; Sutherland, 1963)? Sensorama provided a multisensory experience of riding a motorcycle by combining three-dimensional (3-D) movies seen through a binocularlike viewer, stereo sound, wind, and enticing aromas (see chap. 56, this volume). Some aspects of the technology have improved substantially since Sketchpad and Sensorama, such as greater visual resolution (see chap. 3, this volume), spatialized audio (see chap. 4), and haptic interaction (e.g., the net force and torque feedback used in tool usage; see chaps. 5 and 6), while others have yet to make any significant strides. In particular, the small grills placed near the nose of Sensorama's passenger that emitted authentic aromas are arguably as sophisticated as today's olfactory technology (see chaps. 14, 21, and 40), although digiScents.com now promises to bring the sense of smell to our computer. In addition, the generation of tactile sensations (i.e., distribution of force fields on the skin during contact with objects) remains elusive (see chaps. 5 and 6).

Perhaps a more appropriate yardstick by which to judge the current state of the art in VE technology would be the agenda set by Durlach and Mavor (1995) a half decade ago in the seminal National Research Council (NRC) report *Virtual Reality: Scientific and Technological Challenges*. That report developed a set of recommendations that, if heeded, should assist in realizing the full potential of VE technology (see Table 1.1). While this work provided many suggestions, the importance of improved computer generation of multimodal images and advancements in hardware technologies that support interface devices were stressed, as was improvement in the general comfort associated with donning these devices. As the following sections will discuss, the former objectives have largely been met by astounding technological advances, yet the latter has yet to be fully realized, as VE users are still impeded by cumbersome devices and binding tethers (but that will soon change with technologies such as Bluetooth). This chapter focuses on a number of key recommendations put forth by Durlach and Mavor (1995), while many others are described in detail in other chapters in this handbook (see status notes in Table 1.1).

2. TECHNOLOGY

Virtual environments are driven by the technology that is used to design and build these systems. This technology consists of the human-machine interface devices that are used to present multimodal information and sense the virtual world, as well as the hardware and software used to generate the virtual environment. It also includes the techniques and electromechanical systems used in telerobotics, which can be transferred to the design of VE systems, as well as the communication networks that can be used to transform VE systems into shared virtual worlds.

2.1 Human–Machine Interface

Human–machine interfaces consist of the multimodal devices used to present information to VE users. For multimodal VE applications, advances in peripheral connections to the computer are the single largest issue. When an input device is connected, such as a body or limb tracker, a serial port is generally utilized, a port typically designed for character input and not high-speed

data transfer. A solution to the input device connectivity issue that is available on commodity computing is the great unsolved problem. At some point, this input-port speed problem needs to be solved, and that resolution must be included on mass-marketed PCs or their descendants.

Visual displays, especially head-mounted displays (HMDs), have come down substantially in weight but are still hindered by cumbersome designs, obstructive tethers, suboptimal resolution, and insufficient field of view (see chap. 3). (Note: For an excellent comparative source on HMDs, see the “HMD/VR-Helmet Comparison Chart,” Bungert, 2001.) Recent advances in wearable computer displays (e.g., Microvision, MicroOptical), which can incorporate miniature LCDs directly into conventional eyeglasses or helmets, should ease cumbersome design and further reduce weight (Lieberman, 1999). There are several low- to mid-cost HMDs (InterSense’s InterTrax i-glasses, Olympus Eye-Trek FMD, Interactive Imaging Systems’ VFX3D, Sony Cybermind, Sony Glasstron, and Kaiser ProViewXL) that are lightweight (approximately 39 g to 1,000 g) and provide a horizontal field of view (30 to 35 degrees per eye) and resolution (180 K to 2.4 M pixels/LCD) exceeding predecessor systems. While the resolution range looks impressive, most consumer-grade HMDs (those around 180 K pixels/LCD) use three pixels (red, green, and blue) to produce one colored pixel, providing a true resolution of only about 60 K pixels per LCD (Bungert, 2001).

Virtual Retinal Displays (VRDs) may bring truly revolutionary advances in display technology. VRD technology, which was invented in 1991 at the University of Washington’s HIT (Human Interface Technology) Lab, holds the promise for greatly enhanced optics (Kleweno et al., 1998). With this technology, an image is scanned directly onto a viewer’s retina using low-power red, green, and blue light sources, such as lasers or LEDs (Urey, Wine, & Lewis, online). The VRD system has superior color fidelity, brightness, resolution, and contrast compared to LCDs and CRTs, as it typically uses spectrally pure lasers as the light source.

With advances in wireless and laser technologies and miniaturization of LCDs, during the next decade visual display technology should realize the substantial gains necessary to provide high-fidelity virtual imagery in a lightweight noncumbersome manner.

In the area of virtual auditory displays there have also been tremendous gains (see chap. 4). For example, while early spatialized audio solutions (Blauert, 1997) were expensive to implement, it is currently feasible to include spatialized audio in most VE systems. (For an excellent source on spatialized audio, see “The Ultimate Spatial Audio Index,” [http://www.speakeeasy.org/~draught/spataudio.html](http://www.speakeasy.org/~draught/spataudio.html).) On the hardware side, systems are available that present multiple sound sources to multiple listeners using positional tracking. Technology for designing complex spatial audio scenarios, including numerous reflections, real-time convolution, and head tracking is currently under way. Software solutions are also under development, which provide low-level control of a variety of signal processing functions, including the number and position of reflections, as well as allowing for normal head-related transfer function (HRTF) processing (see chap. 4), manipulation of acoustic radiation patterns, spherical spreading loss, and atmospheric absorption. HRTFs have yet, however, to effectively include reverberation or echoes. Adding reverberation to a VE causes auditory sources to seem more realistic and provides robust information about relative source distance; thus, further research is needed in the development of tractable reverberation algorithms for real-time systems. Advances in HRTF individualization (i.e., to the physiological makeup of a listener’s ear) are also of great importance for localizing sounds, especially for distinguishing front from back and up from down. In particular, means to tailor HRTFs to an individual listener without explicitly measuring HRTFs for that individual are needed. This may be possible, since the transfer functions of the external ear have been found to be similar across different individuals (Middlebrooks, Makous, & Green, 1989).

Current haptic technology provides net force and torque feedback (i.e., simulating tool usage) but has yet to develop effective tactile feedback (e.g., simulating skin contact or dynamic flexibility, such as the sensation of bumps, scratches, and deformations due to flexion of body

TABLE 1.1
Status of Durlach and Mavor's (1995) Recommendations for Advancing VE Technology

Area	Recommendation	Status ¹
Technology: human-machine interface	<ul style="list-style-type: none"> • Address issues of information loss due to technology shortcomings (e.g., poor resolution, limited field of view, deficiencies in tracker technology) • Improvements in spatialization of sounds, especially sounds to the front of a listener and outside of the “sweet spot” surrounding a listener’s head • Improvements in sound synthesis for environmental sounds • Improvements in real-time sound generation • Better understanding of scene analysis (e.g., temporal sequencing) in the auditory system • Improvements in tactile displays that convey information through the skin • Better understanding of the mechanical properties of soft tissues that come in contact with haptic devices, limits on human kinesthetic sensing and control, and stimulus cues involved in the sensing of contact and object features • Improvements in locomotion devices beyond treadmills and exercise machines • Address fit issues associated with body-based linkage tracking devices; workspace limitations associated with ground-based linkage tracking devices; accuracy, range, latency, and interference issues associated with magnetic trackers; and sensor size and cost associated with inertial trackers • Improvements in sensory, actuator, and transmission technologies for sensing object proximity, object surface properties, and applying force • Improvements in the vocabulary size, speaker independence, speech continuity, interference handling, and quality of speech production for speech communication interfaces • Improvements in olfactory stimulation devices • Improvements in physiological interfaces (e.g., direct stimulation and sensing of neural systems) • Address ergonomic issues associated with interaction devices (e.g., excessive weight, poor fit both mechanically and optically) • Better understanding of perceptual effects of misregistration of visual images in augmented reality • Better understanding of how multimodal displays influence human performance on diverse types of tasks • Improvements in techniques to minimize the load (i.e., polygon flow) on graphics processors • Improvements in data access speeds • Development of operating systems that ensure high-priority processes (e.g., user tracking) receive priority at regular intervals and provide time-critical computing and rendering with graceful degradation 	S M (see chap. 4) M M M L (see chaps. 5–6) L M (see chap. 11) M (see chap. 8) M (see chaps. 5–6) S L M (see chap. 7) M (see chap. 41) M (see chap. 37) M (see chaps. 14, 21) S (see chap. 12) S L
Technology: computer generation of virtual environments		

	<ul style="list-style-type: none"> • Improvements in rendering photorealistic time-varying visual scenes at high frame rates (i.e., resolving the trade-off between realistic images and realistic interactivity) • Development of navigation aids to prevent users from becoming lost • Improvements in ability to model psychological and physical models that “drive” autonomous agents • Improved means of mapping how user’s control actions update the visual scene • Improvements in active mapping techniques (e.g., scanning-laser range finders, light stripes) • Improvements in the ability to create and maintain accurate registration between the real and virtual worlds in augmented reality applications • Development of display and control systems that support distributed telerobotics 	M
Technology: telerobotics	<ul style="list-style-type: none"> • Development of supervisory control and predictive modeling for addressing transport delay issues • Development of network standards that support large-scale distributed VEs • Development of an open VE network • Improvements in ability to embed hypermedia nodes into VE systems • Development of wide-area and local-area networks with the capability (e.g., increased bandwidth, speed, and reliability, reduced cost) to support the high-performance demands of multimodal VE applications • Development of VE-specific applications-level network protocols 	M (see chap. 24) M (see chap. 15) M (see chaps. 12, 13) M (see chap. 8) M (see chap. 48)

¹L = limited to no advancement; M = modest advancement; S = substantial advancement.

segments, see chaps. 5 and 6). Srinivasan (see chap. 5) suggests that for the foreseeable future advances in haptic technology will be limited by the development of new actuator hardware. In addition, hardware required to simulate distributed forces on the skin may require substantial gains in miniature rotary and linear actuators or advances in alternative technologies, such as shape memory alloys, piezoelectrics, microfluidics, and other microelectromechanical systems.

Advances in tracking technology have been realized in terms of drift-corrected gyroscopic orientation trackers, outside-in optical tracking for motion capture, and laser scanners (see chap. 8). The future of tracking technology is likely hybrid tracking systems, with an acoustic-inertial hybrid on the market (see <http://www.isense.com/products/>) and several others in research labs (e.g., magnetic-inertial, optical-inertial, and optical-magnetic). In addition, ultrawideband radio technology holds promise for an improved method of omni-directional point-to-point ranging.

Led largely by the Information Society Directorate General of the European Union and the Information Science and Engineering Directorate of the National Science Foundation, the quality of speech recognition and synthesis systems have made substantial gains in the past half decade. Speaker-independent continuous speech recognition systems are currently commercially available (Germain, 1999; Huang, 1998); however, additional advances are needed in acoustic and language modeling algorithms to improve the accuracy, usability, and efficiency of spoken language understanding. Synthetic speech can now be produced that reasonably resembles the acoustic and prosodic characteristics of the original speaker; however, improvements are required in the areas of naturalness, flexibility, and intelligibility of synthesized speech (Institution of Electrical Engineers, 2000). Speech recognition and synthesis are not addressed in detail in this handbook, not due to any implied lack of importance but rather because there are many significant works whose sole focus is speech technology (see Gibbon, Mertins, Moore, 2000; Varile & Zampolli, 1998). (For an excellent information source on commercial speech recognition, see <http://www.tiac.net/users/rwilcox/speech.html>; see <http://www.cs.bham.ac.uk/~jpi/museum.html> for resources on speech synthesis systems; see <http://research.microsoft.com/research/srg/> for the latest in Microsoft's speech technology efforts).

Taken together, these technological advancements, along with those poised for the near future, provide the infrastructure on which to build complex, immersive multimodal VE applications.

2.2 Computer Generation of Virtual Environments

Computer generation of VEs requires very large physical memories, high-speed processors, high-bandwidth mass storage capacity, and high-speed interface ports for input/output devices (Durlach & Mavor, 1995). Remarkable advances in hardware technologies have been realized in the past half decade that will better meet these VE demands. Moore's law (see chap. 28) is being surpassed, with processor speeds doubling in less than 12 months (Nicholls, 2000a). In addition, technological advances (e.g., tantalum oxide chip gates, extreme ultraviolet [EUV] lithography, new microarchitecture, and better insulation) may help microprocessor speeds reach 20 gigahertz within the next decade (Kanellos, 2000). The memory bandwidth problem is being assuaged by 100-(peak bandwidth 800 Mbyte/sec) and 133-MHz (peak bandwidth 1.1 Gbyte/sec) SDRAM, with promises of 400 MHz and higher-speed memory in the near term. The gigahertz barrier has been surpassed by both Advanced Micro Devices' Athlon's and Intel's Pentium III and Willamette, and more advances will soon be realized with Intel's Itanium and McKinley, Sun's Ultrasparc III, Hewlett-Packard's 8700, and IBM's Power4, the latter of which can build an eight-processor system in a hand-size module. Yet this is just the

start. The future promises massive parallelism in computing as we approach the molecular-feature-size limits in integrated circuits (Appenzeller, 2000).

Software development of VE systems has progressed tremendously, from proprietary and arcane systems, to development kits that run on general-purpose operating systems, such as Windows in most of its flavors, while still allowing high-end development on Silicon Graphics workstations (Pountain, 1996). Virtual environment system components are becoming modular and distributed, thereby allowing VE databases (i.e., editors used to design, build, and maintain virtual worlds) to run independently of visualizer and other multimodal interfaces via network links. Standard application program interfaces (APIs; e.g., OpenGL, Direct-3D, Mesa) allow multimodal components to be hardware-independent. Virtual environment programming languages are advancing, with APIs, libraries, and particularly scripting languages allowing nonprogrammers to develop virtual worlds. Using these tools, commercial applications developers can build a range of VEs, from the most basic mazes to complex medical simulators, from low-end single-user PC platform applications to collaborative applications supported by client-server environments.

A number of 3-D modeling languages and tool kits are available which provide intuitive interfaces and run on multiple platforms and renderers (e.g., AC3D Modeler, Clayworks, MR Toolkit, MultiGen Creator and Vega, RealiMation, Renderware, VRML, WorldToolKit). Beyond these languages, which deal with display devices that paint pixels on the screen and define higher-level inputs via triangles and polygons, a new approach to the computer generation of VEs is to use a scene management engine (RealiMation, 2000). This approach allows programmers to work at a higher level, defining characteristics and behaviors for more holistic concepts (e.g., attacker, enemy), thereby enabling developers to concentrate on content design (see chap. 25) without being concerned about how that content is delivered to users.

Photorealistic rendering tools are evolving toward full-featured physics-based global illumination rendering systems (e.g., Raster3D—<http://www.bmsc.washington.edu/raster3d/raster3d.html>; RenderPark—<http://www.cs.kuleuven.ac.be/cwis/research/graphics/RENDERPARK/>; Heirich & Arvo, 1997; Merritt & Bacon, 1997). Such physically based rendering techniques allow quantitative prediction of the illumination in a virtual scene and generation of photorealistic computer images, in which illumination effects such as soft shadows and glossy reflections are reproduced with high fidelity (Suykens, 1999).

Computer generation of autonomous agents is a key component of many VE applications involving interaction with other entities, such as adversaries, instructors, or partners. There has been significant research and development in modeling embodied autonomous agents (see chap. 15). Notable in this area is a spin-off from the MIT Artificial Intelligence Laboratory, Boston Dynamics, Inc. (BDI, <http://www.bdi.com/>). BDI has adapted advances in robotics systems, such as motion caching, variable motion interpolation, and task-level control optimization techniques to display dozens of lifelike articulated agents at one time. BDI's products allow system developers to work directly in a 3-D database, interactively specifying agent behaviors, such as paths to traverse and sensor regions. The resulting agents move realistically, respond to simple commands, and travel about a VE as directed. Further integration of tele-robotics techniques (see chap. 48) into autonomous agent design is certain to lead to even more impressive advances. While the aforementioned gains are noteworthy, there are still a number of unsolved problems in agent design and development (see Table 15.3 of chap. 15).

Research in VE navigation has led to the development of design guidelines and aids that enable wayfinding in virtual worlds. These aids include maps, landmarks, trails, and direction finding (see chap. 24). In addition, for closed VEs (e.g., buildings), tools that demonstrate the surrounding area (maps, exocentric 3-D views) are recommended if training or exposure time is short, while internal landmarks (i.e., along a route) are recommended for longer exposure durations (Stanney, Chen, & Wedell, 2000). For semiopen (e.g., urban areas) and open

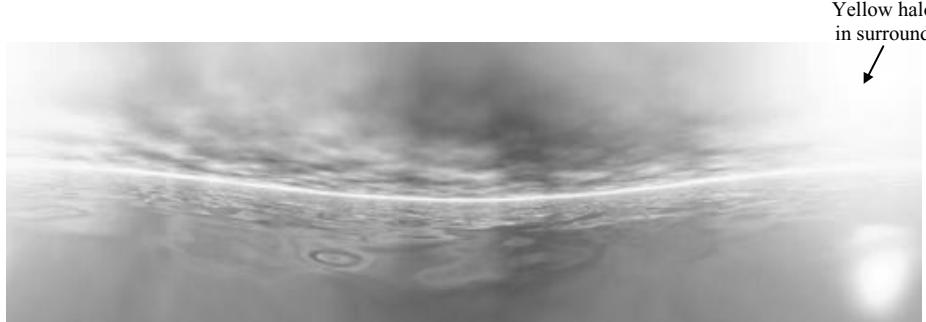

FIG. 1.1. Sea scene with window of normative color encircled by yellow halo indicating going off-course.

environments (e.g., sea, sky), demonstrating the surround is appropriate for short exposures, while use of external landmarks (i.e., outside a route) is recommended for long exposure times. Based on these and other guidelines, aids need to be developed to guide navigation in virtual environments. One such aid was designed by Stanney, Chen, and Wedell (2000), which provides wayfinders with a “window” of normative color shaded on the edges in a symbolic color (e.g., yellow or red), which appears when off-course (see Fig. 1.1). The scene appears in normative color when wayfinders are on-course, gradually changing to yellow and then to red as a wayfinder moves further off-course. While this is just an example, and one whose effectiveness has yet to be validated, it is shared here because it is an example of a collaborative effort between engineers and a graphic artist. Such multidisciplinary collaborations are likely to serve as the crux for truly innovative advances in VE design. More work is needed in the area of navigational aiding, as making one’s way through a VE has been found to be one of the most significant usability issues influencing VE task performance (Ellis, 1993; Jul & Furnas, 1997).

The NRC report (Durlach & Mavor, 1995) indicated the need for a real-time operating system for virtual environments, but the expectation from that committee that such an effort would be funded was low. That proved to be an accurate assessment, as current operating systems (OSs) are perhaps less-supportive of VEs than six years ago, at the time of the NRC report’s debut. Certainly there are a variety of Windows derivatives (Nicholls, 2000b), yet no one is convincingly arguing their appropriate use as OSs for VEs, with the exception that if one wants wide acceptance, a Windows variant allows for broad usage. Linux is available, which is a less-capable but open source derivative of Unix. At the same time, there is diminished use of Silicon Graphics (SGI) Irix. SGI Irix, to many of those on the bleeding edge of VE technology, was *the* operating system for developing VEs, and the many features of that system not found elsewhere are direly missed. So the right OS for developing VEs is still an open issue.

2.3 Telerobotics

Beyond the advantages to autonomous agent design discussed above, there are many areas (e.g., sensing, navigation, object manipulation) in which VE technology can prosper from the application of robotics techniques. Yet, if these techniques are to be adopted, issues of communication time delay (i.e., transport delay) and real-time control architecture design must be resolved. Chapter 48 discusses a number of techniques for addressing these issues. In that chapter, Kheddar, Chellali, and Coiffet note that

a cleverly conceived yet “simple” VE intermediary representation contributes to solving the time delay problem, offers ingenious metaphors for both operator assistance and robot autonomy sharing problems, enhances operator sensory feedback through multiple sensory modalities admixtures,

enhances operator safety, offers a huge possible combination of strategies for remote control and data feedback, shifts the well known antagonistic transparency/stability problem into an operator/VE transparency one without compromising the slave stability, offers the possibility to enhance—in terms of pure control theory—remote robot controllers, allows new human-centered teleoperation schemes, permits the production of advanced user-friendly teleoperation interfaces, makes possible the remote control of actual complex systems, such as mobile robots, nano and micro robots, surgery robots, etc.

To achieve these gains, however, advances in VE modeling techniques and means of addressing error detection and recovery inherent to VE—real environment discrepancies are needed (see discussion in chap. 48).

2.4 Networks

The NRC report (Durlach & Mavor, 1995) suggested that with improvements in communications networks, virtual environments would become shared experiences, in which individuals, objects, processes, and autonomous agents from diverse locations interactively collaborate. Advances in the Internet have been substantial in the time since that report, due particularly to the U.S. government's Next Generation Internet (NGI) effort and the University Corporation for Advanced Internet Development's (UCAID's) Internet2 (Langa, 2001). The NGI initiative (<http://www.ngi.gov/>) is connecting a number of universities and national labs at speeds 100 times faster than the 1996 Internet, and a smaller number of institutions at speeds 1,000 times faster in order to experiment with collaborative-networking technologies, such as high-quality video conferencing and audio and video streams. Of particular interest to VE developers, technologies have been developed to “mark” data streams as having specific characteristics (e.g., time-critical, lockstep) so that differentiated services can enable different types of data to be handled with different quality of service levels. Internet2 is using existing networks (e.g., the National Science Foundation's VBNS—Very-High-Speed Backbone Network Service) to determine the transport designs necessary to carry real-time multimedia data at high speed (<http://apps.internet2.edu/>). Networked VE applications, which require the ability to recognize and track the presence and movements of individuals as well as physical and virtual objects, while projecting them in realistic, multiple, geographically distributed immersive environments on stereo-immersive surfaces, are ideal for Internet2, as they leverage its special capabilities (i.e., high bandwidth, low latency, low jitter; Singhal & Zyda, 1999).

3. PSYCHOLOGICAL CONSIDERATION

There are a number of psychological considerations associated with the design and use of VE systems. Some of these focus on techniques and concerns that can be used to augment or enhance VE interaction and transfer-of-training (e.g., perceptual illusions, design based on human-information-processing transfer rates), while others focus on adverse effects due to VE exposure. In terms of the former, we know that perceptual illusions exist, such as auditory-visual cross-modal perception phenomena (see chap. 22), yet little is known about how to leverage these phenomena to reduce development costs while enhancing one's experience in a virtual environment. Perhaps the one exception isvection (i.e., the illusion of self-movement), which is known to be related to a number of display factors (see Table 23.1 of chap. 23). By manipulating these display factors, designers can provide VE users with a compelling illusion of self-motion throughout a virtual world, thereby enhancing their sense of presence (see chap. 40) often with the untoward effect of motion sickness, as well (see chap. 23). Other such illusions exist (e.g., visual dominance—see chap. 22) and could likewise be leveraged. While

current knowledge of how such perceptual illusions occur is limited, it may be sufficient to know that they do occur in order to leverage them to enhance VE system design and reduce development costs. Substantially more research is needed in this area to identify perceptual and cognitive design principles that can be used to trigger and capitalize on these illusory phenomena.

Another psychological area in need of research is that of transfer of training. Stanney, Mourant and Kennedy (1998, p. 330) suggest that: "To justify the use of VE technology for a given task, when compared to alternative approaches, the use of a VE should improve task performance when transferred to the real-world task because the VE system capitalizes on a fundamental and distinctively human sensory, perceptual, information processing, or cognitive capability." Yet there is very limited understanding of the types of tasks or activities for which the unique characteristics of VEs (i.e., egocentric perspective, stereoscopic 3-D visualization, real-time interactivity, immersion, multisensory feedback) can be leveraged to provide significant gains in human performance, knowledge, or experience. One notable exception is the area of spatial knowledge, for which VE training has been found to be advantageous. For example, Darken and Bunker (1998) conducted a study to evaluate whether or not a VE could serve as a useful tool in familiarizing individuals with unknown environments. In this experiment, three groups of participants (beginner, intermediate, and advanced orienteers) were tasked with learning a real-world environment by either: (1) studying an orienteering map; (2) exploring the real-world environment with an orienteering map; or (3) exploring a high-fidelity VE in addition to studying the orienteering map. Based on the results, Darken and Bunker (1998) summarized that:

1. Experience level was a more important factor than training method in affecting navigation performance.
2. Intermediate orienteers benefited more from VE training than either advanced or beginner orienteers.
3. The VE allowed for time compression in training, permitting more area to be traversed in a shorter time.

Waller (1999) conducted related studies in a maze-shaped VE as well as in the real world. He examined a number of individual variables, including, spatial ability, real world presentation and navigational ability, gender, imaging strategy, computer experience and usage, the ability to acquire and transfer spatial knowledge from a VE, and proficiency with the navigational interface of the virtual environment. Variables that significantly contributed to spatial knowledge retrieval and transfer from the VE included: the proficiency with the navigational interface; spatial ability, especially spatial visualization and spatial orientation ability; and gender. Waller (1999) found that users' proficiency with the virtual interface (a joystick) was the most important factor in determining transferability of spatial knowledge. Those who experienced difficulties in operating the joystick usually retrieved less spatial knowledge from the virtual environment. Taken together, the Darken and Waller studies suggest that while VE training can enhance spatial knowledge of real-world environments, both individual and VE system factors may temper this transfer of knowledge. These findings provide impetus for further study of VE transfer of training. Without this knowledge, the unique benefits of VE technology may never be fully understood or realized.

In contrast to the limited knowledge concerning perceptual and cognitive design principles that augment or enhance VE interaction, more is known about identifying and controlling the adverse effects of VE exposure. Adverse effects are of particular concern because they can persist for some time after exposure, potentially predisposing those exposed to harm. These effects are both physiological (see chaps. 30, 31, 37–39) and psychological (see chap. 33), with considerable effort currently focused on the former and less on the latter. A survey of the current

state of knowledge regarding physiological aftereffects concluded that the two most critical research issues in this area are: standardization and use of measurement approaches for VE aftereffects; and identification and prioritization of sensorimotor discordances that drive these aftereffects (Stanney, Salvendy et al., 1998). While significant gains have been made toward the former goal (see chaps. 30, 37–39), there is still insufficient knowledge concerning the latter, particularly in terms of prioritization (see chap. 31). Some are also concerned that exposure to VEs that portray violent content, as is often found in entertainment venues, could lead to aggressive, antisocial, or criminal behavior (see chap. 33). Thus, a proactive approach is needed that weighs the physiological and psychological risks and potential consequences associated with VE exposure against the benefits. Waiting for the onset of harmful consequences should not be tolerated.

Taken together, the research into psychological considerations of VE exposure indicates that more research is needed to derive perceptual and cognitive design strategies that enhance VE interaction, and that there are risks associated with VE exposure. However, usage protocols have been developed that, if successfully adopted, can assist in minimizing these risks (see chap. 36). Thus, VE technology is not something to be eschewed as it has many advantages for enticing and didactic experiences; it is rather something to leverage wholly yet vigilantly, taking care to address the associated risks.

4. EVALUATION

Most VE user interfaces are fundamentally different from traditional graphical user interfaces, with unique I/O devices, perspectives, and physiological interactions. Thus, when developers and usability practitioners attempt to apply traditional usability engineering methods to the evaluation of VE systems they find few if any that are particularly well suited to these environments (see chap. 34). Subsequently, very few principles for the design and evaluation of VE user interfaces exist, of which none are empirically derived or validated (Kaur, Maiden, & Sutcliffe, 1999).

While limited work on VE usability has been conducted to date, there are early works that have attempted to improve VEs from users' perspective by integrating a systematic approach to VE development and usability evaluation (Bowman, 1999; Gabbard & Hix, 1997; Kalawsky, 1999; Kaur, 1999; chap. 24). By addressing key characteristics unique to VEs (e.g., perceived presence and real-world fidelity, multidimensional interactivity, immersion), their work has identified limitations of existing usability methods for assessing VE systems (see Table 1.2).

TABLE 1.2
Limitations of Traditional Usability Methods
for Assessing Virtual Environments

-
- Traditional point-and-click interactions are not representative of the multidimensional object selection and manipulation characteristics of 3-D space.
 - Quality of multimodal system output (e.g., visual, auditory, haptic) is not comprehensively addressed by traditional evaluation techniques.
 - Means of assessing sense of presence and aftereffects have not been incorporated into traditional usability methods.
 - Traditional performance measurements (i.e., time and accuracy) do not comprehensively characterize VE system interaction.
 - Traditional single-user task-based assessment methods do not consider VE system characteristics in which two or more users interact in the same environment.
-

Based on these shortcomings, it is suggested that novel aspects of human–VE interaction require new evaluation tools. Toward this end, Gabbard and Hix (1997) have developed a taxonomy of VE usability characteristics that can serve as a foundation for identifying usability criteria that existing evaluation techniques fail to fully characterize. Stanney, Mollaghaseemi, and Reeves (2000) used this taxonomy as the foundation on which to develop an automated system, *MAUVE* (Multi-Criteria Assessment of Usability for Virtual Environments), which organizes VE usability characteristics into two primary usability attributes (VE system usability and VE user considerations); four secondary attributes (interaction, multimodal system output, engagement, and side effects); and 11 tertiary attributes (navigation, user movement, object selection and manipulation, visual output, auditory output, haptic output, presence, immersion, comfort, sickness, and aftereffects). Similar to the manner in which traditional heuristic evaluations are conducted, *MAUVE* can be used at various stages in the usability engineering life cycle, from initial storyboard design to final evaluation and testing. It can also be used to compare system design alternatives. The results of a *MAUVE* evaluation not only identify a system's problematic usability components and techniques, but also indicate why they are problematic. Such results may be used to remedy critical usability problems, as well as to enhance the design for usability of subsequent system development efforts.

In terms of the cost-effectiveness of VE systems, models are currently available to evaluate the selling process of VE applications (see chap. 28). With these tools, developers can evaluate if VE technology offers financial advantages over current practices or technologies. This is an essential determination if VE technology is to thrive both commercially and in research domains.

Durlach and Mavor (1995) suggested that serious commercial applications would not be realized for 5 to 10 years (thus, sometime between 2000 and 2005), and those insights appear well founded. While viable applications exist today (see chaps. 42–55), most are still in the developmental stages. Further research is required to determine areas in which VE applications can lead to significant gains in experience or performance.

5. CONCLUSIONS

As seen from the above discussion and from the remaining chapters in this handbook, there has been considerable technological progress for the VE field since the advent of the NRC report (Durlach & Mavor, 1995). The NRC report was an inflection point in the VE field. Before the report, there were many technology futurists seeking headlines indicating that “VR [virtual reality] would destroy your television” and that VR was coming soon, perhaps even next week. The NRC report provided a more sobering assessment and indicated that, in some areas, there was as much as a decade or two of work yet to be done. Some of the prognosticators continue to this day with glowing reports and predictions, but we know that much careful work is required. The remainder of this text highlights some of the completed work and points out what is yet to be done. Those research directions will hopefully lead us to a platonic virtual reality that is sufficiently convincing to our minds.

6. ACKNOWLEDGMENTS

The authors would like to thank Nat Durlach and Tom Furness for their comments on an earlier version of this work. Their insights are greatly appreciated. This material is based in part on work supported by the Naval Air Warfare Center Training Systems Division (NAWC TSD)

under contract No. N61339-99-C-0098. Any opinions, findings, conclusions, or recommendations expressed in this material are those of the authors and do not necessarily reflect the views or the endorsement of NAWC TSD.

1. INTRODUCTION

In just the past decade virtual environment (VE) applications have emerged in entertainment, training, education, and other areas (see Chapters 43–55, this volume). In that time extensive research in VE technology has also been conducted. However, the terminology used to characterize this technology is still evolving. In fact, Durlach and Mavor (1995, p. 2) indicate that “inadequate terminology [is] being used” to describe VE technology and its applications. It is thus important to describe the key terms that are used in this handbook. The objective is not to resolve differences between disparate uses (in fact often multiple, even conflicting definitions are presented) but rather to provide a coherent set of commonly used terms. While it is customary to present a glossary at the end of handbooks such as this one, this work starts out with a glossary so that readers may develop a common understanding of the terms used throughout the handbook. Paradoxically, the one term that remains particularly elusive is *virtual environment*. Many authors, especially those among the application chapters (see chaps. 43–55, this volume) have catered the definition of VE to fit the forms of the technology that best suit their needs. Perhaps this definitional multiplicity demonstrates the versatile nature of VE technology and its wide array of potential uses.

While the definitions in this chapter have been presented in a relatively informal manner, we continue to work toward a set of standard definitions through the VR Terminology Project. This involves a multiphase effort on the part of the IEEE Computer Society under the auspices of the IEEE Standards Association, of which the first phase is the establishment of a working group on virtual reality terminology (VI-1392).

2. IMPORTANCE OF STANDARDS

Standards are critical for systematic and robust development of any emerging technology. Specification standards provide for practical descriptions of product characteristics and limitations, critical to an end user. Interface standards allow for interchangability of components developed by different manufacturers, thus permitting specialization and robust competition in the marketplace. Safety standards ensure the health and safety of product users. Terminology standards ensure that technical terminology is used in a consistent and rigorous manner, thus preventing confusion and ambiguity in scientific and technical reports and specifications.

2.1 Process of Establishing Standards

The process of establishing standards is quite possibly as important as the standards ultimately produced, for that process establishes a forum for open and systematic dialog between researchers, developers, manufacturers, and end users on the current and future needs and directions of an industry. It often progresses at a “glacial pace,” meaning it could take years to actually reach agreement on a standard, which ensures a systematic, objective, and rigorous examination of all aspects of an issue by all who have interest or involvement.

There are many standards setting organizations, each having its own rules and procedures. For electrical, electronic, and computer-related standards, the two primary international organizations are the International Electrotechnical Commission (IEC) and the International Organization for Standardization (ISO). Most standards related to VEs will originate in the IEEE Computer Society, which is a part of the Institute of Electrical and Electronic Engineers (IEEE). The IEEE Standards Association (IEEE-SA), in turn, belongs to the American National Standards Institute (ANSI). Standards organizations can and do work together, but there are no requirement that they do so. Rather, obtaining the broadest possible acceptance of standards is the motivation for cooperation and collaboration. For example, the ISO and IEC have formed the Joint Technical Committee Number One (JTC1) to deal with information technology standards. They also cooperate on issues involving safety, electromagnetic radiation, and the environment.

The first step to establishing one or more VE standards (usually a group of related standards) in the IEEE Computer Society is for an individual to prepare a project authorization request (PAR) for submission to the IEEE Standards Board. If approved, that PAR is given an identifying label (e.g., vi-1392 in the case of VE terminology), and a working group is set up under that label to study the problem and make recommendations. All interested parties are invited to participate, and every attempt is made to ensure a broad representation. After much informal discussion and deliberation, the working group prepares draft standards. A balloting group is then assembled to vote on the standards and/or modify them if necessary. In contrast to the working group, the process and membership of the balloting group become very formal to ensure a balanced and fair consideration of the issues and proposed standards. The last step in establishing a standard by the IEEE-SA is for the IEEE Standards Board to approve the submission of the balloting group. When the standards being proposed overlap between two or more existing groups, a standards coordinating committee (SCC) is involved to ensure proper coordination and collaboration. The work of the IEEE-SA is supported by its publication of the standards. Various procedures must be followed throughout the standards process to ensure that the publication rights to each standard produced belong to the IEEE.

3. IMPORTANCE OF OFFICIAL TERMINOLOGY

Any standard set by the IEEE or other standards development organizations contains definitions. When multiple uses of a term are found in the literature or are in common use, it should

help to have a careful record of the variations, including recommendations and cautions. Consider, for example, the term “megabyte”. It may mean $10^6 = 1,000,000$ bytes, or it may mean $2^{10} = 1,024 \times 1,024 = 1,048,576$ bytes, or even $1,000 \times 1,024 = 1,024,000$ bytes. A consumer needs to be aware of these disparities. One important task of the VR Terminology Project is to provide consumers, including government contractors, reliable definitions so they can properly evaluate product descriptions and proposals. If these definitions are readily available to users and producers, reliable commerce will be enhanced.

A short glossary of terms is given in the next section. Most are technical terms that were provided by the authors of other chapters in this handbook because of their occurrence in those chapters, and many appear in more than one chapter. Although all have definitions in the professional literature, almost none of those definitions have been universally adopted by any standards organization. In preparing this chapter much discussion took place with the authors, as well as between various authors of this handbook, to ensure a reasonable degree of clarity and consistency. However, in some cases we found it necessary to provide multiple, sometimes even contradictory, definitions reflecting current usage.

4. A SHORT GLOSSARY

6DOF: six degrees of freedom, typically specified by three spatial directions and three angles of orientation.

Accommodation: change in the focal length of the eye’s lens to maintain focus on a moving close object.

Aftereffect: any effect of *VE* exposure that is observed after a participant has returned to the physical world.

Archetypes: prototypes that provide templates to guide learning, development, and the construction of the personality, or psyche.

Attentional inertia: attentional mechanism in which the person’s visual system gets locked into engaging, interesting experiences.

Attitudes: description of team members’ affective views, both individually and collectively, on their abilities and motivation to accomplish goals.

Aubert effect or phenomenon: the apparent displacement of an isolated vertical line in the direction opposite to which the observer is tilted. This happens when an observer has a large tilt, e.g., 90 degrees.

Audification: an acoustic stimulus involving direct playback of data samples. See also *Sonification*.

Augmented reality: the use of transparent glasses on which a computer displays data so the viewer can view the data superimposed on real-world scenes.

Avatar: character that represents a player in second-person virtual systems.

Binocular: displaying a different image to each eye for the purpose of stereographic viewing.

Binocular parallax: same as parallax. See also *Motion parallax*.

Bi-ocular: displaying the same image to each eye. Sometimes this is done to conserve computing resources when depth perception is not critical. See also *Stereopsis*.

BOOM: Fake Space Labs’ Binocular Omni Orientation Monitor, which consists of a visual

display supported on a pedestal; users hold the display head with their hands and adjust the view direction in a manner similar to that of a pair of binoculars.

Bots: robots or intelligent agents who roam MUDs and other virtual environments.

CAVE: Cave Automatic Virtual Environment—a SID where images are projected on the walls, floor, and ceiling of a room that surrounds a viewer. Oftentimes a principal viewer’s head position is tracked to determine view direction and content, while other viewers “come along for the ride.”

Cognitive map: mental representation of an environment (also referred to as a mental map).

Communication channel: when applied to HCI, it is a pathway between the user and the simulation that allows human–computer interaction.

Computer assisted teleoperation (CAT): bilateral control of teleoperation through computers, including computer assistance in both robot control and information feedback.

Convergence: occurs in stereoscopic viewing when the left and right eye images become fused into a single image.

Convolve: to filter and intertwine signals (e.g., sounds) and render them three-dimensional. Used in VE applications to recreate sounds with directional cues.

Coriolis, or cross-coupling, effect: effect resulting from certain kinds of simultaneous multi-axis rotations, especially making head movements while rotating. This illusion is characterized by a feeling of head or self-velocity in a curved path that is roughly orthogonal to the axes of both body and head rotation, which can lead to simulator sickness.

Culling: removing invisible pieces of geometry and only sending potentially visible geometry to the graphics subsystem. Simple culling rejects entire objects not in the view. More complex systems take into account occlusion of some objects by others, e.g., a building hiding trees behind it.

Cutaneous senses: skin senses, including light touch, deep pressure, vibration, pain, and temperature.

Cybersickness: sensations of nausea, oculomotor disturbances, disorientation, and other adverse effects associated with VE exposure.

Cyberspace: the universe of digital data.

DataGlove: VPL Research, Inc., device for sensing hand gestures, which uses fiber-optic flex sensors to track hand orientation and position, as well as finger flexure.

Deformable object technology (DOT): virtual objects, which bend and deform appropriately when touched.

Depth cueing: use of shading, texture mapping, color, interposition, or other visual characteristics to provide a cue for the distance of an object from the observer.

Desktop virtual systems: virtual experiences that are displayed on a two-dimensional desktop computer; the person can see through the eyes of the character on the screen, but the experience is not three-dimensional.

Dolly shot: display of a scene while moving forward or backward. See also *Pan shot* and *Track shot*.

Dynamic accuracy: system accuracy as a tracker’s sensor is moved. See also *Static accuracy*.

“E” effect: same as the Muller effect.

EBAT: Event-Based Approach to Training—provides the strategies, methods, and tools that are essential for an effective learning environment in a structured and measurable format for training and testing specific KSAs.

Egocenter: sense of one’s own location in a virtual environment.

Embodiment: being inside a body.

Ergonomics: study of human factors, i.e., the interaction between the human and his or her working environment.

Exoskeletal device: flexible interaction devices worn by users (e.g., gloves and suits) or rigid-link interaction systems (i.e., jointed linkages affixed to users).

EyePhone: A VPL Research, Inc., display device consisting of two tiny television monitors (one per eye), earphones, and a sensor for tracking head position and orientation.

Fidelity: degree to which a VE or SE duplicates the appearance and feel of operational equipment (i.e., physical fidelity) and sensory stimulation (i.e., functional fidelity) of the simulated context.

Field of view (FOV): angle in degrees of the visual field. Since a human’s two eyes have overlapping 140-degree FOV, binocular or total FOV is roughly 180 degrees in most people. A FOV greater than roughly 60 to 90 degrees may give rise to a greater sense of immersion.

Fish tank VE: illusion of looking “through” a computer monitor to a virtual outside world using a stereoscopic display system. When looking “out” through the stereo “window,” the observer imagines him/herself to be in something resembling a fish tank.

Formative evaluation: to assess, refine, and improve user interaction by iteratively placing representative users in task-based scenarios in order to identify usability problems, as well as to assess a design’s ability to support user exploration, learning, and task performance.

Force feedback: output device that transmits pressure, force, or vibrations to provide a VE participant with the sense of resisting force, typically to weight or inertia. This is in contrast to tactile feedback, which simulates sensation to the skin.

Formal features: audiovisual production features that structure, mark, and represent media experiences.

Fractal: self-similar graphical pattern generated by using the same rules at various levels of detail, that is, a graphical pattern that repeats itself on a smaller and smaller scale.

Frustum of vision: three-dimensional field of view in which all modeled objects are visible.

Functional fidelity: see *Fidelity*.

Graphical user interface (GUI): user interface that presents information graphically, typically with draggable windows, menus, buttons, and icons, as opposed to a textual user interface, where information is presented on a text-based screen and commands are all typed.

Gravitoinertial force: resultant force combining gravity and virtual forces created by acceleration.

GUI: abbreviation for *graphical user interface*.

Guidelines-based evaluation: see *Heuristic evaluation*.

Gustatory: pertaining to the sense of taste.

Haptic: skin-related, or cutaneous, information. Sometimes refers to information obtained by active touch and manual exploration.

Haptic interface: interface involving the human hand and manual sensing and manipulation.

HCI: abbreviation for *human-computer interaction*.

Heads-up display: display device that allows users to see graphics superimposed on their view of the real world; a form of augmented reality.

Heuristic evaluation: cost-effective and popular method for evaluating a user interface design; the goal is to find usability problems in a design so that they can be attended to as part of an iterative design process; involves having a small set of evaluators examine the interface to determine its compliance with recognized usability principles (the “heuristics”).

Hidden surface: surface of a graphics object that is occluded from view by intervening objects.

HMD: abbreviation for head-mounted display. Though not required, most HMDs include not only a visual display attached to the head, but position tracking to provide a computer with the location and orientation of the head.

Human-computer interaction (HCI): study of how people work with computers and how computers can be designed to help people effectively use them.

Hypotension: a condition in which the body has difficulty regulating the blood pressure, especially when one is upright. There seems to be a misconnection between the brain and the nerves that control the blood pressure and heart rate. The reason is unknown.

Immersion: experience of being physically immersed within a VE experience. The term is sometimes subcategorized into external and internal immersion, and sensory and perceptual immersion. See also *Presence*.

Intelligent user interface: user interface that is adaptive and has some degree of autonomy.

Kinesthesia: ability to perceive extent, direction, or weight of movement.

Kinesthetic: all muscle, joint, and tendon senses. Excludes skins senses, such as touch and vestibular, visual, etc. A subset of somatosensory, which is usually applied to limb position and movement but would also include non-vestibular sensation of head movement (e.g., via neck musculature).

Kinesthetic dissonance: mismatch between feedback or its absence from touch or motion during VE experiences.

KSA: team competencies of knowledge, skills, and attitudes.

Latency: lag between user motion and tracker system response. Delay between actual change in position and reflection by the program. Delayed response time.

Level of detail (LOD): model of a particular resolution among a series of models of the same object. Greater graphic performance can be obtained by using a lower LOD when the object occupies fewer pixels on the screen or is not in a region of significant interest.

Locomotion: means of travel restricted to self-propulsion. Motion interfaces can be subdivided into those for passive transport (inertial and noninertial displays) and those for active transport (locomotion interfaces).

Magic wand: three-dimensional input device used for pointing and interaction. A kind of three-dimensional mouse.

Master: force-reflecting device that can be used to feel and manipulate virtual objects.

Master–slave system: bilateral coupled teleoperator, where the master is the operator control handle and the slave is the remote executing device.

Matching: degree to which a VE mimics reality not only in form but also in terms of function and the behaviors the VE elicits from users.

Meneire's disease: physiological disorder due to abnormal pressure of the vestibular organ producing a wide range of symptoms, which can include turbulent eye movements, extreme vertigo, severe nausea, and distortions in hearing.

Metaball: surface defined about a point specified by a location, a radius, and an “intensity.” When two metaballs come in contact, their shapes blend together.

MOO: MUD object-oriented. See *MUD*.

Motion parallax: means whereby the eyes can judge distance by noticing how closer objects appear to move more than distant ones when the observer moves. See also *Binocular parallax* and *Parallax*.

Motion platform: controlled physical system that provides real motion to simulate the displayed motion in a VE world.

Move-and-wait strategy: typical teleoperation control mode when time delays occur (with direct feedback).

MUD: a multiuser domain where users can jointly interact and play games, such as Dungeons and Dragons.

Muller effect (or “E” effect): tendency to perceive an objectively vertical line as slightly tilted in the same direction as the observer when the observer is tilted by only a moderate amount.

Multimodal command: command issued by the user to a computer simulation using several input communication channels.

Multimodal system: when applied to HCI, a system that allows communication with computers via several modalities, such as voice, gesture, gaze, touch, etc.

Nanomanipulator: a device that allows manipulation on a very microscopic scale.

Navigation: aggregate task of wayfinding and motion (i.e., motoric element of navigation).

Neural interface: ultimate human–computer interface, which connects directly to the human nervous system.

Nystagmus: reflexive eye movements that usually serve to keep the world steady on the retina during self-motion. These eye movements are driven by vestibulo-ocular, cervical-ocular, and optokinetic reflexes. A rapid sideways snap of the eye followed by a slow return to normal fixation or rapid oscillatory movements of the eye, as in following a moving target, in blindness, or after rotation of the body.

Occipital cortex: back of the brain receiving retinotopic projections of visual displays.

Occlusion: hiding an object or a portion of an object from sight by interposition of other objects.

Oculogravic illusion: illusion of visual target displacement that is actually caused by body acceleration. The visual component of the somatogravic illusion (e.g., when an aircraft accelerates and there is a backward rotation of the resultant force vector, in addition to feeling a “pitch up” sensation, the pilot may sense an apparent upward movement of objects in his or her visual field).

Oculoryal illusion: illusion of visual target displacement that is actually caused by body rotation (e.g., the illusory movement of a faint light in a darkened room following rotation of the body).

Olfactory: pertaining to the sense of smell.

Orientation: sense of up and down or north, south, east, and west. Allows an individual to determine: Where am I now? Where did I come from? Where do I want to go?

Otoconia: hair cell mechanoreceptors that are embedded in gelatinous membranes containing tiny crystals of calcium carbonate, through which the otolith organs detect changes in the magnitude or direction of linear acceleration vectors.

Pan: angular displacement of a view along any axis of direction in a three-dimensional world.

Pan shot: display of a scene while moving about any axis. See also *Dolly shot* and *Track shot*.

Parallax: difference in viewing angle created by having two eyes looking at the same scene from slightly different positions, thereby creating a sense of depth. Also referred to as binocular parallax. See also *Motion parallax*.

Parietal cortex: area of the brain adjacent and above the occipital cortex, which processes spatial location and direction information.

Persona: public display, or mask, of the self. Players create persona or characters for their personal use on Internet MUDs.

Perspective: rules that determine the relative size of objects on a flat viewing surface to give the perception of depth.

Phase lag: when output from computer generated images lags the actual position of tracking sensors.

Phi phenomenon: illusion of continuous movement through space induced by a sequence of discontinuous events (e.g., lights flashing in sequence, as on a marquee).

Phong shading: method for calculating the brightness of a surface pixel by linearly interpolating points on a polygon and using the cosine of the viewing angle. Produces realistic shading.

Physical fidelity: see *Fidelity*.

Presence: illusion of being part of a virtual environment. The more immersive a VE experience, often the greater the sense of being part of the experience. See also *Immersion*.

Proprioceptive: internal sense of body position and movement. Includes kinesthetic and vestibular senses, but excludes outwardly directed senses such as vision, hearing, etc. This term is not a subset of somatosensory, nor is it synonymous with kinesthesia.

Prosocial behavior: socially valued behaviors, such as helping, sharing, cooperating, and engaging in constructive imaginary activities.

Pseudo: false.

Radiosity: diffuse illumination calculation system for graphics based on energy balancing that takes into account multiple reflections off many walls.

Ray tracing: technique for displaying a three-dimensional object with shading and shadows by tracing light rays backward from the viewing position to the light source.

Reality engine: computer system for generating virtual objects and environments in response to user input, usually in real time.

Refresh rate: frequency with which an image is regenerated on a display surface.

Registration: correspondence between a user's actual position and orientation and that reported by position trackers.

Render: conversion of image data into pixels to be displayed on a screen.

Retinal binocular disparity (RBD): ratio of the convergence angle of an image to the convergence angle of an object.

Scenes view: virtual display viewed on a large screen or through a terminal window rather than with immersive devices.

Scientific visualization: graphical representation of complex physical phenomena in order to assist scientific investigation and make inferences that are not apparent in numerical form.

SE: common abbreviation for *synthetic experience*.

Second-person virtual systems: virtual environment experiences in which a person is represented by an on-screen avatar rather than being fully immersed in the environment.

Semantic unification: the process of integration and synchronization of information from several input modalities (gesture, speech, gaze, etc.).

Semioclusion: occlusion to one eye only.

Sensorial redundancy: presenting same or related sensory information to a user using several communication channels.

Sensorial substitution: using a different sensory channel to present information normally presented in the replaced modality.

Shared mental models: overlapping knowledge or understanding a task, team, equipment, and situation between team members.

Shutter glasses: glasses that alternately block out the left and right eye views in synchrony with the computer display of left and right eye images to provide stereoscopic images on the computer screen.

SID: spatially immersive display—semisurrounding projected stereo displays.

Side effects.: See *Aftereffects*.

Simulation overdose: spending too much time in virtual environments.

Simulator sickness: various disturbances, ranging in degree from a feeling of unpleasantness, disorientation, and headaches to extreme nausea, caused by various aspects of a synthetic experience. Possible factors include sensory distortions such as abnormal movement of arms and heads because of the weight of equipment, long delays or lags in feedback, and missing visual cues from convergence and accommodation.

Situational awareness: perception of elements in an environment within a volume of time and space, comprehension of their meaning, and projection of their status in the near future; “up-to-the-minute” cognizance required to operate or maintain the state of a system.

Somatogravic illusion: illusions of false attitude occur mainly in pitch or roll. When lacking appropriate visual cues, the balance organs and brain are unable to sort out a force vector (such as delivered by motion of an aircraft), which differs in magnitude and/or direction from the gravitational vector.

Somatosensory or somesthesia: stimuli or senses arising from the cutaneous, muscle, and joint receptors. Touch and pressure cues. Includes all body senses of the skin, muscle, joint, and internal organs (including Mittelstaedts kidney receptors) but excludes vestibular, visual, auditory, and chemical senses (taste and smell). Forms a superset of kinesthetic, tactile, and haptic stimuli or senses.

Sonification: data are used to control various parameters of a sound generator, thereby providing the listener with information about the controlling data. See also *Audification*.

Sopite syndrome: chronic fatigue, lethargy, drowsiness, nausea, etc.

Static accuracy: ability of a tracker to determine the coordinates of a position in space. See also *Dynamic accuracy*.

Stereopsis: binocular vision of images with different views by the two eyes to distinguish depth.

Summative evaluation: typically performed after a product or design is more or less complete. Its purpose is to statistically compare several different systems, for example, to determine which one is “better”—where better is defined in advance; involves placing representative users in task-based scenarios.

Synthetic experience (SE): experience created through a virtual environment. Some authors include passive virtual environments, such as a movie ride where there is no interaction, in the SE classification, while reserving the term *virtual environment* for active synthetic experiences, where the user interacts with the virtual world.

Tactile: sensory information arising from contact with an object, detected through nerves within the skin. Sometimes restricted to passive information, such as air currents over the skin, in contrast to haptic, which is then applied to active manual exploration. See also *Proprioceptive* and *Kinesthetic*.

Tele-: operating from a remote location.

Teleoperation: technology of robotic remote control.

Teleoperation time delay: communication delay necessary to transmit control data to a remote robot or to receive information feedback from the remote location to the operator.

Teleoperator: machine that operates on its environment and is controlled by a human at a distance. It is typically a combination of telesensor or telemanipulator.

Telepresence: perception that one is at a different location, created by sensory data transmitted from that location and possibly interaction with the environment at that location through telemanipulators.

Texture mapping: bitmap pattern added to an object to increase realism.

Track shot: rotating display of the same scene. See also *Dolly shot* and *Pan shot*.

Transparency: teleoperation performance measurement (i.e., fidelity of both information feedback and direct remote robot control).

Update rate: tracker's ability to output position and orientation data.

Usability: the effectiveness, intuitiveness, and satisfaction with which specified users can achieve specified goals in particular environments, particularly interactive systems. Effectiveness is the accuracy and completeness of goals achieved in relation to resources expended. Intuitiveness is the learnability and memorability of using a system. Satisfaction is the comfort and acceptability of using a system.

Usability engineering: methodical “engineering” approach to user interface design and evaluation involving practical, systematic approaches to developing requirements, analyzing a usability problem, developing proposed solutions, and testing those solutions.

Usability evaluation: any of a variety of techniques for measuring or comparing the ease of use of a computer system, including: usability inspection; user interface critiques; user testing of a wide variety of kinds; safety and stress testing; functional testing; and field testing.

User-centered design: design around the needs and goals of users and with users involved in the design process; design with usability as a primary focus.

User-centered evaluation: approach to evaluating (typically a computer’s user interface) that employs representative or actual system users. The evaluation typically involves users performing representative task scenarios in order to reveal how well or poorly the interface supports a user’s goals and actions.

User task analysis: process of identifying and decomposing a complete description of tasks, subtasks, and actions required to use a system, as well as other resources necessary for user(s) and systems to cooperatively perform tasks.

VE: common abbreviation for virtual environment.

Vection: illusion of self-motion, usually elicited by viewing a moving image, but also achievable through other sensory modalities (e.g., audition, somesthesia).

Vestibular: sensory structure of the labyrinth of the inner ear that reacts to head and gross bodily movement. The sense organs embedded in the temporal bone on each side of the head are known collectively as the labyrinthine organs or simply the labyrinths. They include the organ of hearing, or cochlea, the three semicircular canals, and the otolith organs, or utricle and saccule.

Vestibular nucleus: a brain stem structure responsible for processing real or apparent motion stimuli, and implicated in the maintenance of stable posture and reflexive gaze control. On each side of the brain stem there are four principal vestibular nuclei: the lateral, medial, superior, and inferior.

Vestibulo-ocular reflex (VOR): when head moves in any direction, the vestibular apparatus senses this movement and sends velocity information directly to the oculomotor system, which responds by driving the eyes (conjunctively) at an approximately equal rate but opposite direction to compensate for head movement and help keep the visual image stabilized on the retina.

Vibratory myesthetic illusions: illusory feeling of limb or body movement that may accompany certain vibrations of the skeletal muscle. For example, vibration of the biceps tendon with the subject’s arm fixed and his eyes closed can elicit an illusion of arm extension.

Virtual: simulated or artificial.

Virtual environment (VE): three-dimensional data set describing an environment based on real-world or abstract objects and data. Usually *virtual environment* and *virtual reality* are used synonymously, but some authors reserve VE for an artificial environment that the user interacts with.

Virtual heritage: use of computer-based interactive technologies to record, preserve, or recreate artifacts and sites of historic, artistic, religious and cultural significance, and to deliver the results openly to a global audience in such a way as to provide a formative educational experience through electronic manipulations of time and space.

Virtual mechanism: passive artificial modeling structure used in a haptic controller; linked to both a master device (haptic feedback interface) and controlled robot (real or virtual) to allow intuitive and stable (since passive) control and feedback.

Virtual prototyping: product design that is based on VE technology; provides an alternative concept for the design-test-evaluation cycle by eliminating the fabrication of physical prototypes.

Virtual reality: See *Virtual environment*.

Virtual team members (VTMs): multifunctional autonomous agents or simulated images of humans within a VE that function in the role programmed to them.

Visual suppression of the vestibulo-ocular reflex: use of visual information to suppress the normal eye-beating reflex. An example would be reading text at the same time as undergoing a turning movement while riding on a bus.

Voxel: three-dimensional generalization of a pixel. An indivisible small cube that represents a quantum of volume.

VR: common abbreviation for *virtual reality*.

Wayfinding: the cognitive element of navigation.

1. INTRODUCTION

This chapter is intended to provide the reader with knowledge of the pertinent aspects of human visual processing that are relevant to virtual simulation of various environments. Before considering how real-world vision is simulated, it is perhaps prudent to review the kinds of information that are usually extracted by the visual system. It would, of course, be fruitless to provide visual detail that is rarely or never available to the senses, and it may be fatal to the endeavor to omit detail that is crucial. Thus, an overview of normal visual capabilities and idiosyncrasies is provided in section 2. Section 3 reviews some of the ways that perceptual systems provide short cuts to simulating the visual world. The existence of these phenomena allows system developers to compensate for hardware shortcomings with user inferences. One of the most exciting advantages of virtual environment (VE) technology is that it allows a more elaborate and complex interaction between the VE and the observer. A later section reviews a number of the ways in which we interact with the world and how these mechanisms might augment and detract from virtual simulation. After the discussion of what vision entails, a discussion of techniques that use two-dimensional renditions of the visual world to simulate normal viewing of the three-dimensional (3-D) world is provided in Section 5. The emphasis here will be to address the design requirements of VE displays and to determine if existing displays are machine- or observer-limited. Considering what is optimally required by the user, a review of the adequacy of existing visual displays is also provided in section 6. Suggestions are made as to how existing limitations might be overcome and speculations are made concerning what new technology might allow in section 7.

2. WHAT ARE THE LIMITS OF NORMAL VISION? (USER REQUIREMENTS)

Research on human visual capacities is an active field of endeavor. There are still many aspects of visual performance that are not well understood, but knowledge has been accumulating at an accelerating pace throughout the last century. The inquiry continues, but it is important to set forth, from time to time, a compendium of what we think we know. The formal study of vision is perhaps one of the oldest disciplines, and the community of visual scientists is larger than for any other sense. Since the early psychophysicists initiated the systematic investigation of the senses, the notion has been to map the subjective sensations against the physical scales of interest and express the relationship as a “psychometric function” that defines the limits of sensitivity and the subjective scaling of the dimension. That approach will be employed here, but it is important to acknowledge that, in practice, we may utilize little information near the limits of visual abilities. It is conservative, in a sense, to employ this approach to ensure that display technologies meet these user capabilities, but we may learn to “cheat” on these limits if the task requirements allow.

A comprehensive attempt to list human performance capabilities was collated in 1986 and published as the *Engineering Data Compendium: Human Perception and Performance*. (Boff & Lincoln, 1988; see also Boff, Kaufman, & Thomas, 1986). In this chapter we will offer more in the way of explanation of the phenomena described, but the *Engineering Data Compendium* is still an excellent starting location for determining performance limits.

2.1 Luminance

The human visual system is sensitive to a broad range of ambient illumination, extending from absolute threshold ($\sim -6 \log \text{cd/m}^2$) to levels where irreversible damage to the system can result ($\sim 8 \log \text{cd/m}^2$). Many stimulus factors (e.g., size, wavelength, retinal location) have profound influences on the lower limits of this range (Hood & Finkelstein, 1979). The human visual system contains two types of photoreceptors (rods and cones) with significantly different sensitivities. The lowest absolute threshold is mediated by the more sensitive rods, and the cone threshold is achieved about 2.5 log units above that limit ($-3.5 \log \text{cd/m}^2$). At about $1 \log \text{cd/m}^2$ the rod responses begin to saturate, and at higher luminance levels they provide no significant information because saturation is complete. The cones mediate vision above that point. Thus, the entire range can be broken up into a scotopic region (rods only), a mesopic region (rods and cones), and a photopic region (cones only). Many of the visual abilities reviewed below are different in rod- and cone-mediated vision. They also vary, with luminance level in the ranges subserved by each photoreceptor type. These adjustments take some time and are referred to as light (and dark) adaptation. For example, an observer moving from a sunny street into a dark room may take up to 30 min to reach maximum sensitivity for detecting the presence of a target.

2.2 Spatial Abilities

Much of human vision is concerned with discerning differences in luminance and color across space. The extent of the visual field of view, visual acuity, contrast sensitivity, and spatial position accuracy are reviewed in this section. The display factors that relate directly to providing adequate stimulation for such abilities are discussed later.

2.2.1 Visual Fields

The monocular visual field of view is determined by having a subject fixate a point in the center of a viewing area (180 deg H \times 150 deg V) and presenting targets throughout the

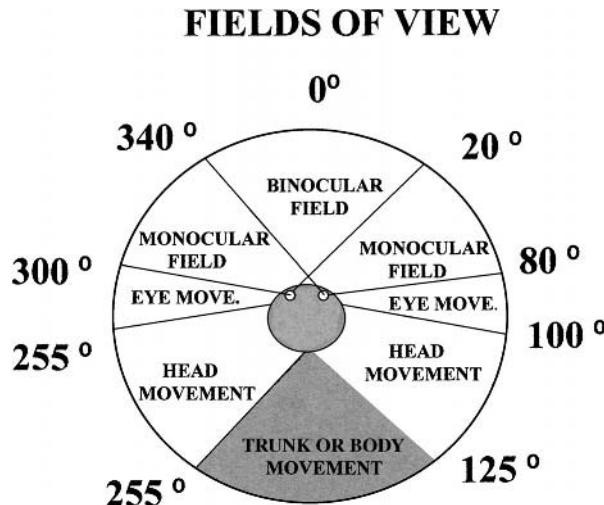

FIG. 3.1. A depiction of the horizontal monocular and binocular visual fields with straight ahead fixation, lateral eye movements, lateral head movement, and bodily rotation.

extent of the area. The limits of the field are defined as the most peripheral points at which target detection achieves some criterion (e.g., 75% correct). These limits vary somewhat with the choice of criterion and also as a result of stimulus factors such as the luminance of the background, the luminance of the target, the size of the target, and the wavelength of the target. In normal individuals with a target subtending approximately 20 arcmin, the horizontal extent is approximately 160 deg, and the vertical extent is approximately 120 deg (see Fig. 3.1). The shape is roughly circular, but is limited by the physiognomy of the nose, brows, and cheeks. Most fields show a restriction in the area of the lower nasal quadrant. A smaller target, subtending one arcmin, may only be detectable within a 20-deg-diameter area (Borish, 1970). The measured field size is also greatly reduced if the observer needs to name the hue of the light, rather than just detecting its presence. This effect also varies with the hue to be named. Arakawa (1953) found a 105-deg horizontal diameter when detecting blue, but only 75 deg for detecting red and 55 deg when detecting green. Similar changes occurred vertically. The consequence of this finding suggests that tasks requiring identification of hue should be centered within the visual field.

Careful probing of the area of the visual field about 13 to 18 deg temporal to the fixation point reveals the blind spot, a scotoma formed by the optic nerve head. It is roughly circular, with a diameter of about 5 deg. The areas of visibility that are common between the two monocular fields form what is termed the binocular visual field. It is roughly circular and is approximately 40 deg in diameter. Binocular viewing helps to compensate for the blind spot, because what is not visible in one eye is visible in the other. However, the disparity cues for depth (see section 2.3.4) are lost in this region.

2.2.2 Visual Acuity

The upper limit of the ability to resolve fine spatial detail is termed visual acuity. It has been measured with numerous techniques (Thomas, 1975), with the normal threshold for spatial resolution ranging between approximately 0.5 to 30 sec of arc, depending on the task. The two detection techniques that yield the lowest values are minimum visible and vernier acuity tasks. In the first task, the width of a single line is varied, and the minimally visible width (0.5 min of arc) is determined. In the second, the lateral offset between two

vertically oriented line segments is determined (1–2 sec of arc). While these are both referred to as acuity tasks, they measure different abilities. The former measures contrast sensitivity (see section 2.2.3) because the change in line width has a greater impact on the retinal luminance-difference between the line and background than on the width of the retinal luminance-change distribution. This outcome is a result of the line-spread function of the eye. Even in a good optical system, a point of light is spread while passing through the optics. In the human system, this spread covers approximately 1 arcmin. Thus, reducing the width of a small bright line will change the total amount of light passing through the optics, but the spread of light on the retina will change very little. Consequently, a very high acuity for changes can be obtained if those changes create a threshold difference in luminance contrast. Levi, Klein, and Aitsebaomo (1985) used a target composed of five parallel lines in which one of the inner lines was displaced to the left or the right. The displacement varied the width of the gaps on either side of the central line. This produced a contrast difference between the gaps on the two sides of the line, which was detectable with only a 0.5-sec line shift—a remarkable spatial discrimination, but a normal contrast discrimination.

The vernier acuity task is more appropriately viewed as a position discrimination task. The misalignment of the bars may be detected by discriminating either a difference in the horizontal location of two vertical bars or a difference in the orientation of the overall figure (Watt, Morgan, & Ward, 1983). This task is discussed further later in the chapter.

Resolution tasks require the observer to determine the minimal separation in space of two or more luminance defined borders. Similar results are obtained with each of two types of commonly employed patterns: gratings and letters. The gratings are high-contrast black lines on a white background with 50% duty cycle, square-wave luminance profiles. The letters are created so that the width of the lines composing the letter is one-fifth of the overall letter size. The acuity measure is calculated from the size of the line width such that the visual angle equals $\text{atan}([\text{line width}] / [\text{distance between observer and letter}])$.

Since different letters vary in the orientation and position of the lines, it is common to use Landolt rings instead. The rings have the same line width to overall size ratio, but also have a gap the same size as the stroke width of the ring. The observers must resolve the gap and identify its location on the ring. Grating tasks and the Landolt ring task can also be used as discrimination tasks by varying the orientation of the stimuli. These three tasks result in similar thresholds (~ 30 sec of arc in healthy young adult eyes). Numerous variables affect visual acuity performance. Visual acuity increases with luminance, from thresholds of about 1 min of arc at 1 cd/m^2 to 30 sec of arc at 100 cd/m^2 (Shlaer, 1937). The recommended standard for illumination for visual acuity measurement is 85 cd/m^2 . Under photopic conditions, visual acuity is optimal for targets presented to the center of the visual field (the fovea) and falls off rapidly (see Fig. 3.2 for a demonstration). The minimum resolvable detail declines from 30 sec of arc at fixation to 20 min of arc at 60 deg eccentricity for Landolt ring acuity (Millodot, Johnson, Lamont, & Leibowitz, 1975). At scotopic levels, acuity is best about 4 deg from the fixation point. The estimates provided above assume that the targets are presented at the optimal distance. There is a limit to the ability to focus on nearby objects. Targets closer than this near point are blurred, and resolution is reduced. The near point recedes with age due to hardening of the lens (presbyopia). This distance may exceed 1 to 2 meters by age 60 and needs to be considered when providing artificial displays, because resolution cannot be good if the display is closer than the near point. Optical correction will frequently be needed for older observers.

2.2.3 Contrast Sensitivity

While visual acuity has been one of the time-honored descriptors of human spatial ability, it only provides information about the extreme upper limit of the spatial dimension to which

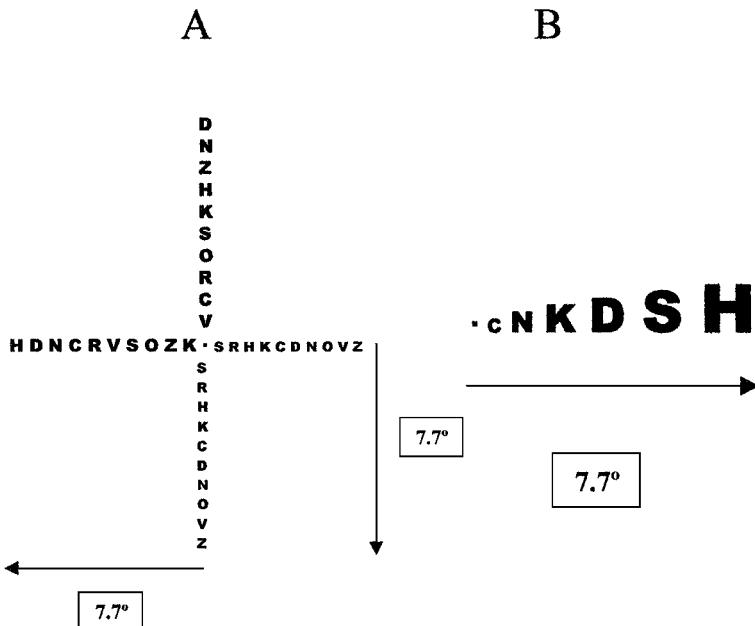

FIG. 3.2. The reader is invited to fixate the small dot in the center of the display at the left and, while maintaining fixation of the dot, take note of how the visibility of the letters declines as more peripheral letters are considered. The figure on the right attempts to compensate for the decline in visual acuity in the periphery by increasing the size of the letters proportionally.

humans are sensitive. Much of what humans see and use may not involve spatial detail near these limits. A popular approach to evaluating human sensitivity for objects of different sizes has been to specify the contrast necessary to detect them. In the simplest case, a light bar on a dark background, contrast (C) can be defined as $C = \Delta L/L$, where L is the background luminance and ΔL is luminance increment (or decrement) provided by the bar. Most visual stimuli are more complex, and thus a measure is needed that can provide a sensitivity estimate for these complex patterns. An alternate method takes into account the nature of the neural units early in the visual pathways. At the first stages of processing in the cortex, units are sensitive to short, oriented line segments. Most units give a strong response to a bar of the correct orientation that is surrounded by other bars of the opposite contrast polarity. The underlying weighting function for the cell's response to light can be approximated by a Gabor function that is produced by multiplying a sinusoidal luminance variation by a Gaussian envelope (Field & Tolhurst, 1986). An image of a Gabor contains a set of bars that alternate between high and low luminance, with contrast that is high in the center of the patch and reducing to zero at the edge of the envelope. When the Gabor is used to represent a weighting function, the bright bars represent excitatory regions and the dark bars inhibitory regions. Individual neurons may vary in the spatial extent of the envelope, the orientation of the cosine, the cosine's spatial frequency, and the cosine's position in the envelope (spatial phase). Since these are the early detectors, one common strategy has been to measure the minimum amount of contrast required for these detectors to reach threshold. Typically, sinusoidal patterns are employed as stimuli, and with these pattern's contrast is defined as $(L_{MAX} - L_{MIN})/(L_{MAX} + L_{MIN})$, where L_{MAX} and L_{MIN} are the maximum and minimum luminance of the image, respectively. With centrally viewed patches of grating of limited envelope size (e.g., 5 deg of arc) and a large surround (e.g., 30 deg) of the same average luminance, the function is band-limited from approximately 0.5 to 60 cycles per degree (c/deg). The peak sensitivity (the reciprocal of

the contrast at thresholds of 0.0033 and 0.0025) is approximately 300 to 400 between 3 and 10 c/deg.

One of the important motivations for this approach to describing visual sensitivity was the power of the tools of Fourier analysis and now Wavelet analysis (Press, Teukolsky, Vetterling, & Flannery, 1992). Using these tools it is possible to describe any image as a collection of sinusoidal gratings varying in orientation, spatial frequency, phase, and contrast. The similarity between the basis functions employed for this analysis and the weighting functions of some visual neurons led to the suggestion that the visual system may be performing a similar analysis. While this may not be true, it is nevertheless valid to argue that the neurons will only respond to that restricted range of spatial frequencies and orientations within an image to which its receptive field is tuned. Thus, if one could determine the sensitivity of a unit and the amount of contrast in the passband of that unit within an image, it should be possible to predict whether that unit will respond to the particular image. In many cases such prediction is possible (Campbell & Robson, 1968; Graham, 1980). However, the utility of this approach is limited by the lack of generality of the foveal contrast sensitivity function. In the periphery of the visual field, high spatial frequencies are increasingly poorly resolved, and thus a different contrast sensitivity function is obtained at each eccentricity. Contrast sensitivity declines with luminance (Van Ness & Bouman, 1967), and varies with target motion (Kelly & Burbeck, 1980; Robson, 1966), orientation (Mitchell & Ware, 1974) and chromaticity (Metha, Vingrys, & Badcock, 1993; Mitchell & Ware, 1974; Mullen, 1985). While these limitations are significant, the contrast sensitivity function is a more comprehensive measure of visual sensitivity than spatial acuity alone, and is used extensively to characterize the performance of the visual system.

2.2.4 Spatial Position

The ability to accurately localize image features is an important precursor to object recognition, shape discrimination, and interaction with a cluttered environment. The appreciation of a form presupposes the accurate relative localization of elements of the form, and the perception of peripherally viewed stimuli serves to guide eye movements and locomotion. Approaches to the characterization of such ability in the frontal plane involve: relative judgements of the spatial position of two or more objects (Badcock, Hess, & Dobbins, 1996; Westheimer & McKee, 1977); bisection of visual space (Levi et al., 1985); and localization of briefly presented target positions (Solman & May, 1990; Watt, 1987). In central vision, relative spatial position thresholds are on the order of 0.05 to 1.0 sec of arc (see vernier acuity previously mentioned) and once again, the threshold depends on the spatial scale of the pattern. If Gaussian luminance increments or Gabor patches are employed, the threshold is proportional to the standard deviation of the Gaussian envelope (Toet, van-Eekhout, Simons, & Koenderink, 1987). These thresholds can be 10 times higher when targets are presented eccentrically by just 10 deg (Westheimer, 1982), a decline that is substantially more rapid than that obtained for visual acuity estimates (Levi, Klein, & Aitsebaomo, 1985).

Partitioning studies also indicate that, at eccentricities of 10 deg, position thresholds vary with the size of the area to be partitioned, increasing from about 0.05 deg at 0.50 deg separation to 0.11 deg at 1.1 deg separation and remaining constant thereafter (Levi & Klein, 1990). Spatial location discrepancies for briefly presented, single targets increase with eccentricity from about 0.04 deg at 2 deg eccentricity to 3.5 deg at 12 deg eccentricity (Solman & May, 1990; Solman, Dain, Lim, & May, 1995). It is clear that the relative spatial sense measured with two or more objects, or partitioning, is more precise than is the localization of targets with more limited spatial landmarks (Matin, 1986). Apparent position is also influenced by the spatio-temporal proximity of nearby objects. Badcock and Westheimer (1985) showed that objects closer than 3-arcmin result in an apparent shift of the target toward the distractor's spatial position, whereas larger distances cause repulsion in apparent position (see also Fendick, 1983;

Rivest & Cavanagh, 1996). A similar phenomenon occurs over large distances, where spatial intervals appear smaller if a larger interval is present nearby, and vice versa (Burbeck & Hadden, 1993; Hess & Badcock, 1995).

2.3 Depth

Theoretically, detection of targets in depth is limited by the spatial resolution of the visual system. If the target is large enough (e.g., our moon) an individual can easily see it at a great distance (245,000 miles). At great distances, two objects (e.g., our sun and our moon) subtending the same visual angle (0.5 deg) appear to be the same size and an individual cannot discern which is closer to them (except during an eclipse). At near distances, however, an individual has little difficulty determining the relative distances of two objects because of the presence of numerous depth cues. The cues are traditionally discussed in terms of those available with monocular and binocular viewing.

2.3.1 Monocular Cues

Monocular cues are those that would be available to an observer using just one eye.

2.3.1.1 Pictorial Cues. Pictorial cues are spatial arrangements that convey relative differences in depth. They are employed by artists adept at conveying 3-D impressions with 2-D depictions. They are:

1. Relative Size: In the absence of information about the absolute size of an object, its apparent size influences judgments of its distance. The zebras in Fig. 3.3 (A–F) appear to be at increasingly greater distances largely because of their progressively smaller sizes.
2. Height Relative to the Horizon: For objects below the horizon (the mice in Fig. 3.4), objects lower in the visual field appear closer than objects higher in the visual field. For objects above the horizon (the butterflies in Fig. 3.4), the reverse is true.
3. Interposition or Occlusion: When objects are opaque, those nearby occlude the view of parts of those objects that are further away and convey an immediate sense of depth. For example, the hill in Fig. 3.4 is interposed between the viewer and the bottom of the trees.
4. Shadows and Shading: A directed light source will strike the nearest parts of an object in its path and be prevented from striking other features on the same path. Thus,

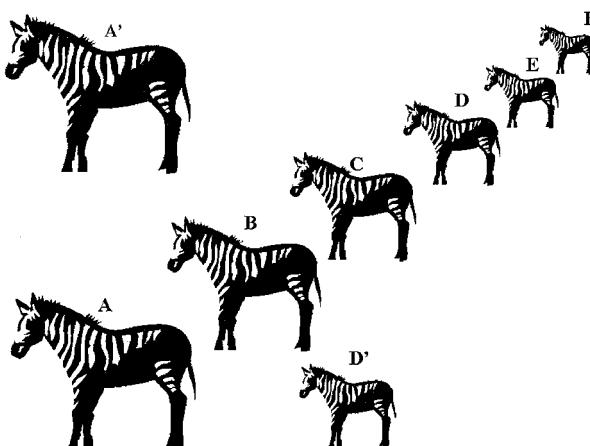

FIG. 3.3. These images convey differences in apparent depth from decreasing size. The smallest zebra appears farther away than the larger ones.

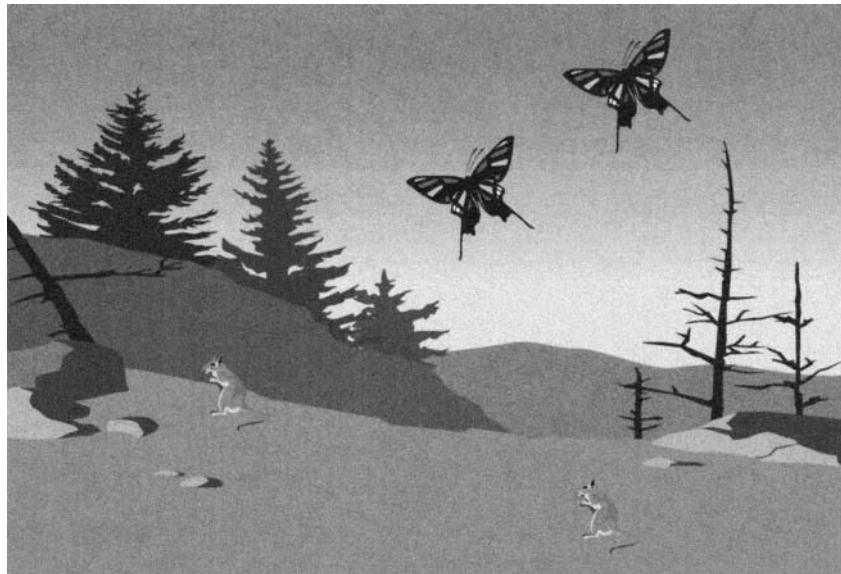

FIG. 3.4. This scene includes demonstrations of height relative to the horizon and interposition or occlusion cues in determining relative apparent depth. (See text for explanation.)

differences in the intensity of the light reflected from object parts can contribute to the appreciation of depth and 3-D shape (see Fig. 3.5a,b). In situations where the position of the light source is not detectable from the image, the visual system resolves ambiguous shading cues by assuming that the light source is above the object (see Fig. 3.5c). In addition, objects often cast shadows on surfaces near them, adding additional cues to figure ground configurations by occlusion or interpolation. The degree of occlusion of a shadow by the object casting it can serve as a cue to the distance between an object and the background. These cues are conveyed in 2-D objects by shading (see Fig. 3.5 d–f).

5. Aerial Perspective: The light reflected from objects is both scattered and absorbed by particles in the medium through which it is observed, causing near objects to be perceived as brighter, sharper, and more saturated in color than far objects. Thus, one cue to distance is the brightness of objects (compare objects A and B in Fig. 3.5).

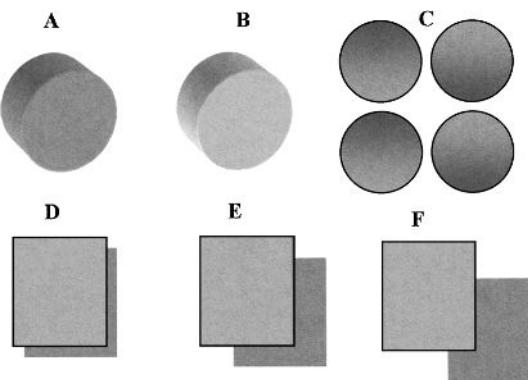

FIG. 3.5. Figures A and B differ in brightness, causing figure B to appear to be somewhat closer than A. The other figures offer other examples of how shadows and shading offer cues to depth. (See text for detail.)

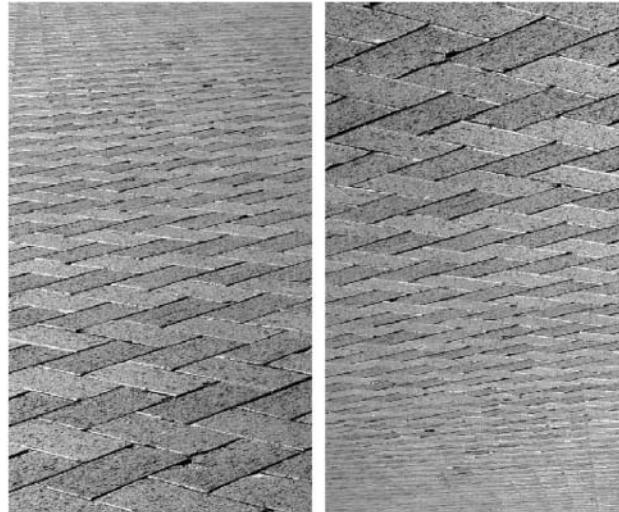

FIG. 3.6. The sidewalk on the left is an example of how texture differences convey depth information. The image on the right is an inverted image of the left panel. In this case depth is still conveyed, but the image is more easily seen as a textured ceiling.

6. Linear Perspective: When parallel lines recede in distance from an observer (e.g., railroad tracks) their projection on the 2-D retina produces a convergence of the lines as distance increases. The contours do not have to be straight, but merely equally spaced as they become more distant (e.g., a winding roadway). This change in perspective with distance provides a compelling cue for depth and is a consequence of representing 3-D scenes on 2-D surfaces.
7. Texture Gradients: Most natural objects are visibly textured. When the image of those objects is projected onto a 2-D surface like the retina, the density of the texture of the surface increases with distance between the surface and the observer. These gradients of texture density are highly salient cues to relative depth (see Fig. 3.6).

2.3.2 Accommodation and Vergence

The human visual system contains an elastic lens that can change curvature and refractive index. If an individual looks at an object positioned within about 3 meters, the curvature of the lens is adjusted to focus the image sharply on the retina, and the muscular contraction necessary for that adjustment can serve as a cue for the distance of the object. Theoretically, differences in these muscle contractions and differences in sharpness for objects at different distances might also be used as depth cues. With binocular viewing, the two eyes converge when viewing near objects and diverge when viewing objects farther away. Information from the extrinsic eye muscle tension is thought to convey information about eye position to the brain, and it might also serve as a cue to depth. Accommodation and vergence are normally linked and covary with the depth plane of the target observed. Some doubt the utility of these potential physiological cues to depth, but these variables may be quite important for virtual simulations where depth may be produced by disparity cues between two screens that are near the eyes. Under these circumstances, the necessary accommodation and convergence may not be congruent with normal visual experience. The consequences of this are discussed in chapter 37 (this volume) and later in this chapter.

2.3.3 Motion Parallax

All of the cues so far discussed have concerned static scenes and a stationary observer, but additional depth information is conveyed when the scene is moving relative to the observer, or the observer is moving relative to a static scene. The typical example is an observer on a moving train viewing the landscape as it passes. If the observer fixates a point midway between the train and the horizon, two movement-related phenomena can be observed. First, objects beyond the plane of fixation appear to move in the direction that the observer is moving, while objects closer than the fixation plane move in the direction opposite of the observer's movement. Second, the retinal speed of objects is proportional to the distance of the object from the fixation point. Not only do these phenomena provide important information about the depth of objects in the field, but they also tell us about our movement relative to the environment (Rogers & Graham, 1982). A special case of motion parallax, known as the kinetic depth effect, occurs when an individual views a moving 3-D object. Imagine a sphere constructed of a meshwork of fine wire. When it is stationary it may be difficult to appreciate its shape, but when it is rotated the contours near the observer move in one direction, whereas the contours farther away move in the opposite direction. This shape information can even be recovered from a shadow cast by the sphere onto a 2-D screen.

2.3.4 Binocular Cues

Although most people view the world through two eyes, they usually see a single unified view of the world. By viewing a scene alternatively with one eye and then the other, an individual can appreciate the differences in the two views. Ignoring the differences in field of view provided, the individual can also notice slight differences in the relative position of objects within the overlapping regions of the two monocular views. These differences are fused to form a singular view when the individual uses two eyes. The horopter (see Fig. 3.7) is a hypothetical surface in space determined by the point in depth for which the eyes are converged (and accommodated). For a given depth of focus, all the points on the horopter are associated with homologous pairs of points on the two retinae. The theoretical horopter defines the curved

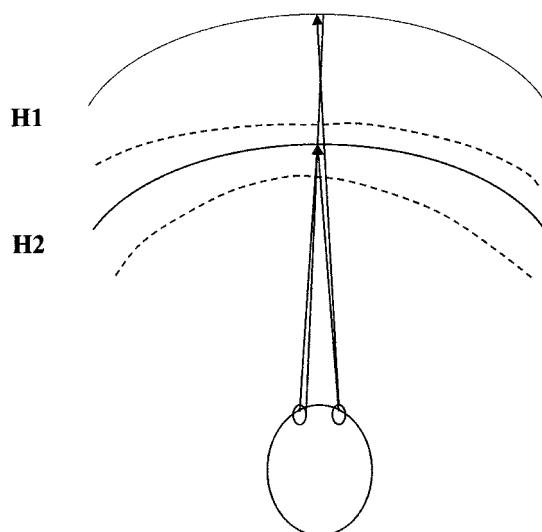

FIG. 3.7. A depiction of two horopters (H1 and H2) associated with fixation in two different depth planes. The existence of Panum's fusional area (dotted lines) is depicted only for H2.

region in which there is no disparity between the two monocular views. The area in front of the horopter contains disparities that are said to be “crossed” (because it would be necessary to cross the eyes to bring the points onto homologous retinal areas), and the area beyond the horopter contains disparities, which are said to be “uncrossed.”

The region of binocular fusion is a zone approximately centered on the horopter. The reader can appreciate this fact by viewing two objects (e.g., fingers) in different depth planes. If the near object is fixated, attending to the far object reveals double images of that object (diplopia), but a single image of the fixated object. If the far object is fixated, attending to the near object reveals double images of that object (diplopia), but a single image of the fixated object. When fixating 3-D objects, the binocular image contains some areas that fall in front of or behind the horopter and must therefore contain retinal disparities, but these double images are fused and seen as one object. The region in depth over which disparities are fused and singular vision is perceived is termed Panum’s fusional area (dotted lines in Fig. 3.7). This area encompasses the horopter and includes areas behind and in front of it.

Studies that have involved dichoptic viewing (presenting separate images to the two eyes) have revealed that subjects will strive to overcome diplopia with vergence eye movements that seek to reduce retinal disparity. If two images can be brought into register with only slight disparity between aspects of the two views, then fusion is achieved and singular vision is experienced. If, however, the disparities are too great, diplopia ensues and binocular rivalry between the two views is often experienced (seeing one view but not the other, or seeing part of one view and part of the other).

Fusion of disparate images brings with it not only singularity of view, but also more importantly, a vivid sense of depth. For example, imagine viewing dichoptically, two separate vertical, square-wave gratings. When fused they will appear as a single grating in the frontal plane without any depth differences. If the spatial frequency of one of the gratings is shifted slightly lower, the image remains fused but appears to rotate in depth. Retinal disparity is ubiquitously present in our binocular view of the 3-D world, and it may be simulated in 2-D to produce depth information (Howard & Rogers, 1995). The smallest disparity that provides depth information is termed the threshold for stereopsis. This threshold is smallest when the target is viewed foveally and on the horopter (Badcock & Schor, 1985). In the fovea, this threshold may be only a few seconds of arc, but the thresholds increase with the eccentricity of the target to about 300 sec at 8 deg.

2.4 Color Vision

In addition to our ability to discern differences in luminance across space and time, humans may also discriminate between the wavelength of light across these dimensions. The history of research on color vision is, perhaps, the most extensive consideration of any human ability and our understanding of the mechanisms by which humans appreciate color differences reflects that impressive effort. The concern here, however, is to define the limits of that human ability and not to explain the mechanisms underlying them. Humans are sensitive to electromagnetic radiation in the range of 370 to 730 nm (Wandell, 1995). Various light sources (e.g., the sun, tungsten bulbs, fluorescent lights) provide a broad band of radiation across and beyond this visible spectrum. Traditional methods of studying color vision have involved various methods of restricting the spectrum to narrow bandwidths. Transparent devices (e.g., filters, diffraction gratings, prisms) are characterized in terms of spectral transmittance, while opaque media (e.g., paper, paint) are described in terms of their spectral reflectance.

The first question addressed concerning sensitivity to chromaticity involved determining the threshold for detecting the presence of a light composed of only a narrow range of wavelengths. Measures at scotopic levels (rod-mediated vision) revealed that the sensitivity varied with a

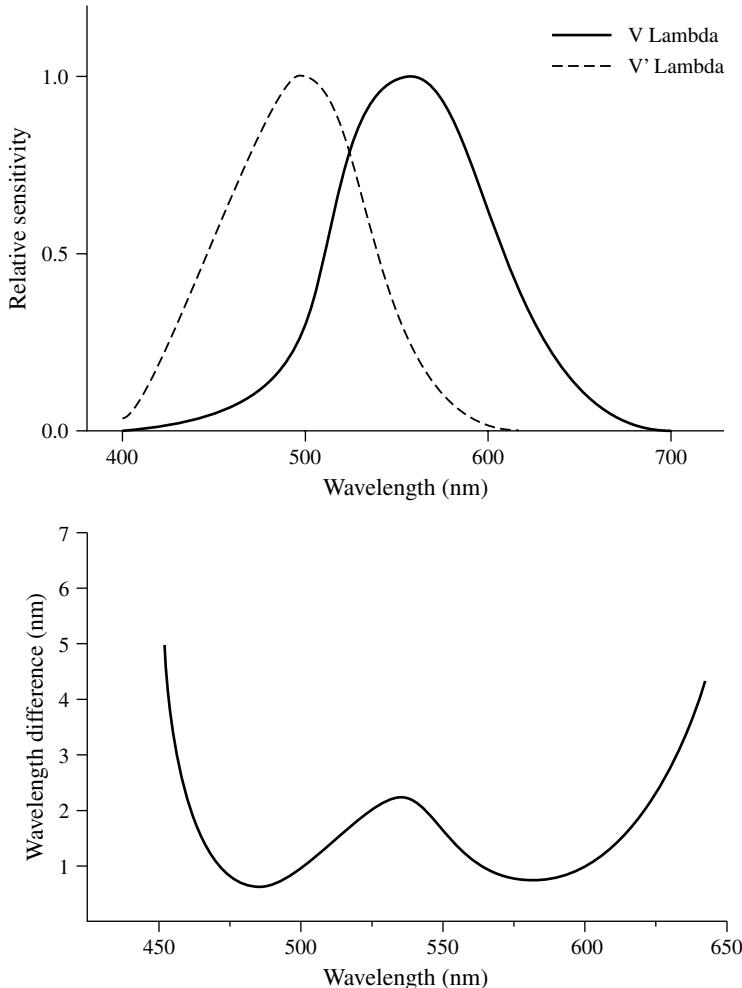

FIG. 3.8. The upper panel contains the function depicting the spectral sensitivity of the human eye under scotopic (A) and photopic (B) conditions, CIE V' and CIE V respectively. The two functions have been normalized to remove the overall increased sensitivity of the scotopic system. The lower panel contains the function that describes wavelength discrimination across the spectrum (from Hurvich, L. M. [1981]. Color Vision, Sinauer and Assoc., Inc., Sunderland).

peak at about 500 nm (the Commission Internationale de l'Eclairage, CIE, V' function; see upper panel of Fig. 3.8). At photopic levels, a similar function was observed, with a peak at 555 nm (the CIE V function; see upper panel of Fig. 3.8). At mesopic levels the measured functions are a combination of the other two. It must be noted that these curves only reflect the sensitivity to light of different wavelengths. They do not address the ability to identify or discriminate between colors. Color vision is defined as the ability to discriminate between stimuli of equal brightness on the basis of wavelength alone. Under scotopic conditions this is not possible, but under photopic conditions the full extent of color vision is measurable.

Wavelength discrimination tasks involve asking the observer to vary the wavelength of a comparison stimulus until it can be differentiated from a standard that is of some given wavelength. The increment in wavelength necessary to discern a difference when the stimuli are of equal brightness is plotted against wavelength (see lower panel of Fig. 3.8). The wavelength

varies between about 1 and 13 nm, and the function contains two minima in the ranges of 450 to 500 and 550 to 600 nm. This kind of discrimination varies with a number of parameters. Chromatic discrimination ability decreases with luminance, especially at lower wavelength (Brown, 1951; Clarke, 1967; Farnsworth, 1955; Siegal & Siegal, 1972), but remains fairly constant above 100 td. (Trolands are a measure of retinal luminance that incorporate the effects of changes in pupil diameter: $I[\text{Trolands}] = R \cdot [\text{pupil area in mm}^2] \cdot [\text{luminance in cd} \cdot \text{m}^{-2}]$, where $R = 1 - 0.0106d^2 + 0.0000416d^2$ and $d = \text{pupil diameter in mm}$). Discrimination is reduced with field size below 10 deg (Brown, 1951; Wyszecki & Stiles, 1967) but is relatively unaffected by separation between comparison fields (Boynton, Hayhoe, & MacLeod, 1977). If comparison fields are presented successively, discrimination is unaffected until a stimulus onset asynchrony (SOA) of 60 ms, but declines at higher intervals (Uchikawa & Ikeda, 1981). Discrimination for some wavelengths (400 and 580 nm) asymptotes at 100 msec, whereas other wavelengths (480 and 527 nm) require 200 msec for best performance (Regan & Tyler, 1971). Discrimination is poor at eccentricities beyond about 8 deg.

In addition to discrimination of hue, human observers can discern differences in the purity of white light. The threshold for colormetric purity is defined as the amount of chromatic light that is added to white light to produce a just noticeable difference (JND). Additional JNDs can be observed with increasing steps in the chromatic additive. The number of JNDs observed varies with the wavelength of the additive and is least at about 570 nm. The term *saturation* is used to describe the subjective correlate of colormetric purity. A highly saturated light appears to have little white light “contamination”.

If the JND is taken as the step size in the dimensions of hue, brightness, and saturation, Gouras (1991) has suggested that there are about 200 JNDs for hue, 500 JNDs for brightness, and 20 JNDs for saturation. This suggests that human color vision capability involves the discrimination of about two million chromatic stimuli ($200 \times 500 \times 20 = 2,000,000$).

The visual subsystem that processes chromatic information differs in a number of significant ways from the subsystem that encodes luminance variation. Critically, for artificial systems where bandwidth limitations are significant, the chromatic system has substantially poorer spatial (Mullen, 1985) and temporal (Cropper & Badcock, 1994) resolution, and thus chromatic properties can be rendered more coarsely in both space and time. Mullen (1985) estimates that the spatial resolution for red-green gratings is three times worse than for achromatic gratings (10 to 12 c/deg instead of 60 c/deg), whereas Cropper and Badcock (1994) reported a twofold reduction in temporal resolution.

2.5 Motion

Humans can see objects moving with respect to themselves, whether they are stationary or moving, and they can detect their own movements through space in a static environment or with objects moving around them. Information about one object’s movement relative to another (exocentric motion) is obtained from the image of the objects moving across the retina. An observer may attribute motion to the object that is actually moving or may see movement of a stationary object if the frame around it is displaced (induced movement). Information about object movement relative to an observer’s own position or movement (egocentric motion) comes from translations in the retinal image in relation to nonvisual senses (e.g., vestibular and kinesthetic senses) that are involved in body, head, and eye movements. Mere translation of the object on the retina cannot provide information about egocentric information. Humans do not perceive object motion relative to themselves if they move their head or eyes while looking at or away from a stationary object (position constancy).

There are several ways in which one might measure a minimum motion threshold. First, one could measure the minimum distance a feature has to be displaced in order for the

direction of motion to be detected. When a visual reference is present, displacements as small as 10 arcsec are sufficient for this judgment (Westheimer, 1978). Second, one could measure the minimum temporal frequency required to detect movement in a temporally extended motion sequence. This threshold depends on both the contrast and the spatial structure of the moving pattern (Derrington & Badcock, 1985). The minimum temporal frequency decreases as contrast increases for low-spatial-frequency periodic sinusoidal grating patterns, but is constant for high-spatial-frequency patterns. Third, one could measure the minimum number of dots needed to move in a common direction in a field of randomly moving dots for that direction to be discernible. Edwards and Badcock (1993) have found that as few as 5% to 10% of dots moving in a common direction is sufficient for either frontoparallel motion or for expanding/contracting patterns designed to mimic motion in depth.

Whereas these are impressive abilities, it is also the case that the perception of motion is influenced by a number of stimulus properties. The perceived speed of an object slows if the luminance contrast of the object is reduced (Cavanagh, & Favreau, 1985; Thompson, 1982), and observers are unable to see very high spatial frequency repetitive patterns move at all (Badcock & Derrington, 1985). Objects appear to move more slowly through smaller apertures and at greater distances (Rock, 1975).

Finally, even relatively brief periods of exposure to continuous motion (e.g., 30 sec to 1 minute) produces substantial motion aftereffects, which causes stationary patterns to appear to drift in the direction opposite to the adapted direction (Mather, Verstraten, & Anstis, 1998). In computer environments, these aftereffects commonly arise due to smooth scrolling of stimulus displays, and they can produce compelling impressions ofvection (see later discussion and chap. 23, this volume). A common example is observed when trains pull into a station. The continuous visual adaptation to forward motion creates the egocentric impression of rolling backward when the train is stationary.

2.6 Motion in Depth

Regan and Beverly have developed the notion that motion in depth is mediated by at least two mechanisms: changing size, (Regan & Beverly, 1978a, 1978b) and changing retinal disparity (Regan & Beverly, 1973). Changing size is a monocular mechanism and is characterized by thresholds of about 1 minute of arc. The velocity of the size change is proportional to the perceived motion in depth. Changing retinal disparity is a stereoscopic cue with approximately the same thresholds for detection as changing size. Figure 3.9 summarizes the movement on the retina caused by monocular and binocular viewing conditions. In A, motion of an object toward the viewer results in the edges of the object moving in opposite directions (expansion) on the retina (and vice versa for movement away from the observer, not illustrated). In B, motion toward the observer results in both object expansion and movement of the edges of the object in opposite directions (translation) on the two retinas. In C, motion of an object toward the left eye will result in only expansion in that eye, but translation and expansion in the right eye. In addition to the differences in direction of movement in the binocular case, differences in velocity occur on the retinas when the object is not moving on a trajectory aimed midway between the eyes. Comparisons of monocular and binocular sensitivities to motion in depth reveal the binocular sense to be slightly more sensitive than the monocular case, as in spatial vision (McKee & Levi, 1987). Both mechanisms appear to provide input to a single motion in depth stage, however, because motion perceived in terms of changing size can be “nulled” with conflicting disparity manipulations. This information concerning motion in depth appears to be uniquely derived because this ability cannot be accounted for by static stereoacuity performance and the visual fields for stereo-motion in depth are constricted relative to those observed for static stereopsis. However, receptive fields for motion in depth

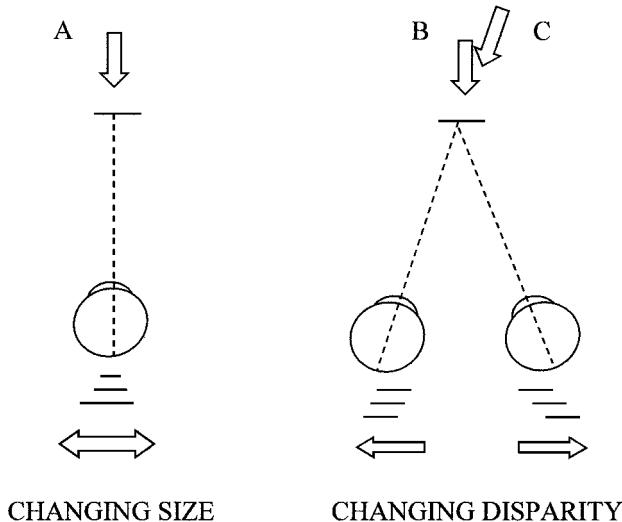

FIG. 3.9. The diagram on the left indicates how the edges of an object on a single retina move in opposite directions under expansion and contraction conditions produced by an object moving toward or away from the observer. The diagram on the right indicates how opposite object motion occurs on the two retinas when it is stereoscopically viewed. (See text for elaboration.)

signaled by optic flow without stereo cues are very large compared to those for stereopsis. Burr, Morrone, and Vaina (1998) have shown signal integration with stimuli up to 70 deg in diameter in psychophysical experiments, and Duffy and Wurtz (1991) have reported single cells with fields up to 100 deg in diameter in cortical area MT. These mechanisms seem ideal for detecting the optic flow produced by locomotion and appear to be centrally involved in its control. Interestingly though, Edwards and Badcock (1993) have shown that observers are more sensitive to contraction than expansion, which is the kind of flow produced by walking backward.

3. WHAT DO WE INFER FROM WHAT WE SEE? (SHORT-CUTS)

Previously, the various visual capabilities with regard to detection and discrimination along a number of stimulus dimensions were enumerated. That approach to visual perception assumes a relatively passive observer and defines the abilities in terms of the physical limitations of the visual system. But the human observer is rarely passive and usually interacts with the environment with expectations, goals, and purposes. These psychological aspects of perception have been the focus of numerous lines of research and have provided insight into various phenomena that serve to facilitate and disambiguate information-processing tasks. In this section, we consider these propensities and the implications for perception within the simulated environment.

3.1 Figure/Ground Organization and Segmentation

Glance at Fig. 3.10a and ask yourself what you saw first. You might say lots of Ss, or Hs made of Ss, or an E made of Hs made of Ss. Whatever it was that you perceived first, it is easily possible to see the other possibilities with further examination. While humans rarely think about it, similar perceptual processes are employed in the analysis of all images. An observer

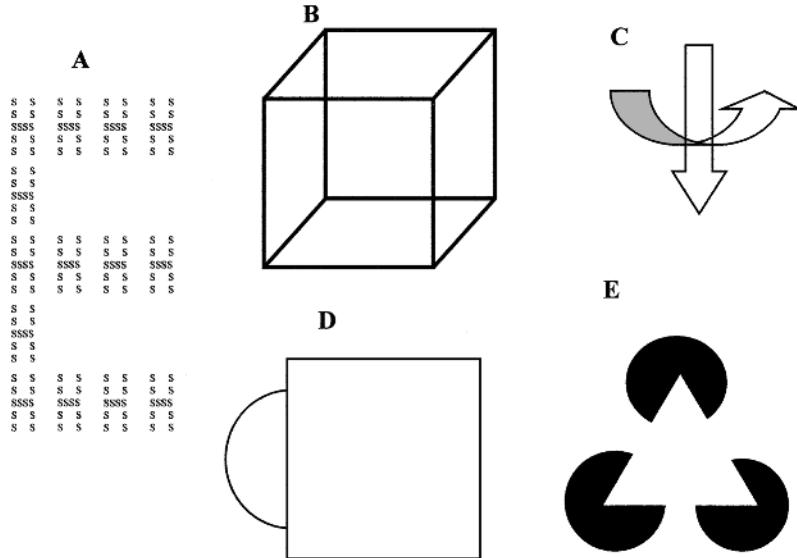

FIG. 3.10. Stimuli that provide examples of perceptual organization and the Gestalt laws that have been proposed to facilitate it. (See text for details.)

might stare at a forest and see its global outline against the sky, or look at a particular tree as an element in the forest, or attend to a leaf on one of its branches. In each case, the observer can describe the object of their attention as an object perceived against a background (or ground). Since nothing need change in the scene in order for the observer to experience these different perceptual figure–ground organizations, they are forced to conclude that the experiences are not driven by stimulus change but are determined either physiologically (through adaptation) or psychologically, through directed attention and/or perceptual set. Consider Fig. 3.10b, the Necker cube. Although the figure is static, an observer can perceive two possible perceptual organizations involving different depth planes, one with the box protruding to the upper right, the other with the box protruding to the lower left. Much of the visual work accomplished is cognitively driven wherein the observer searches for objects or serially processes objects (e.g., reading) against a background. Early Gestalt psychologists (e.g., Koffka, 1922) proposed a set of “laws” which suggest what stimulus configurations facilitate perceptual organization. Recent work has been attempting to determine the algorithmic and physiological bases for some of these phenomena. They are still poorly understood but have proven to be useful for scene segmentation in computational models. The factors are:

1. Proximity: Given an array of elements, those closest together are more likely to be grouped into a global structure. Elements that are close to one another tend to be seen as an object (e.g., the *H* in Fig. 3.10a).
2. Similarity: Similar objects tend to be grouped together to form a global structure (e.g., the *H* in Fig. 3.10a).
3. Good Continuation: Lines are perceived as continuing with the minimum angular deviation necessary. In Fig. 3.10c the vertical lines of the vertical arrow could deviate sharply along the horizontal arrow but the default grouping avoids this solution. Field, Hayes, and Hess (1993) have described an association field that quantifies the likelihood of binding elements on a smooth path as a function of angular deviation of the path.

4. Common Fate: Elements of an image that undergo a common transformation over time are frequently grouped as one object. The most extensively studied transformation is lateral motion, which produces rapid segmentation of complex scenes. The precise mechanisms are yet to be revealed, but single cells in the medial temporal cortical area (MT) have stimulus preferences for dot patterns moving in different directions to their surroundings and thus may form a neural substrate for this segmentation (Allman, Miezin, & McGuinness, 1985).
5. Closure: When a form is drawn with broken or incomplete contours, the perceptual system perceives that form that would result if the contours were complete (Rock, 1975). This is not to say that the breaks in the contours are not detectable, but rather that those breaks do not prevent grouping for object recognition (see Fig. 3.10d).

These principles may be applied to images containing a broad array of stimulus attributes. Interestingly, once grouping has occurred quite distinct boundaries may be formed that are not physically present in the luminance profile of the image. For example, Fig. 3.10e appears to be interpreted by the visual system as a white triangle overlapping the black circles. An illusory brightness difference is usually perceived between the inferred center of the triangle and the surrounding area. The border between these two zones can appear to be very sharp. Some of these borders may be seen because they stimulate nonlinear texture detection processes within the visual system (Wilson, Ferrera, & Yo, 1992), but no adequate model exists for the full array of illusory contours at this stage.

3.2 Perceptual Constancies

Although the 2-D representation of objects on the retina may undergo considerable translations in lightness, color, orientation, size and position, humans maintain an appreciation for these basic properties of the object. Thus, a white piece of paper (on a gray background) viewed in direct light and in a cast shadow appears to be the same brightness despite the fact that one reflects more light than the other. Likewise, a piece of colored paper (on a gray background) viewed under different colored lights will appear a very similar color despite the differences in hue of the illuminant. This page is viewed as rectangular whether viewed from directly above or from a 45-deg angle and it is perceived to be the same size whether viewed from 18 inches or 18 feet. The page is seen to be in the same position in space whether an observer looks directly at it or gazes to the side. While the mechanisms whereby these constancies are achieved are still the subject of active research, most explanations emphasize a ratio principle. For lightness and color constancy, it is proposed that the ratio of the lightness or the hue of both the object and the background is extracted and if the ratio is the same, constancy is achieved. For shape and size constancy, the critical ratio refers to the size and orientation of elements in the object relative to size and orientation in the background under different viewing conditions. See Palmer (1999) for a recent review of these mechanisms. Position constancy will be elaborated upon later.

3.3 Exocentric Motion

Consider a small, stationary point of light in a totally dark room. That object appears to move in a quasi-random fashion and subjects find it quite difficult to specify its position (by pointing or touching its location). This illusion of exocentric motion is termed the autokinetic effect (Sandström, 1951), and it indicates how difficult it is to determine the motion of an object without a visual frame of reference. The effect is actually caused by implicit eye, head, and body movement in the absence of the stabilizing effect of visual information and is really an

egocentric illusion. In a lighted room with referential stimuli, the object is seen as stationary (Mack, 1986). The next question concerns how much that object must be displaced for the observer to detect movement. With a frame of reference, the displacement threshold has been estimated to be 1 to 2 min, but that value increased tenfold when the reference was removed (Aubert, 1886; Bourdon, 1902; Grim, 1911). With real movement, the moving object is always visible. It moves a given distance (or is visible for a given time), and its movement generally has a fixed velocity (in the simple case). The upper threshold for the detection of movement depends on many factors (luminance, field of view, spatial pattern), but long before an object moves too fast to be seen, the form of the object is obscured. One estimate of this threshold point is termed dynamic visual acuity, and it indicates that form vision as measured by Landolt C acuity is compromised above about 60 to 100 deg/sec (Ludvigh & Miller, 1958). However, very large objects may be detectable up to 3000 deg/sec provided the temporal frequency of the stimuli falls inside the critical flicker fusion limit (Burr & Ross, 1982). There is a belief that, at moderate velocities, displacements are perceived as movement, but at lower velocities motion is based on change in position (Anstis, 1980; Exner, 1875). Some suggest that with brief durations (< 0.25 sec) only velocity is sensed and only at long durations would velocity thresholds be improved by a framework (Gregory, 1964; Liebowitz, 1955). Velocity thresholds increase in the periphery (Aubert, 1886). There is also a common misconception that the peripheral retina is better at motion detection than the central retina. On the contrary, Tynan and Sekuler (1982) reported minimum movement thresholds to be on the order of 0.03 deg/sec in the fovea, increasing to 0.45 deg/sec at 30 deg eccentricity.

When two objects are moved in the visual field, the difference threshold for velocity has been estimated to be in the range of 30 sec/sec (Graham, Baker, Hecht, & Lloyd, 1948) to 2 min/sec (Aubert, 1886). But with two objects, induced movement and motion contrast effects come into play. Induced movement is an illusion of motion in which the displacement of some elements results in the attribution of movement in other elements. For example, moving a frame around a stationary object often results in an apparent movement of the object in the direction opposite to frame movement. Motion contrast is a type of induced movement that occurs at the borders of adjacent fields of moving elements. Adjacent elements moving in different directions and/or at different velocities can induce illusory directional and velocity attributes (Levi & Schor, 1984).

3.4 Egocentric Motion

Motion in the visual field due to one's own movement is easily discriminated from motion in the visual field due to object motion. The mechanisms that underlie this ability involve a comparison between the movement sensed on the retina and nonvisual signals associated with one's own movements. When movement of an object on the retina is negatively correlated with eye, head, or body movement (later discussed), position constancy holds and objects are seen as stationary. Any mismatch between the visual and nonvisual information signals movement of the object relative to the observer. The limits of position constancy define the precision of these mechanisms. For head movements, position constancy breaks down with displacement ratios (retinal movement/head movement) of 1.5% (Wallach & Kravitz, 1965). While humans are quite accurate at detecting displacements during fixation (2–3 min), displacements as large as 6 min go undetected if they occur during a saccadic eye movement (Stark, Kong, Schwartz, Hendry, & Bridgeman, 1976). Target displacements of less than 1/3 saccadic displacements are rarely seen (Bridgeman, Hendry, & Stark, 1975). Thus, the resolution of the position constancy mechanism during saccades is degraded relative to fixation. When a moving target is tracked with smooth-pursuit eye movements, its perceived speed has been reported to be 63% of that reported when it is moved through the field when the eyes are fixated (Dichgans, Koener, & Voight, 1969; Turano & Heidenreich, 1999). In addition, stationary objects in the field appear

to move (the Filehne Illusion) when the eyes track another moving object (Filehne, 1922). Wertheim (1994) argues that reference signals are generated through visual, oculomotor, and vestibular interactions, and it is the comparison of the retinal and reference signal that mediates the perception of self and object motion. He suggests that while oculomotor-generated signals encode how the eyes move in orbits, vestibular signals must be added to form these reference signals to encode how the eyes move in space.

3.5 Visually Induced Self-motion

Various senses contribute to human's perception of motion through the environment (see chaps. 7 and 23, this volume), but one of the most important inputs is from motion in the visual array. When motion information from nonvisual inputs is in correspondence to visual information, humans perceive themselves to be moving in a more or less veridical fashion. There are, however, instances when nonvisual inputs might be expected to signal no self-motion, but the visual array contains scene translations that would signal that the entire environment is moving relative to the observer (a situation that rarely occurs in nature without bodily movement). According to the notions about egocentric motion discussed above, one might expect this situation to result in the perception that one is stationary and the world is moving, but in many cases one perceives an illusory sense of self-motion. Parametric studies which have sought to outline the stimulus conditions that result in such illusions offer important knowledge about how visual inputs provide information about self-motion as opposed to scene movement, and how self-motion might be simulated with purely visual displays.

Mach (1875) was the first to investigate illusory self-motion. He noted that if an observer, seated on a stationary platform, is placed inside a rotating drum, the internal surface of which is covered with vertical stripes, they often report a vivid perceptual illusion of self-rotation in the direction opposite to that of the drum rotation. He referred to this illusion as circularvection (CV). Dichgans and Brandt (e.g., 1973) have provided the most extensive series of studies on the topic. They noted that such stimulation also causes optokinetic nystagmus (OKN—see section 4.1.2 below), regular eye-movement patterns in which smooth pursuits in one direction are interleaved with rapid return flicks. Stimulus parameters that effect the preponderance of CV are: field of view (FOV); fixation of a stationary target; cylinder rotational velocity; and the spatial frequency of the stimulus contours. The latency to onset of CV seems to map onto the differences in stimulation from the vestibular and visual system during real bodily rotation. In that situation, the two senses agree at the onset of motion, but as rotation ensues at a constant angular velocity, the vestibular system ceases to respond and only visual evidence of rotation continues. Studies of illusory CV indicate that at high levels of drum rotation (> 5 deg/sec) CV latency increases, but below that level the sensation is almost immediate. That finding is commensurate with the fact that vestibular stimuli are not effective at low levels of acceleration and would not be expected to provide a stabilizing source of stimulation. The velocity of CV is proportional to the velocity of drum rotation up until about 90 deg/sec, when the duration of CV declines.

Depth cues also affect CV (Brandt, Wist, & Dichgans, 1975). Displays farther away from the subject are more effective at producing illusory self-motion. Some argue that CV is dependent on peripheral-visual-field stimulation, whereas OKN requires only central field stimulation (Dichgans & Brandt, 1973), but Post (1988) reported that CV can be obtained with a restricted FOV. Young, Dichgans, Murphy, and Brandt (1973) showed that CV could be augmented or suppressed with bodily accelerations in the same or different directions, respectively, and that the threshold for detection of bodily movement was raised when the visual and vestibular stimuli were in conflict. Stern, Hu, Anderson, and Leibowitz (1990) reported that subjects who viewed rotating stripes with fixation reported somewhat less CV, and a restricted FOV (15 deg) resulted in greatly reduced CV. Brandt, Dichgans, and Koenig, (1973) found that CV was still

present in a situation where stripes in the whole visual field moved in one direction, whereas OKN was elicited by stripes moving in the opposite direction in a small central field.

In addition to illusions of continuous self-rotation, displays that lead to CV also can elicit illusions of bodily tilt in the direction opposite to drum rotation (Held, Dichgans, & Bauer, 1975). The individual does not experience continuous "barrel rotation," but rather experiences a static illusion of tilt that increases with the velocity of the drum up to a value of about 15 deg. This illusion is more influenced by peripheral stimulation and has a latency of about 18 sec. These sensations are exacerbated by inclination of the head during stimulation (Young, Oman, & Dichgans, 1975). Illusions of "pitch" fore and aft are created with displays that rotate around the horizontal axis of the body. In these situations, observers experience a constant feeling of rotation in the direction opposite to drum rotation, with a concomitant static illusion of body inclination in the direction of illusory self-motion (Young et al., 1975).

Stimuli that involve movement in depth often give rise to illusory sensations of linearvection (LV). These stimuli also elicit vergence eye movements (Collewijn, Erkelens, & Steinman, 1995; Erkelens & Regan, 1986). Most stimulus conditions that produce the illusion of LV involve wide FOV; however, Anderson and Braunstein (1985) were able to produce strong sensations of LV with a small FOV. These authors and others (Telford & Frost, 1993) emphasize the strong influence of depth cues (kinetic occlusion, optical velocity, and size change). They suggest that the central visual field conveys a different kind of movement information (detailed depth information) than the periphery, and that if both mechanism are stimulated, synergistic or antagonistic influences on self-motion may be obtained. Many individuals become motion sick with prolonged exposure tovection-inducing stimulation (see chaps. 30, 32, and 36, this volume).

4. HOW DO WE LOOK AT AND MANIPULATE OBJECTS? (MOVEMENT OF THE OBSERVER)

Interaction with the real world is rarely passive, but instead involves purposive movement of the eyes, head, arms, legs and body. The way in which an individual accomplishes this involves complex sensory-motor systems that are characterized by reflexive and volitional components. These processes must be considered when simulating the environment, especially when attempting to incorporate simulation of the results of bodily movement within a virtual environment. Some of the systems involved in visual inspection of the world and their implications for man-machine interface are now considered.

4.1 Eye Movements

There are a variety of eye movements, and they may be described generally as being conjunctive or disjunctive. Conjunctive eye movements involve the eyes moving in the same direction (OKN, smooth pursuit and saccades), whereas disjunctive eye movements involve the eyes moving in opposite directions (convergence and divergence). A major consideration in ocular control concerns the ability to control the eyes when examining objects. While this is often done while the head and object are stationary (fixation), it is also done while the object moves (smooth pursuit) or when the head moves (see the vestibulo-ocular reflex—VOR—chap. 7, this volume). Visual capabilities are quite different during these oculomotor behaviors.

4.1.1 Fixation

When observers look at objects in the environment they position their eyes so that the object of interest falls on the area of the retina that has the best visual acuity (the central 5 deg

around the optic axis of the eye termed the macula). When this is achieved the observer is said to have fixated the object. With a stationary target, fixation stability may be defined as the degree to which the eye is stable with reference to some fixation point on the object. Fixation stability is surprisingly poor. The eye may drift as much as a degree without the observer being aware of the drift in fixation. Even with well-controlled fixation, the eye is in constant motion, with microsaccades (movements) of many arcsec (Riggs, Armington, & Ratliff, 1954). These ocular tremors are necessary for continuous viewing of an object. Artificial conditions that render the stimulus stabilized on the retina result in disappearance of the stimulus (Kelly, & Burbeck, 1980). Attempts at maintaining fixation during image movement (see smooth pursuit, section 4.1.3) or head movement involve interactive inputs to and from the vestibular system.

4.1.2 Optokinetic Nystagmus

If a contoured visual field is rotated before a stationary observer, OKN is elicited. The eyes drift in the direction of field rotation and then snap back in the opposite direction, and this cyclic pattern of eye movements is repeated in bursts, interrupted by short periods of relative gaze stability. The initial tracking response (slow phase) is seen as a period of smooth pursuit and the compensatory snap back (fast phase) as a corrective saccade (see section 4.1.4). The existence of this reflex is seen as evidence that there are visual mechanisms that take into account the effect of movement of stationary aspects of the visual field on the retina as the head or the eyes move, and that these mechanisms can provide, together with the VOR, additional complementary information about how the eye should move during head movements to provide gaze stability. Unlike the VOR, this response does not abate with continuous stimulation. While the VOR is thought to adapt because the vestibular end organs cease to respond at constant velocities, OKN is seen as a compensatory response for this failing. Another difference between the two responses is that the VOR has a short latency and a slow decay, while OKN has a long latency and slow buildup. While OKN is seen as a reflex, it also can be suppressed with fixation of a stationary target.

4.1.3 Smooth Pursuit

Observers are quite capable of tracking moving objects with the head held stationary. This is generally considered a voluntary response engaging the smooth pursuit system, which must calculate the speed of moving objects to maintain fixation. This system requires a moving object. Smooth-pursuit eye movements can not be made in total darkness or in a visual field devoid of movement. It is assumed that this system requires volition, because it is also possible to fixate a point when other moving objects are present. The upper limit of this response is about 100 deg/sec.

4.1.4 Saccades

Another response, which has generally been considered voluntary, is the saccade. This is a ballistic movement between one fixation and another. Its latency ranges from about 150 to 200 milliseconds, and its velocity is proportional (within limits) to the distance the eye must be moved. Saccades can occur with speeds up to 900 deg/sec. Whereas saccades usually are made from one target to another in space, saccades can be executed with high deg of precision to spatial positions defined cognitively (signals in other modalities, verbal commands, memories of spatial locations). Whereas this suggests voluntary control, aspects of saccades (direction, velocity or amplitude) can not be changed after they are initiated. However, saccadic latency can be shortened significantly if a presaccadic fixation target is removed shortly before the saccadic target is presented, indicating that disengagement from one target is necessary prior

to a saccade (Abrams, Oonk, & Pratt, 1998; Forbes & Klein, 1996). Another characteristic of vision during saccades is that visibility of achromatic, but not chromatic, stimuli are suppressed throughout the eye movement (Burr, Morrone, & Ross, 1994). Chromatic stimuli are usually not perceived, however, because the retinal velocities exceed the resolution limits of the chromatic pathways.

4.1.5 Vergence/Accommodation

All of the eye movements so far considered are conjugate, but vergence movements are also necessary to focus on objects in depth. Accommodation of the crystalline lens is linked to vergence in normal observers, and changes in the refractive power of the eyes are correlated such that objects are maintained in sharp focus and registered with retinal disparities on the order of min of arc.

4.2 Head and Body Movements

One of the most important aspects of contemporary virtual simulations is the ability to provide shifts in the scene contingent on head, hand, or body movement. Position tracking technology provides a major contribution to sense of presence (see chap. 40, this volume) and is described elsewhere in this volume (see chap. 8, this volume). The aim of the present section is to review the implications of the visual forcing functions on head and body movement that might be expected to influence the ability to provide realistic scene translations.

Postural stability is maintained through the vestibular reflexes acting on the neck and limbs. These reflexes are under the control of three classes of sensory inputs: muscle proprioceptors, vestibular receptors, and visual inputs. As previously discussed, a comparison of the vestibular and visual inputs is necessary to determine if the observer or the environment is moving. Visual inputs that give rise tovection have been shown to result in bodily sway and falling (Lee, 1980). It is reasonable to expect that such stimulation may result in reflexive neck muscle activity that can lead to head movements. When all or a large part of the visual field is filled with moving contours, standing observers lean in the direction of scene motion (Lee & Lishman, 1975; Lestienne, Soechting, & Berthoz, 1977). There is a compensatory leaning in the opposite direction upon the cessation of stimulation that may last for many seconds (Reason, Wagner, & Dewhurst, 1981). If the virtual scene is driven by head movement, such unintentional reflex head and body movements (and the aftereffects thereof, see chaps. 37–39, this volume) may serve to impede or interfere with scene shifts intended to simulate voluntary attempts at navigation through the virtual environment. In some cases, reflex movements can be suppressed, but this may imply that some learning must occur to achieve efficient and unnatural adjustments that are necessary to facilitate optimal performance.

5. HOW DO WE DEPICT THE 3-D WORLD IN 2-D DISPLAYS? (HARDWARE REQUIREMENTS)

Modern VE technology is an extension of all past endeavors to depict renditions of the visual world. There has been an orderly progression in the mastery of monocular cues for depth in 2-D static displays to the movement and disparity cues for depth that are so compelling in dynamic displays. The advent of computer-controlled displays has provided the possibility of greater user interaction with these virtual depictions, and with it comes an illusory sense of presence (see chap. 40, this volume) and some adaptational problems for the user (see chap. 31, this volume).

5.1 Static 2-D Displays

A first approximation to simulating the 3-D world is the traditional 2-D display ubiquitously embodied in drawings, paintings, and photographs. What can be provided relative to the capabilities of the human visual system? Two-dimensional displays can provide fine spatial detail, variations in contrast, differences in hue, the spatial position of objects in the frontal plane, and indications of 3-D using the pictorial cues for depth (relative size, height in the field, occlusion, shading, texture, and linear and aerial perspective). Using a single image on paper, canvas or film, one cannot provide the stimulus conditions to provoke motion parallax, kinetic depth, motion, or retinal disparity. The field of view is usually restricted and viewed within a 3-D framework provided by the rest of the real world. Some have argued that because of human sensitivity to the actual flatness of the 2-D plane on which 3-D simulations are viewed, the pictorial cues are in conflict with other cues provided simultaneously in the 3-D world and are rendered less effective (Ames, 1925; Nakayama, Shimojo, & Silverman, 1989).

As previously noted, in real 3-D views the ability to focus and converge on different depth planes may provide reafferant information for depth judgments, but these are missing in a depiction of 3-D in only one depth plane. Can these other important visual capabilities be recruited with other manipulations of static 2-D displays? This is possible only if stereoscopic viewing conditions are provided—presenting two versions of the same scene with fusible retinal disparities. This is done in various ways. The first stereo displays were achieved with stereoscopes that allowed viewing of two disparate pictures superimposed by means of prismatic lenses. The two pictures were often obtained by simultaneous photography of the same scene with two cameras in slightly different positions. The anaglyphic approach is to render the two members of the stereo pair in different wavelengths (e.g., red and green) and let the observer view the two disparate scenes with glasses that segregate the visual images with different chromatic filters in front of the eyes. The two images can then be fused to provide rather striking depth information and limited motion parallax. A similar technique involves the use of polarizing filters. Two disparate scenes are presented through orthogonally polarized filters. Each eye of the observer views through a polarizer matched to only one of the scenes. The visual system combines the two views and is able to detect the disparity cues. The stereoscopic images so popular in the comics section of Sunday papers use an anaglyphic approach, which does not require chromatic glasses, but requires the observer to converge or diverge the eyes to achieve fusion. The motivation to attempt such viewing is to find the hidden figure not visible in the monocular or nonfused binocular view. While the gain in level of quality of 3-D simulation provided by stereo viewing is impressive, the static 2-D display lacks the vividness that scene motion conveys.

5.2 Dynamic 2-D Displays

In the early part of this century, considerable amusement was provided to those fortunate enough to own a stereoscope. The excitement generated by such devices paled in comparison to the first moving pictures, however. Movement in nature is an extremely compelling sensation, providing immediate impressions of one's position relative to other objects in the world. The simulation of movement in static displays was first accomplished with a deck of cards, wherein an ordered sequence of pictures denoting differences in scene position was presented in rapid succession by slight of hand. The deck was bent and individual cards were allowed to slip off the thumb to reveal a simulation of motion. The motion picture projector was developed using the same rudimentary principle, rapidly sequencing a series of still pictures. These pictures were captured on filmstrips with cameras capable of rapid photography. The current standard for film projection is 24 frames/sec, and each frame is transilluminated for about 30 msec.

A rotary shutter blade is interposed while the film is advanced (taking about 10 msec), yielding a frame rate of about 24 frames/sec. This simple arrangement provides a series of still pictures, but also produces considerable detectable flicker. By increasing the rate of flicker (to 50–60 Hz), the achromatic critical flicker-fusion limit for the human observer is surpassed and an acceptable sensation of smooth movement is attained (Cropper & Badcock, 1994).

While these developments added realistic movement to simulations of the real world, stereoscopic and motion parallax cues were still not available. In the 1950s, the first 3-D movies were screened, and this technology combined the anaglyphic technique for stereo vision with the cinematic technique for motion, providing quite compelling perception of motion in depth and some limited motion parallax information. Modern cinematography has become a ubiquitous source of entertainment and education in this century, but it does not approach a true simulation of our normal experiences with the 3-D world. In most cases, the observer is quite passive and relatively immobile. That is also the case with standard video simulations, which although technically more advanced electronically, suffer from the same inadequacies. Video, however, affords the possibility to interface with sophisticated computer systems that offer the possibility to incorporate user movements into the simulated environment.

5.3 Electronic Displays and the User Interface

The cathode ray tube (CRT) began as a method of rendering simple electronic activity immediately visible. For example, oscilloscopes are often used to display voltage changes over time. The early versions involved an electron “gun” aimed at a phosphorescent surface. Deflection plates or coils controlled the direction of the gun, and the intensity of fluorescence was varied via accelerating plates that determined the rate of electron flow. Originally, control of the gun was accomplished with “vector scanning” that addressed only the points (pixels) on the screen necessary to “draw” the image in question. This proved adequate for simple geometric shapes, but more complex scenes required the more elaborate “raster scanning” approach wherein every pixel was addressed. In raster scanning, the stream of electrons is swept across the screen horizontally from left to right and then snapped back and down one line in order to paint the next row. This procedure is repeated until the entire screen has been painted and the gun is turned off (blanked) during retrace (snap back). One complete painting of the screen is termed a frame, and frame rates above the human flicker fusion point (50–60 Hz) result in a flicker-free sequence of pictures. This technology provided the basis for black-and-white television. This relatively simple system has been expanded to provide color television by including more guns and colored (red, green and blue) phosphors. One problem with CRT displays is that the tube length increases as the tube width and height increase, resulting in large displays that are quite bulky. More recent advances in display technology involve attempts to reduce the size of the apparatus. Liquid crystal, plasma, and electroluminescent displays are steps in this direction, but have disadvantages associated with resolution, color or expense; these shortcomings are rapidly being corrected. The discussion of relevant parameters for meeting user specifications will be undertaken with regard to CRT displays, but the principles will apply to all display technologies. The parameters of importance for meeting the user requirements are provided in TABLE 3.1.

5.3.1 Spatial Parameters

The field of view for modern displays varies widely, from the tiny screens produced for miniature television to the panoramic screens employed in IMAX and movie theaters. The small screens have been incorporated into head-mounted displays (HMDs), with optics designed to

TABLE 3.1
Relevant Display Factors Relating to Human Visual Abilities

Spatial vision	Pixel size and spacing	Pixel number	Screen size	Intensity resolution (bit depth)
Color vision	Phosphor types	Phosphor number	Gun independence and stability	Intensity resolution (bit depth)
Image motion	Phosphor decay	Raster rate	Pixel size and spacing	Intensity resolution (bit depth)
Stereopsis	Interlaced frames	Frame disparity	Monocular monitors	Intensity resolution (bit depth)
Observer motion	Scene update rate	Field of view	Frame rate	Intensity resolution (bit depth)

allow sharp focus of images within the near point of vision and to provide a large field of view. Video projection systems can fill the human field of view but often present problems of spatial resolution, image distortion, and are limited to relatively low luminance levels (although this is rapidly improving). CRT-based HMDs currently have a limited field of view (< 80 deg), and LCD displays offer somewhat larger fields of view (105 deg). Although the peripheral retina has poor spatial resolution, a wide field of view provides valuable information for visually guided behavior and for producing the illusion ofvection (see chap. 23, this volume).

The spatial resolution of most displays does not approach the limits of human visual acuity or spatial positioning ability unless viewing distance is extended, which, of course reduces field of view. This trade-off between field of view and spatial resolution is an important limitation for visual simulation, but solutions may soon be forthcoming. For projection systems and large screen devices, resolution must be increased, and for HMDs both spatial resolution and display size must be increased. Few visual tasks push the limits of visual acuity, and the major cost of less than optimal resolution is a sacrifice of texture and the sudden appearance of objects at simulated distance. This latter characteristic is potentially very serious. Castiello, Badcock, and Bennett (1999) have shown that when observers are reaching to grasp an object, a suddenly illuminated distractor object changes the motor aspects of reaching behavior. This change only occurs if the illumination is sudden; gradual onset has no effect, and if a spotlight suddenly illuminates the peripheral scene but there is no object the motor movement isn't affected. Thus, in VE setups, suddenly occurring peripheral objects would be expected to be the most disruptive of all possible object appearance modes if an observer is trying to make motor movements in the setup. Higher resolution renditions are needed to overcome this problem.

To match or exceed the contrast sensitivity of the human visual system, the luminance steps (gray scale) must be small enough to provide differences in luminance to which humans are insensitive. For many natural scenes, 24-bit (8 bits on each of the red, green, and blue guns) graphics systems are adequate. However, if fine contrast discrimination is required most observers will require either higher contrast resolution or that the full range of steps be compressed into the near threshold range of contrasts being presented. The latter has the consequence of restricting the maximum contrast range available at any instant but does allow small contrast steps to be presented. Computers that boast 16-bit digital-to-analog converters (DACS) for each gun are preferable, but expensive and uncommon. Many commercially available monitors provide adequate luminance (up to 100 cd/m²) and support photopic viewing levels. Thus, the current limitation in intensity resolution is usually provided by the DACs employed.

5.3.2 Color

Many modern monitors are capable of providing high spatial resolution ($1,600 \times 1,200$ pixels) and moderate temporal resolution (60–150-Hz frame rates) while also providing a colored image. The monitors contain three electron guns, which are each aimed at a different phosphor type so that in near spatial proximity on the screen, red, green, and blue signals can all be produced. There are a number of important monitor characteristics that are required for high-fidelity color rendition.

The range of achievable colors depends on the chromaticity coordinates of the phosphors used. However, current monitors are only capable of producing a small part of the full range of chromaticities detectable by the human visual system. Figure 3.11 depicts the full color gamut specified in the CIE 1931 xy chromaticity space for normal human vision, with the gamut available on a typical RGB monitor plotted as a dark triangle.

Within the available gamut, accurate color rendition requires high gun stability over time and gun independence, but both of these factors need to be rated against the intended use of the display. Gun stability is often a problem during the first hour a monitor is turned on. During this period, the luminance and chromaticity of a display will vary, even in very good monitors. Metha, Vingrys, and Badcock (1993) provide some representative data and a method for evaluating the visual salience of these changes.

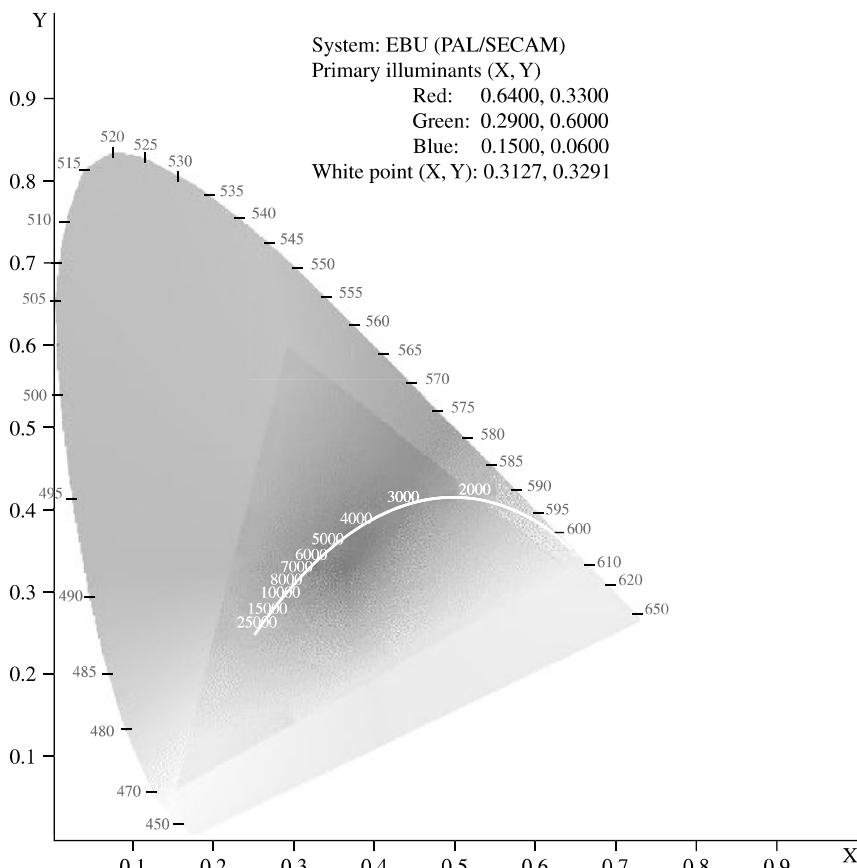

FIG. 3.11. The CIE (1931) xy chromaticity space for normal human vision is depicted with the gamut of color available, with the typical RGB monitor depicted as a dark triangle.

Gun interactions are more problematic. On less expensive monitors the intensity of the output from one gun will vary as the output of the other guns increases. The consequence is that there is not a fixed relationship between a given intensity level specified in the driving software and the output of a particular gun. The output will vary with different images. Observers are quite tolerant of these changes for noncritical applications (e.g., word processing), but the interactions are likely to be destructive when accurate color discriminations are required. Expensive monitors are more likely to avoid this problem, but the only way to be sure is to measure the light output for each gun independently and compare the output for several levels of activation of the other guns (see Metha et al., 1993). This check has become more critical recently, as many manufacturers of monitors are deliberately building in a gun interaction that affects the upper half of the intensity range to minimize the amount of flashing when users move pointers from one window to another in graphical user interfaces.

The final issue of significance for rendering color is the variation in light output across the monitor screen. Some variation is due to nonuniformity of the phosphor deposition during manufacture, but most of it is due to the design characteristics of the shadow mask technology. All such monitors are brightest in the center of the screen, and luminance drops considerably toward the periphery. In part, this is due to the smaller effective aperture in the shadow mask at shallower angles of incidence, but the loss is also due to the polarity of the emitted light. The output is much more intense in the direction continuing the path of the electron beam, a direction that points to one side of an observer aligned with the center of the screen. Metha et al. (1993) found this loss to affect luminance more than chromaticity but ideally stimuli requiring accurate luminance and chrominance discriminations should be small and placed centrally on the screen to minimize spatial variations due to the monitor.

5.3.3 Image Motion

Two factors that have a strong influence on simulated motion are phosphor persistence and frame rate. Phosphor persistence refers to how quickly the phosphorescence fades after it has been energized. Long persistence phosphors reduce flicker but will also result in image smear when image movement is simulated. Short persistence phosphors require higher update rates for pixels that convey the presence of static parts of the image and, if the rate is too low, flicker may be a problem. In practice, it is quite easy to determine whether the quantization of motion will be detectable. If the temporal frequency components introduced by the quantization fall within the range detectable by an observer, then the observer will be able to discriminate between smooth and sampled motion sequences (Cropper & Badcock, 1994; Watson, Ahumada, & Farrell, 1986). Other factors may be critical if either speed difference judgments or very slow speeds need to be produced. In both these cases, the achievable steps in speed will depend on a combination of the frame rate of the monitor and the spatial resolution. The quantization in both time and space limits the minimum speed and minimum difference in speed achievable.

5.3.4 Stereopsis

Stereoscopic vision is currently supported by either providing separate monitors for each eye (e.g., HMDs and boom-mounted devices), shutter glasses, anaglyphic glasses, or projectors and autostereoscopic displays. Dichoptic presentation using two monitors presents two views of the same scene, one to each eye, and depends on binocular fusion to yield stereopsis. Electronic shutter glasses present alternating views of the display synchronized to the frame rate such that one interleaved frame in each pair is presented to each eye. The display provided in each set of odd or even frames contains a disparity between the two eyes and binocular fusion provides stereopsis. Anaglyphic glasses filter the images provided to the two eyes with chromatic (usually red and green), lenses and the display contains disparate images rendered in the two

colors. Autostereoscopic systems involve lenses imposed between the viewer and display or use a haploscopic arrangement in which dichoptic stimulation is achieved using mirrors to align a different display with each eye. While most would agree that stereoscopic vision is extremely important for the feeling of immersion and presence (see chap. 40, this volume) that the VE seeks to convey, all current techniques involve unwanted attributes. HMDs are bulky, have insufficient field of view, and can cause eyestrain if the optics create competition between the accommodative and vergence systems (see chap. 37, this volume). Electronic shutter glasses are less cumbersome, but are also restricted in field of view and require higher frame rates to avoid flicker. With flicker fusion thresholds near 60 Hz at current display luminances, a frame rate of 120 Hz or greater is required for flicker-free vision. The anaglyphic techniques are compromised because color is used to separate the signals for the two eyes and cannot simultaneously render a true-color image. They are also limited by the restrictions of field of view imposed by glasses. Most autostereoscopic systems offer only small display sizes. Stereoscopic capability is desirable, however, because it provides binocular depth cues through motion parallax and motion in depth.

6. WHAT ARE THE SUCCESSES AND FAILURES OF OUR ATTEMPTS TO SIMULATE THE "REAL WORLD"? (THE STATE OF THE ART AND BEYOND)

6.1 Successes

As observed above, the spatial aspects of visual simulation seem to be adequate for representing small regions of real-world scenes. Emerging technology promises higher resolution and more encompassing field of view. HMDs should benefit from less mass and projection systems should involve less peripheral distortion. As previously discussed, the depiction of color approximates or exceeds the limits of most human abilities. The temporal characteristics of most displays are adequate and might be expected to improve with increased raster rates and reduced persistence. These improvements will support more realistic depiction of object motion and smooth scene translation. As simulation of motion profiles improves, more pronouncedvection and a more realistic sense of presence can be expected. Improving the sense of presence, however, might produce more rather than fewer problems for users.

6.2 Failures

One of the most problematic areas in VE system design concerns the simulation of environment motion relative to the observer as the observer's head or body moves in the simulator. The relevant parameters appear to be related to display update rates that are limited by the speed with which graphic depictions can be generated in accordance with movement signals. This limit depends in part on the graphics detail in the scenes depicted. The best contemporary systems boast 40 msec update rates, but these technologies achieve these rates at a sacrifice of resolution. In many systems with inadequate update rates, disorientation and simulator sickness abound (see chaps. 30–32, this volume). These are produced by the mismatch between visual and vestibular cues to motion. The lag in updating the scene means that a vestibular cue to head movement is followed by, rather than being coincident with, retinal-image motion. This particular problem can potentially be overcome by increased computational power that may eventually allow the time lag to become imperceptibly small. A much more difficult problem is the need to provide vestibular input more generally. When observers are free to navigate around a scene, there is often a mismatch between visually indicated changes and cues from the vestibular system. In the extreme, vision may indicate locomotion while the vestibular system

indicates that the body is stationary. This mismatch frequently produces feelings of nausea. The relationship between visual and vestibular inputs is also under constant recalibration. Thus, periods of mismatch can lead to recalibration, which will maintain feelings of nausea in the natural environment until the normal relationship has been relearned (see chap. 31, this volume). Improving visual display technology will not reduce this particular problem. Providing appropriate vestibular inputs might reduce it (see chap. 7, this volume).

While current projection displays do afford FOVs that approach the limits of human observers, HMDs are limited by the size of small monitors relative to the interocular distance and the optics necessary to allow clear vision within the near point. Many optical compensatory arrangements result in eye strain and visual aftereffects. Research on the aftereffects generated with the use of HMDs has indicated another conflict situation in apparent motion situations. Stereoscopic displays that require near viewing often give rise to induced binocular stress. Mon-Williams, Wann, and Rushton (1993) reported loss of visual acuity and eye muscle imbalance after only a 10-min exposure to such displays, with some of the symptoms associated with motion sickness. They suggest that these aftereffects stem from adaptation of the accommodation–vergence system due to the disparity between the stereoscopic depth cues provided and the image focal depth. They later reported that displays that preserve the concordance between vergence and accommodation do not produce these aftereffects with viewing times of 30 min (Rushton, Mon-Williams, & Wann, 1994).

7. NEW RESEARCH DIRECTIONS

The development of VE systems has proceeded without an abiding concern for the intricacies of human sensory systems. As these factors are considered in simulator design, the dearth of knowledge of many aspects of human perception is highlighted. In many respects, efforts to create realistic VE serves to drive and motivate basic research efforts, but it also points up the limitations of classical research settings. One major problem in the approach to the study of human abilities centers on the way in which efforts have been compartmentalized (Kelly & Burbeck, 1984). The use of VE technology has forced, and will continue to force, a broadening in the scope of interests and considerations in the study of sensory motor interactions. As researchers begin to delve more deeply into these problems, the apparatus necessary to address these issues will require higher resolution on both spatial and temporal dimensions, and become more expensive. This may dictate that research goals must be narrowed. It may be laudable, but not practical, to attempt to generate realistically natural displays that are valid in every VE application.

One way that research tasks may be limited is to address perceptual problems of the particular device in question. While one can predict, to some extent, how well a display might meet the requirements of the human user, a more empirical approach might be to address the adequacy of the instrument with psychophysical experiments in the simulator at the outset. This approach may also reveal idiosyncratic problems that emerge through the use of the device and belie concerns based on theoretical predictions.

7.1 Limitations of Classical Research

Much of the research reviewed above was generated in laboratories developed for the study of a particular visual capability (e.g., color, motion) without regard to how that ability might be compromised when other sensory and motor systems are in operation. In many experimental situations, the aim was to study the ability in isolation to avoid sources of psychological interference (e.g., arousal, attention, expectation). The aim in VE, however, is often quite different. The user is often actively engaged in tasks where many systems are employed.

Perhaps the greatest research impetus from the use of VE technology has been to emphasize sensory–sensory and sensory–motor interactions. There is a pressing need for increased information with regard to visuo-vestibular interactions. In part, this is to alleviate some of the negative effects of using VE technology (e.g., nausea) but also because vestibular inputs can change basic properties of visual neurons, such as their preferred orientation of line stimuli (Kennedy, Magnin & Jeannerod, 1976). It will be important to determine to what extent vision is identical when vestibular inputs are decorrelated.

7.1.1 Sensory and Sensory Motor Interactions

The synthesis of classical theories of color vision into the current view of multistage processing is perhaps a model for how researchers will proceed in elaborating knowledge of visual processing relative to nonvisual sensory and motor processes. While considerable psychophysical and physiological evidence supported both the trichromatic and opponent process views, the controversy cooled when we learned how these mechanisms were staged and integrated. In similar fashion, our understanding of vision during various eye movements (previously discussed) is a step toward understanding how vision is compromised during such activity, but we have yet to fully appreciate how visual scene movement might elicit reflexive eye, head, and body reactions. Becker (1989) reported that head movements are a regular feature of gaze shifts greater than 20 deg. Some of the studies that have addressed coincident eye, head, and hand movements, have done so while the subjects performed a volitional task (e.g., Pelz, Ballard, & Hayhoe, 1993), and they reveal the sequential ordering of gaze, head, and hand movements. With the use of head trackers and other pointing devices, it may be the case that these systems are requiring learned modifications to the natural interaction of the sensory and motor systems.

7.1.2 Esoteric Devices and Generalization

If it is the case that users are forced to adapt to the idiosyncrasies of a particular VE, then the traditional laboratory work from which researchers hope to predict visual performance may not provide the basis for legitimate generalization. Studies of basic human visual function may not tell about the human capability to cope with unique sensory–motor rearrangements. Investigations designed to study these abilities (e.g., chap. 31, this volume) cannot anticipate all the kinds of interactive adaptations that might be required by new technology. For this reason, systematic research on basic visual function and sensory–motor interactions should be incorporated into the design and testing of new VE systems at the outset.

7.2 Basic Research in Simulators

Many of the more sophisticated VE systems in use today were developed to address practical problems in training and performance. Various vehicular simulators, for example, are used to train operators initially, and to help them maintain their skills. Since this represents the primary mission of the apparatus, little or no time is allotted for investigation of many of the human-interface problems that might exist unless they severely compromise that mission. It is important for the successful development of future systems to document such problems in existing systems and to identify causal variables and usage protocols to prevent them. The work of Kennedy and others (see chap. 36, this volume) serves as an exemplary first step in this direction.

7.2.1 Machine- or Observer-Limited

The basic question asked of vision scientists concerning VE systems is: Will this system meet or exceed the visual requirements of the human user? This chapter has been concerned

with the answer to that question, and has attempted to review visual capabilities and relate them to technical specifications. While such an approach has considerable heuristic value, many assumptions are made and conclusions based on such analyses are, in a sense, still quite theoretical. A more direct and empirical approach is to measure visual function within the VE system in question. Some things are readily predictable from extant data. For example, one might ask if the contrast scaling of a display is fine enough to exceed the contrast discrimination capacity of the user. However, the relationship between perceived distance traveled using visual information and the simulated distance traveled is less predictable (Harris, 1999). The most straightforward way to answer that question would be to measure the function of interest inside the VE system and compare the results to measures obtained with more standard methods. If similar findings are obtained with the two methods, the system could be described as observer-limited and adequate in that particular dimension. If performance on that measure was poorer in the VE system than by conventional testing, performance could be termed machine-limited, and this finding would indicate that the system falls short of the user's capability. It is an open question at the moment, as to whether VE systems need always be observer-limited to be adequate for a given application. Many visual tasks are not performed with stimuli at the limits of visual capability, but this is sometimes not clear until the tasks are performed with observer-limited and machine-limited systems.

7.2.2 Adaptation and Emerging Problems

Many early and continuing studies of human perception indicate that considerable adaptation occurs under conditions of perceptual rearrangement. Such adaptation can result in a rescaling of the perceptual systems and to corresponding changes in perceptual-motor responses. With brief exposures (< 10 min) to such stimuli, adaptation occurs but recovery is relatively fast. With prolonged exposures (> 10 min to several days), such adaptation might be more permanent and require readaptation over an extended period to restore normal perception and performance (Kohler, 1972; see also chap. 31, this volume). One notion is that as more realistic visual simulations are developed, less adaptation might occur and this may alleviate the problems associated with VE aftereffects (Stanney, et al., 1998). While this seems a reasonable hypothesis for visual adaptation, it may not hold true for adaptation to mismatches between the senses or the perceptual-motor linkages.

In traditional psychophysical experiments, it is often the case that the variance of the measurements is initially quite high and reduces with continued data collection. It is recognized that subjects often need experience in the paradigm to adopt the best perceptual set and response strategy. Thus, some forms of adaptation to the VE might be expected to occur through perceptual-motor learning and some through changing cognitive problem-solving strategies. These modifications in perceptual set and response strategy would not be expected to result in debilitating aftereffects, and might best be considered VE-specific effects. Little research has been carried out on these important but indirect effects on visual processing in VE systems.

1. INTRODUCTION

Auditory processing is often given minimal attention when designing virtual environments (VEs) or simulations. This lack of attention is unfortunate, because auditory cues play a crucial role in everyday life. Auditory cues increase awareness of surroundings, cue visual attention, and convey a variety of complex information without taxing the visual system. The entertainment industry has long recognized the importance of sound to create ambience and emotion, aspects that are often lacking in virtual environments. In short, placing someone in a virtual world with an improperly designed auditory interface is equivalent to creating a “virtual” hearing impairment for the user.

Auditory perception, especially localization, is a complex phenomenon affected by physiology, expectation, and even the visual interface. This chapter will consider different methods for creating auditory interfaces. As will be discussed, spatialized audio using headphones is the only audio technique that is truly “virtual” because it reproduces azimuth, elevation, and distance, and offers the sound engineer the greatest amount of control over the auditory experience of the listener. For many applications, especially using projection screens, speaker systems may be simpler to implement and provide benefits not available to headphone systems. Properly designed speaker systems, especially using subwoofers, may contribute to emotional context. The positives and negatives associated with each option will be discussed.

It is impossible to include everything that needs to be known about designing auditory interfaces in a single chapter. The current aim is to provide a starting point and essential theory behind implementing sound in a VE without overwhelming the novice designer. Instead of trying to review all perceptual and technical issues related to creating virtual auditory displays, this chapter focuses on the essential aspects of spatial auditory perception and the generation

of spatial auditory cues as they relate to virtual environments. In addition, unlike the visual channel, very little effort has been put into formulating theories concerning the creation of synthetic sound sources in virtual environments; consequently, the question of how to generate realistic sounds (rather than using sources from some precomputed, stored library of source sounds) is not discussed in this chapter.

Physical properties of sound and basic psychoacoustics are discussed with an emphasis on spatial hearing. Finally, general techniques for producing auditory stimuli (with and without spatial cues) will be discussed. A complete lexicon for understanding and developing auditory displays can be found in Letowski et al. (2000). The technology involved in producing spatialized audio is rapidly changing, and new products are continually introduced to the market while others are removed. Any specific recommendations would quickly be dated. However, a brief overview of current technology and solutions is discussed at the conclusion of the chapter.

1.1 Why Are Virtual Auditory Interfaces Important?

1.1.1 *Environmental Realism and Ambience*

If it does nothing else, an auditory interface should convey basic information about the VE to the user. For instance, in the real world, dismounted soldiers are aware of the sound of their own footsteps, the sounds of other soldiers and the natural environment, and mechanical sounds from various types of equipment such as jeeps, artillery, and rifles. In “control room” situations such as nuclear power plants, air traffic control centers, or the bridge of a ship, sounds such as alarms, switches being toggled, and verbal communications with other people in the room (including sounds of stress or uncertainty) provide vital information for participants. The location of these voices, switches, and alarms also provides information concerning their function and importance. In the absence of these basic auditory cues, situational awareness is severely degraded. The same is true in virtual environments.

The entertainment industry has recognized that sound is a vital aspect of creating ambience and emotion for films. George Lucas, best recognized by the public for stunning visual effects in his movies, has stated that sound is 50% of the movie experience (THX, 2000). In virtual environments, the argument is often erroneously made that sound is secondary. Again, a compelling visual representation of soldiers slogging through the mud, traversing a jungle, or going house-to-house can be created. However, unless appropriate background sounds are provided (machinery, artillery, animals, footsteps, etc), the participant will probably feel detached from the action. The sound of footsteps is different depending on whether you are in grass, on pavement, or in a hallway. Likewise, the action of an M-16 sounds different depending on whether you are inside a room or outside. These are the types of things that create ambience and emotion in film; the same should hold true in virtual environments.

1.1.2 *Presence/Immersion*

Presence (see chap. 40, this volume) can be defined as the “sense of being immersed in a simulation or virtual environment.” Such a nebulous concept is difficult to quantify. Although definitive evidence is lacking, it is generally believed that the sense of presence is dependent on auditory, visual, and tactile fidelity (Sheridan, 1996). Referring back to the previous section, it can be inferred that as environmental realism increases, the sense of presence increases. However, although realism probably contributes to the sense of presence, the inverse is not true. It has been demonstrated that, although virtual or spatial audio does not necessarily increase the perceived realism of a virtual environment, it does increase the sense of presence

(Hendrix & Barfield, 1996). Thus, if implemented properly, appropriately designed audio increases the overall sense of presence in a VE or simulation.

1.1.3 Collision/Tactile Cueing

Auditory cues in a system using head-mounted displays (HMDs) are particularly important and should be given close attention during the design phase. In limited field-of-view (FOV) HMDs, sounds associated with collision detection may play a major role in the user being able to successfully move through the simulation. These auditory collision cues can be used to substitute for tactile collision cues when appropriate.

1.1.4 Cross-modal Enhancement

Response times to visual targets associated with localized auditory cues have been shown to decrease (Perrott, Saberi, Brown, & Strybel, 1990; Perrott, Sadralodabai, Saberi, & Strybel, 1991). It has also been shown that the latency of saccadic eye movements toward a target is reduced when the visual target is aligned with an auditory cue (Frens, Opstal, & Willigen, 1995). In this manner, a properly designed auditory interface may be used to enhance the FOV of an HMD by cueing the user to locations outside the limited FOV of the HMD. Appropriate care must be taken to properly design the auditory interface, as auditory location has been shown to affect perceived visual target location when the visual target is presented on a nontextured background (Radeau & Bertelson, 1976).

1.1.5 Cocktail Party Effect

In a multisource sound environment, it is easier to discriminate and comprehend sounds if they are separated in space. This enhancement in comprehension with spatially disparate sound sources is often called the *cocktail party effect* (Yost, 1994). The ability to understand multiple speakers simultaneously can be useful when applied to multiuser environments such as teleconferencing (Begault, 1999) or multichannel radio communications (Begault, 1993; Begault & Wenzel, 1992; Haas, Gainer, Wightman, Couch, & Shilling, 1997). Even when the perception of location is not optimal, communication is improved in multichannel situations when spatialized auditory displays are employed (Drullman & Bronkhorst, 2000).

1.1.6 Sonification of Data

Auditory cues can be used to represent information that is not normally available in the real world. For instance, if a user makes a response error, or is slow in responding, auditory icons can be created to indicate the deficiency to the user (Gaver, 1986). On the other hand, using a technique called *sonification*, complex information presented visually can be simplified by supplementing it with an auditory representation correlated with some dimension or dimensions of the data set (Rabenhorst, Farrell, & Jameson, 1990). For example, in simulations designed to teach operators how to interpret complex controls and displays (radar, sonar, etc), multidimensional data can be “sonified” to make it easier to interpret. Likewise, sonification could be used as a learning aid to illustrate principles using multidimensional data in physics and chemistry.

1.1.7 Supernormal Auditory Localization

When designing auditory interfaces, it is possible to exaggerate normal auditory cues so that the listener is able to localize sound in the virtual world with better resolution than in the real

world. One way of achieving supernormal localization is to exaggerate the normal head and ear size cues available to the listener (e.g., see Shinn-Cunningham, Durlach, & Held, 1998a, 1998b). Supernormal auditory localization may be of best use in teleoperator applications, and VEs where there is a need to compensate for a limited-FOV HMD. For example, spatialized auditory displays have been designed that exaggerate normal auditory cues and zoom the auditory display as the magnification on the visual display is increased (Shilling, Wightman, Couch, Beutler, & Letowski, 1998; Shilling & Letowski, 2000). Of course, experience with such supernormal systems affects both the accuracy and resolution of perception, and both effects must be evaluated in order to determine the overall cost and benefit of such techniques for a given application (e.g., see Shinn-Cunningham, 2000a).

1.1.8 Virtual Auditory Displays (VADs)

While graphical displays are an obvious choice for displaying spatial information to a human operator (particularly after considering the spatial acuity of the visual channel), the visual channel is often overloaded, with operators monitoring a myriad of dials, gauges, and graphic displays. In these cases, spatial auditory cues can provide invaluable information to an operator, particularly when the visual channel is saturated (Begault, 1993; Bronkhorst, Veltman, & van Breda, 1996; Shilling & Letowski, 2000). Spatial auditory displays are also being developed for use in applications for which visual information provides no benefit, for instance, in limited FOV applications or when presenting information to the blind. In command/control applications, the primary goal is to convey unambiguous information to the human operator. Realism, *per se*, is not useful, except to the extent that it makes the operator's task easier (i.e., reduces the workload). Conversely, spatial resolution is critical. In these applications, signal-processing schemes that could enhance the amount of information transferred to the human operator may be useful, even if the result is "unnatural," as long as the user is able to extract this information (e.g., see Durlach, Shinn-Cunningham, & Held, 1993). It should be noted that when designing spatialized auditory displays for noisy environments such as cockpits, electronic noise cancellation technology should be employed and user's hearing loss taken into account to make certain the displays are localizable (Begault, 1996). Also, for high-g environments, more work needs to be conducted to discover the contribution of g-forces to displacements in sound localization, the so-called *audiogyrus illusion* (Clark & Graybiel, 1949; DiZio, Held, Lackner, Shinn-Cunningham, & Durlach, 2000).

1.1.9 Enhancement of Perceived Quality of a Simulation

The importance of multimodal interactions involving the auditory system cannot be ignored (see chaps. 14, 21, and 22, this volume). It has been shown that using medium- and high-quality auditory displays can enhance the perception of quality in visual displays. Inversely, using low-quality auditory displays reduces the perceived quality of visual displays (Storms, 1998; see also chap. 22, this volume).

2. PHYSICAL ACOUSTICS

2.1 Properties of Sound

Simply put, sound is a pressure wave produced when an object vibrates rapidly back and forth. The diaphragm of a speaker produces sound by pushing against molecules of air, thus creating an area of high pressure (*condensation*). As the speaker's diaphragm returns to its resting

position, it creates an area of low pressure (*rarefaction*). This localized disturbance travels through the air as a wave of alternating low pressure and high pressure at approximately 344 m/sec or 1128 ft/sec (at 70 °F) depending on temperature and humidity.

2.1.1 Frequency

If the musical note “A” is played as a pure sinusoid, there will be 440 condensations and rarefactions per second. The distance between two adjacent condensations or rarefactions equals the wavelength of the sound wave and is typically represented by the symbol λ . The velocity at which the sound wave is traveling is denoted as c . The time one full oscillatory cycle (condensation through rarefaction) takes is called the frequency (f) and is expressed in Hertz or cycles per second. The relationship between frequency, velocity, and wavelength is given by $f = c/\lambda$.

From a modeling standpoint, this relationship is important when considering Doppler Shift. As a sound source is moving toward a listener, the perceived frequency increases because the wavelength is compressed as a function of the velocity (v) of the moving source. This compression can be explained by the equation $\lambda = (c - v) / f$. For negative velocities (i.e., for sources moving away), this expression describes a relative increase in the wavelength (and a concomitant decrease in frequency).

2.1.2 Intensity

The amplitude of the waveform determines the intensity of a sound stimulus. Intensity is measured in decibels (dB). Decibels give the level of sound (on a logarithmic scale) relative to some reference level. One common reference level is 2×10^{-5} N/m². Decibels referenced to this value are commonly used to describe sound intensity expressed in units of dB sound pressure level (SPL). The sound level in dB SPL can be computed by the following equation:

$$\text{dB SPL} = 20 \log_{10} \left(\frac{\text{RMS sound pressure}}{20 * 10^{-5} \text{N/m}^2} \right)$$

The threshold of hearing is in the range of 0 to 10 dB SPL for most sounds, although the actual threshold depends on the spectral content of the sound. When measuring sound intensity in the “real world,” intensity is measured using a sound pressure meter. Most sound pressure meters allow one to collect sound level information using different scales which weight energy in different frequencies differently in order to approximate the sensitivity of the human auditory system to sound at low-, moderate-, or high-intensity levels. These scales are known as A, B, and C weighted scales, respectively. The B scale is rarely used; however, the C scale (dBc) is useful for evaluating noise levels in high intensity environments such as traffic noise and ambient cockpit noise. The frequency response of the dBc measurement is closer to a flat-response than dBA. In fact, when conducting “sound surveys” in a complex noise environment, it is prudent to measure sound level in both dBA and flat-response (or dBc) to make an accurate assessment of the audio environment.

Frequency, intensity, and complexity are physical properties of an acoustic waveform. The perceptual analogues for frequency, intensity, and complexity are pitch, loudness, and timbre, respectively. This distinction between physical and perceptual measures of sound properties is an important one. Thus, it is critical to consider both physical and perceptual descriptions when designing auditory displays.

3. PSYCHOPHYSICS

The basic sensitivity of the auditory system is reviewed in detail in a number of textbooks (e.g., see Gelfand, 1998; Moore, 1997; Yost, 1994). This section provides a brief overview of some aspects of human auditory sensitivity that are important to consider when designing auditory virtual environments.

3.1 Frequency Analysis in the Auditory System

In the cochlea, acoustic signals are broken down into constituent frequency components by a mechanical Fourier-like analysis. Along the length of the cochlea, the frequency to which that section of the cochlea responds varies systematically from high to low frequencies. The strength of neural signals carried by the auditory nerve fibers arrayed along the length of the cochlea varies with the mechanical displacement of the corresponding section of the cochlea. As a result, each nerve fiber can be thought of as a frequency channel that conveys information about the energy and timing of the input signal within a restricted frequency region. At all stages of the auditory system, these multiple frequency channels are in evidence.

Although the bandwidth changes with the level of the input signal and with input frequency, to a crude first order approximation, one can think of the frequency selectivity of the auditory system as constant on a log-frequency basis (approximately one-third-octave wide). Thus, a particular auditory nerve responds to acoustic energy at and near a particular frequency.

Humans are sensitive to acoustic energy at frequencies between about 20 Hz and 22,000 Hz. Absolute sensitivity varies with frequency. Humans are most sensitive to energy at frequencies around 2000 Hz, and are less sensitive for frequencies below and above this range.

The fact that input waveforms are deconstructed into constituent frequencies affects all aspects of auditory perception. Many behavioral results are best understood by considering the activity of the auditory nerve fibers, each of which responds to energy within about a third of an octave of its particular “best frequency.” For instance, the ability to detect a sinusoidal signal in a noise background degrades dramatically when the noise spectrum is within a third octave of the sinusoid frequency. When a noise is spectrally remote from a sinusoidal target, it causes much less interference with the detection of the sinusoid. These factors are important when one considers the spectral content of different sounds that are to be used in an auditory virtual environment. For instance, if one must monitor multiple kinds of alerting sounds, choosing signals that are spectrally remote from one another will improve a listener’s ability to detect and respond to different signals.

3.2 Intensity Perception

Listeners are sensitive to sound intensity on a logarithmic scale. For instance, doubling the level of a sound source causes roughly the same perceived change in the loudness independent of the reference level. This logarithmic sensitivity to sound intensity gives the auditory system a large dynamic range. For instance, the range between just detectable sound levels and sounds that are so loud that they cause pain is roughly 110 to 120 dB (i.e., an increase in sound pressure by a factor of a million). The majority of the sounds encountered in everyday experience span a dynamic intensity range of 80 to 90 dB. Typical sound reproduction systems use 16 bits to represent the pressure of the acoustic signal (providing a useful dynamic range of about 90 dB), which is sufficient for most simulations.

While sound intensity (a physical measure) affects the loudness of a sound (a perceptual measure), loudness does not grow linearly with intensity. In addition, the same decibel increase in sound intensity can result in different increments in loudness, depending on the frequency

content of the sound. Thus, intensity and loudness, while closely related, are not equivalent descriptions of sound.

3.3 Masking Effects

As mentioned above, when multiple sources are presented to a listener simultaneously or in rapid succession, the sources interfere with one another in various ways. For instance, a tone that is audible when played in isolation may be inaudible when a loud noise is presented simultaneously. Such effects (known as “masking” effects) arise from a variety of mechanisms, from physical interactions of the separate acoustic waves impinging on the ear to high-level, cognitive factors. For a more complete description of these effects than is given below, see Yost (1994, pp. 153–167) or Moore (1997, pp. 111–120).

Simultaneous masking occurs when two sources are played concurrently. However, signals do not have to be played simultaneously for them to interfere with one another perceptually. For instance, both “forward” masking (in which a leading sound interferes with perception of a trailing sound) and “backward” masking (in which a lagging sound interferes with perception of a leading sound) occur. Generally speaking, many simultaneous and forward masking effects are thought to arise from peripheral interactions that occur at or before the level of the auditory nerve. For instance, the mechanical vibrations of the basilar membrane are nonlinear, so that the response of the membrane to two separate sounds may be less than the sum of the response to the individual sounds. These nonlinear interactions can suppress the response to what would (in isolation) be an audible event. In other words, because of nonlinearities in the transduction of acoustic signals, the response of the auditory nerve to a given signal may be less robust when a second signal is present.

Other, more central factors influence masking as well. For instance, backward masking may reflect higher order processing that limits the amount of information extracted from an initial sound in the presence of a second sound. The term *informational masking* refers to all masking that cannot be explained by peripheral interactions in the transduction of sound by the auditory periphery. There is ample evidence that informational masking is an important factor in auditory perception. For instance, perceptual sensitivity in discrimination and detection tasks is often degraded when there is uncertainty about the characteristics of a target source (e.g., see Yost, 1994, pp. 219–220).

3.4 Pitch and Timbre

Just as sound intensity is the physical correlate of the percept of loudness, source frequency is most closely related to the percept of pitch. For sound waves that are periodic (including pure sinusoids, for instance), the perceived “pitch” of a sound is directly related to the inverse of the period of the sound signal. Thus, sounds with low pitch have relative long periods and sounds with high pitch generally have short periods. Many real-world sounds are not strictly periodic in that they have a temporal pattern that repeats over time, but has fluctuations from one cycle to the next. Examples of such pseudo-periodic signals include the sound produced by a flute or a vowel sound spoken aloud. The perceived pitch of such sounds is well predicted by the average period of the cyclical variations in the stimulus.

The percept of pitch is not uniformly strong for all sound sources. In fact, nonperiodic sources such as noise do not have a salient pitch associated with them. For relatively narrow sources that are aperiodic, a weak percept of pitch can arise that depends on the center frequency of the spectral energy of the signal. In fact, perceived pitch is affected by a wide variety of stimulus attributes, including temporal structure, frequency content, harmonicity, and even loudness. Although the pitch of a pure sinusoid is directly related to its frequency, there

is no single physical parameter that can predict perceived pitch for more complex sounds. Nonetheless, for many sounds, pitch is a very salient and robust perceptual feature that can be used to convey information to a listener. For instance, in music pitch conveys melody. In speech, pitch conveys a variety of information (ranging from the gender of a speaker to paralinguistic, emotional content of a speech).

The percept of timbre is the sound property that enables a listener to distinguish an oboe from a trumpet. Like pitch, the percept of timbre depends on a number of physical parameters of sound, including spectral content and temporal envelope (such as the abruptness of the onset and offset of sound).

3.5 Temporal Resolution

The auditory channel is much more sensitive to temporal fluctuations in sensory inputs than the visual (see chap. 3, this volume) or proprioceptive (see chaps. 5 and 6, this volume) channels. For instance, the system can detect amplitude fluctuations in input signals up to 50 Hz (i.e., a duty cycle of 20 ms) very easily (e.g., see Yost, 1994, pp. 146–149). Sensitivity degrades slowly with increasing modulation rate, so that some sensitivity remains even as the rate approaches 1000 Hz (i.e., temporal fluctuations at a rate of 1 per ms). The system is also sensitive to small fluctuations in the spectral content of an input signal for roughly the same modulation speeds. Listeners not only can detect rapid fluctuations in an input stimulus, they can react quickly to auditory stimuli. For instance, reaction times to auditory stimuli are faster than for vision by 30 to 40 ms (an improvement of roughly 20%, e.g., see Welch & Warren, 1986).

3.6 Spatial Hearing

Spatial acuity of the auditory system is far worse than that of the visual (see chap. 3, this volume) or proprioceptive (see chaps. 5 and 6, this volume) systems. For a listener to detect an angular displacement of a source from the median plane, the source must be displaced laterally by about a degree. For a source directly to the side, the listener does not always detect a lateral displacement of 10 degrees. Auditory spatial acuity is even worse in other spatial dimensions. A source in the median plane must be displaced by as much as 15 degrees for the listener to perceive the directional change accurately. While listeners can judge relative changes in source distance, absolute distance judgments are often surprisingly inaccurate even under the best of conditions.

Functionally, spatial auditory perception is distinctly different from that of the other “spatial” senses of vision and proprioception. For the other spatial senses, position is neurally encoded at the most peripheral part of the sensory system. For instance, the photoreceptors of the retina are organized topographically so that a source at a particular position (relative to the direction of gaze) excites a distinct set of receptors (see chap. 3, this volume). In contrast, spatial information in the auditory signals reaching the left and right ears of a listener must be computed from the peripheral neural representations. The way in which spatial information is carried by the acoustic signals reaching the eardrums of a listener has been the subject of much research. This section provides a brief review of how acoustic attributes convey spatial information to a listener and how the perceived position of a sound source is computed in the brain (for more complete reviews, see Blauert, 1997; Middlebrooks & Green, 1991; Mills, 1972; Wightman & Kistler, 1993).

3.6.1 Binaural Cues

The most robust cues for source position depend on differences between the signals reaching the left and right ears. Such *interaural* or *binaural* cues are robust specifically because they

can be computed by comparing the signals reaching each ear. As a result, binaural cues allow a listener to factor out those acoustic attributes that arise from source content from those attributes that arise from source position.

Depending on the angle between the interaural axis and a sound source, one ear may receive a sound earlier than the other. The resulting interaural time differences (ITDs) are the main cue indicating the laterality (left/right location) of the direct sound. The ITD grows with the angle of the source from the median plane; for instance, a source directly to the right of a listener results in an ITD of 600 to 800 microseconds (μ s) favoring the right ear. ITDs are most salient for sound frequencies below about 2 kHz, but occur at all frequencies in a sound. At higher frequencies, listeners use ITDs in signal *envelopes* to help determine source laterality, but are insensitive to differences in the interaural phase of the signal.

Listeners can reliably detect ITDs of 10 to 50 microseconds (depending on the individual listener), which grossly correspond to ITDs that would result from a source positioned 1 to 5 degrees from the median plane. Sensitivity to changes in the ITD deteriorates as the reference ITD gets larger. For instance, the smallest detectable change in ITD around a reference source with an ITD of 600 to 800 microseconds (corresponding to the ITD of a source far to the side of the head) can be more than a factor of 2 larger than for a reference with zero ITD.

At the high end of the audible frequency range, the head of the listener reflects and diffracts signals so that less acoustic energy reaches the far side of the head (causing an *acoustic head shadow*). Due to the acoustic head shadow, the relative intensity of a sound at the two ears varies with the lateral location of the source. The resulting interaural intensity differences (IIDs) generally increase with source frequency and angle between the source and median plane. IIDs are perceptually important for determining source laterality for frequencies above about 2 kHz.

When a sound source is within reach of a listener, extra large IIDs (at all frequencies) arise due to differences in the relative distances from source to left and right ears (e.g., see Brungart & Rabinowitz, 1999; Duda & Martens, 1998). These additional IIDs are due to differences in the relative distances from source to left and right ears and help to convey information about the relative distance and direction of the source from the listener (Shinn-Cunningham, Santarelli, & Kopco, 2000). Other low-frequency IIDs that may arise from the torso appear to help determine the elevation of a source (Algazi, Avendano, & Duda, 2001). Most listeners are able to detect IIDs of 0.5 to 1 dB, independent of source frequency.

The perceived location of a sound source usually is consistent with the ITD and IID information available. However, there are multiple source locations that cause roughly the same ITD and IID cues. For sources more than a meter from the head, the locus of such points is approximately a hyperbolic surface of rotation symmetric about the interaural axis that is known as the *cone of confusion* (see left side of Fig. 4.1). When a sound is within reach of the listener, extra large IIDs provide additional robust, binaural information about the source location. For a simple spherical head model, low-frequency IIDs are constant on spheres centered on the interaural axis (see right side of Fig. 4.1). The rate at which the extra-large IID changes with spatial location decreases as sources move far from the head or near the median plane. In fact, once a source is more than a meter or so from the head, the contribution of this “near-field” IID is perceptually insignificant (Shinn-Cunningham, Santarelli, & Kopco, 2000). In general, positions that give rise to the same binaural cues (i.e., the intersection of constant ITD and IID contours) form a circle centered on the interaural axis (Shinn-Cunningham et al., 2000). Since ITD and IID sensitivity is imperfect, the locus of positions that cannot be resolved from binaural cues may be more accurately described as a *torus of confusion* centered on the interaural axis. Such tori of confusion degenerate to the more familiar cones of confusion for sources more than about a meter from a listener.

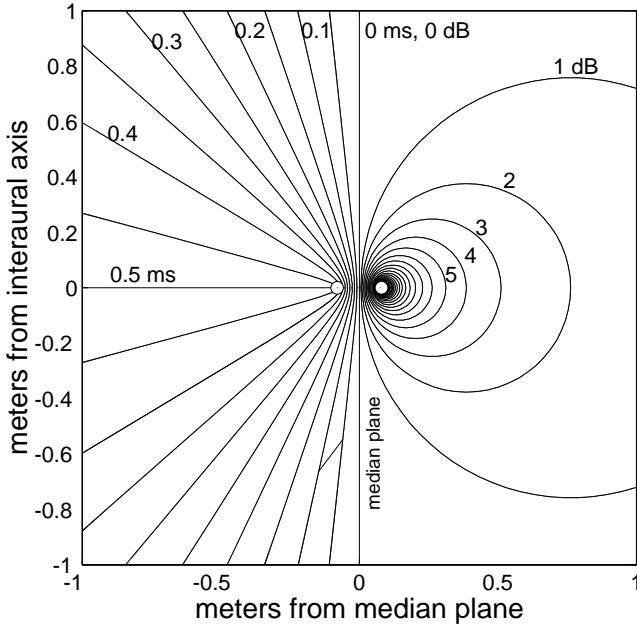

FIG. 4.1. Iso-ITD (left side of figure) and iso-IID (right side of figure) contours of sources near the head. On the left, sources at each location along a contour give rise to nearly the same ITD. On the right, sources at each location along a contour give rise to nearly the same unique near-field ILD component.

3.6.2 Spectral Cues

The main cue to resolve source location on the torus of confusion is the spectral content of signals reaching the ears. These spectral cues arise due to interactions of the outer ear (pinna) with the impinging sound wave that depend on the relative position of sound source and listener's head (Batteau, 1967). Spectral cues only occur at relatively high frequencies, generally above 6 kHz. Unlike interaural cues for source location, spectral cues can be confused with changes in the spectrum of the source itself. Perhaps because of this ambiguity, listeners are more likely to make localization errors in which responses fall near the correct torus of confusion, but are not in the right direction. Individual differences in spectral filtering of the pinnae are large and are important when judging source direction (e.g., see Wenzel, Arruda, Kistler, & Wightman, 1993).

3.6.3 Anechoic Distance Cues

In general, the intensity of the direct sound reaching a listener (i.e., sound that does not come off of reflective surfaces like walls) decreases with the distance of the source. In addition, the atmosphere absorbs energy in high, audible frequencies as a sound propagates, causing small changes in the spectrum of the received signal with changes in source distance. If a source is unfamiliar, the intensity and spectrum of the direct sound are not robust cues for distance because they can be confounded with changes in the intensity or spectral content (respectively) of the signal emitted from the source. However, even for unfamiliar sources, overall level and spectral content provide relative distance information (Mershon, 1997).

3.6.4 Reverberation

Reverberation (acoustic energy reaching a listener from indirect paths, via walls, floors, etc.) generally has little affect on or degrades the perception of source direction (e.g., see Begault, 1993; Hartmann, 1983; Shinn-Cunningham, Zurek, & Durlach, 1993; Shinn-Cunningham, 2000b). However, it actually aids in the perception of source distance (e.g., see Mershon, Ballenger, Little, McMurtry, & Buchanan, 1989; Shinn-Cunningham, Kopco, & Santarelli, 1999). At least grossly, the intensity of reflected energy received at the ears is independent of the position of the source relative to the listener (although it can vary dramatically from one room to another). As a result, the ratio of direct to reverberant energy provides an absolute measure of source distance for a given listening environment.

Reverberation not only provides a robust cue for source distance, it provides information about the size and configuration of a listening environment. For instance, information about the size and “spaciousness” of a room can be extracted from the pattern of reverberation in the signals reaching the ears. While many psychophysical studies of sound localization are performed in anechoic (or simulated anechoic) environments, reverberation is present (in varying degrees) in virtually all normal listening conditions. Anechoic environments (such as those used in many simulations and experiments) seem subjectively unnatural and strange to naive listeners. Conversely, adding reverberation to a simulation causes all sources to seem more realistic and provides robust information about relative source distance. While reverberation may improve distance perception and improve the realism of a display, it can decrease accuracy in directional perception, albeit slightly and may interfere with the ability to extract information in a source signal (e.g., degrade speech) and to attend to multiple sources (e.g., see section 3.6.8).

3.6.5 Dynamic Cues

In addition to “static” acoustic cues like ITD and IID, changes in spatial cues with source or listener movement also influence perception of source position and help to resolve torus-of-confusion ambiguities (e.g., see Wallach, 1940; Wightman & Kistler, 1989). For instance, either a source directly in front or directly behind a listener would cause near zero ITDs and IIDs; however, a leftward rotation of the head results in either ITDs and IIDs favoring the right ear (for a source in front) or the left ear (for a source behind).

While the auditory system generally has good temporal resolution, the temporal resolution of the binaural hearing system is much poorer. For instance, investigations into the perception of moving sound sources implies that binaural information averaged over a time window lasting 100 to 200 ms results in what has been termed *binaural sluggishness* (e.g., see Grantham, 1997; Kollmeier & Gilkey, 1990).

3.6.6 Effects of Stimulus Characteristics on Spatial Perception

Characteristics of a source itself affect auditory spatial perception in a number of ways. For instance, the bandwidth of a stimulus can have a large impact on the perceived location of a source. As a result, one must consider how nonspatial attributes of a source in a VE will impact spatial perception of a signal. In cases where one can design the acoustic signal (i.e., if the signal is a warning signal or some other arbitrary waveform), these factors should be taken into consideration when one selects the source signal.

For instance, the spectral filtering of the pinnae cannot be determined if the sound source does not have sufficient bandwidth. This makes it difficult to unambiguously determine the location of a source on the torus of confusion for a narrowband signal. Similarly, if a source signal does not have energy above about 5 kHz, spectral cues will not be represented in

the signals reaching the ears and errors along the torus of confusion are more common (e.g., Gilkey & Anderson, 1995).

Ambiguity in narrowband source locations arises in other situations as well. For instance, narrowband, low-frequency signals in which ITD is the main cue can have ambiguity in their heard location because the auditory system is only sensitive to interaural phase. Thus, a low-frequency sinusoid with an ITD of half cycle favoring the right ear may also be heard far to the left side of the head. However, binaural information is integrated across frequency so that ambiguity in lateral location is resolved when interaural information is available across a range of frequencies (Brainard, Knudsen, & Esterly, 1992; Stern & Trahiotis, 1997; Trahiotis & Stern, 1989). When narrowband sources are presented, the heard location is strongly influenced by the center frequency of the source (Middlebrooks, 1997).

While spectral bandwidth is important, temporal structure of a source signal is also important. In particular, onsets and offsets in a signal make source localization more accurate, particularly when reverberation and echoes are present. A gated or modulated broadband noise will generally be more accurately localized in a reverberant room (or simulation) than a slowly gated broadband noise (e.g., see Rakerd & Hartmann, 1985; Rakerd & Hartmann, 1986).

3.6.7 Top-down Processes in Spatial Perception

Experience with or knowledge of the acoustics of a particular environment also affects auditory localization (e.g., see Clifton, Freyman, & Litovsky, 1993; Shinn-Cunningham, 2000b). Results show that “top-down” processing of auditory information due to implicit learning and experience affects performance. In other words, spatial auditory perception is not wholly determined by stimulus parameters, but also by the state of the listener. Although such effects are not due to conscious decision, they can measurably alter auditory localization and spatial perception.

3.6.8 Benefits of Binaural Hearing

Listeners benefit from receiving different signals at the two ears in a number of ways. As discussed above, ITD and IID cues allow listeners to determine the location of sound sources. However, in addition to allowing listeners to locate sound sources in the environment, binaural cues allow the listener to selectively attend to sources coming from a particular direction. This ability is extremely important when there are multiple competing sources in the environment (e.g., see Bronkhorst, 2000).

Imagine a situation in which there is both a speaker (whom the listener is trying to attend) and a competing source (that is interfering with the speaker). If the speaker and competitor are both directly in front of the listener, the competitor degrades speech reception much more than if the competitor is off to one side, spatially separated from the speaker. This “binaural advantage” arises in part because when the competitor is to one side of the head, the energy from the competitor is attenuated at the far ear. As a result, the signal-to-noise ratio at the far ear is larger than when the competitor is in front. In other words, the listener has access to a cleaner signal in which the speaker is more prominent when the speaker and noise are spatially separated. However, the advantage of the spatial separation is even larger than can be predicted on the basis of energy: Spatial information can be used to “squelch” signals from directions other than the direction of interest.

A homologous benefit can be seen under headphones. In particular, if one varies the level of a signal until it is just detectable in the presence of a masker, the necessary signal level is much lower when the ITD of the signal and masker are different than when they are the same. The difference between these thresholds, referred to as the *masking level difference* (MLD), can be as large as 10 to 15 dB for some signals (e.g., see Durlach & Colburn, 1978; Zurek, 1993).

The binaural advantage affects both signal detection (e.g., see Gilkey & Good, 1995) and speech reception (e.g., see Bronkhorst & Plomp, 1988). It is one of the main factors contributing to the ability of listeners to monitor and attend multiple sources in complex listening environments (i.e., the “cocktail party effect”; see, for example, Yost, 1997). Thus, the binaural advantage is important for almost any auditory signal of interest. In order to get these benefits of binaural hearing, signals reaching a listener must have appropriate ITDs and/or IIDs.

3.6.9 Adaptation to Distorted Spatial Cues

While a naive listener responds to ITD, IID, and spectral cues based on their everyday experience, listeners can learn to interpret cues that are not exactly like those that occur naturally. For instance, listeners can learn to adapt to unnatural spectral cues when given sufficient long-term exposure (Hofman, Van Riswick, & Van Opstal, 1998). Short-term training allows listeners to learn how to map responses to spatial cues to different spatial locations than normal (Shinn-Cunningham et al., 1998a). These studies imply that for applications in which listeners can be trained, “perfect” simulations of spatial cues may not be necessary. However, there are limits to the kinds of distortions of spatial cues to which a listener can adapt (Shinn-Cunningham et al., 1998b; Shinn-Cunningham 2000a).

3.6.10 Intersensory Integration of Spatial Information

Acoustic spatial information is integrated with spatial information from other sensory channels (particularly vision) to form spatial percepts (e.g., see Welch & Warren, 1986). In particular, auditory spatial information is combined with visual (and/or proprioceptive) spatial information to form the percept of a single, multisensory event, especially when the inputs to the different modalities are correlated in time (e.g., see Warren, Welch, & McCarthy, 1981, see chap. 21, this volume). When this occurs, visual spatial information is much more potent than that of auditory information, so the perceived location of the event is dominated by the visual spatial information (although auditory information does affect the percept to a lesser degree, e.g., see Pick, Warren, & Hay, 1969; Welch & Warren, 1980; chap. 22, this volume). *Visual capture* refers to the perceptual dominance of visual spatial information, describing how the perceived location of an auditory source is captured by visual cues.

Summarizing these results, it appears that the spatial auditory system computes source location by combining all available acoustic spatial information. Perhaps even more importantly, a priori knowledge and information from other sensory channels can have a pronounced effect on spatial perception of auditory and multisensory events.

3.7 Auditory Scene Analysis

Listeners in real-world environments are faced with the difficult problem of listening to many competing sound sources that overlap in both time and/or frequency. The process of separating out the contributions of different sources to the total acoustic signals reaching the ears is known as *auditory scene analysis* (e.g., see Bregman, 1990).

In general, the problem of grouping sound energy across time and frequency to reconstruct each sound source is governed by a number of basic (often intuitive) principles. For instance, naturally occurring sources are often broadband, but changes in the amplitude or frequency of the various components of a single source are generally correlated over time. Thus, co-modulation of sound energy in different frequency bands tends to group these signal elements together and cause them to fuse into a single perceived source. Similarly, temporal and spectral proximity both tend to promote grouping so that signals close in time or frequency are grouped into a single perceptual source (sometimes referred to as a stream). Spatial location

also can influence auditory scene analysis such that signals from the same or similar locations are grouped into a single stream. Other factors affecting streaming include (but are not limited to) harmonicity, timbre, and frequency or amplitude modulation.

For development of auditory displays, these grouping and streaming phenomena are very important, because they can directly impact the ability to detect, process, and react to a sound. For instance, if a masker sound (comprised of a number of constituent modulated sinusoids) is played simultaneously with a target sinusoid that is also modulated, the ability to detect the target improves if the masker sinusoids are modulated with the same envelope (different from the target). This process cannot be explained by peripheral mechanisms, since the peripheral masking produced is independent of whether or not the masker components are temporally correlated. Thus, perceptual segregation of two perceptual streams reduces their interaction and interference, improving performance on signal detection, speech intelligibility, temporal discrimination, and other tasks.

3.8 Speech Perception

Arguably the most important acoustic signal is that of speech. The amount of information transmitted via speech is larger than for any other acoustic signal. For many applications, accurate transmission of speech information is the most critical component of an auditory display.

Speech perception is affected by many of the low-level perceptual issues discussed in previous sections. For instance, speech can be masked by other signals, reducing a listener's ability to determine the content of the speech signal. Speech reception in noisy environments improves if the speaker is located at a different position than the noise source(s), particularly if the speaker and masker are at locations giving rise to different interaural level differences. Speech reception is also affected by factors that affect the formation of auditory streams, such as comodulation, harmonic structure, and related features. However, speech perception is governed by many high-level, cognitive factors that do not apply to other acoustic signals. For instance, the ability to perceive a spoken word improves dramatically if it is heard within a meaningful sentence rather than in isolation. Speech information is primarily conveyed by sound energy between 200 and 5000 Hz. For systems in which speech communication is critical, it is important to reduce the amount of interference in this range of frequencies or it will impede speech reception.

4. SPATIAL SIMULATION

Spatial auditory cues can be simulated using headphone displays or loudspeakers. Headphone displays generally allow more precise control of the spatial cues presented to a listener, both because the signals reaching the two ears can be controlled independently and because there is no indirect sound reaching the listener (i.e., no echoes or reverberation). However, headphone displays are generally more expensive than loudspeaker displays and may be impractical for applications in which the listener does not want to wear a device on the head. While it is more difficult to control the spatial information reaching a listener in a loudspeaker simulation, loudspeaker-based simulations are relatively simple and inexpensive to implement and do not physically interfere with the listener.

Simulations using either headphones or speakers can vary in complexity from providing no spatial information to providing nearly all naturally occurring spatial cues. This section reviews both headphone and speaker approaches to creating spatial auditory cues.

4.1 Headphone Simulation

4.1.1 Diotic Displays

The simplest headphone displays present identical signals to both ears (*diotic* signals). With a diotic display, all sources are perceived as inside the head (not “externalized”), at midline. This internal sense of location is known as *lateralization* not *localization* (Plenge, 1974). While a diotic display requires no spatial auditory processing, it also provides no spatial information to a listener. Such displays may be useful if the location of an auditory object is not known or if spatial auditory information is unimportant. However, diotic displays are the least realistic headphone display. In addition, as discussed in section 3.6.8, benefits of spatial hearing can be extremely useful for detection and recognition of auditory information. For instance, when listeners are required to monitor multiple sounds sources, spatialized auditory displays are clearly superior to diotic displays (Hass, Gainer, Wightman, Couch, & Shilling, 1997).

4.1.2 Dichotic Displays

While normal interaural cues vary with frequency in complex ways, simple frequency-independent ITDs and IIDs affect the perceived lateral position of a sound source (e.g., see Durlach & Colburn, 1978). Stereo signals that only contain a frequency in dependent ITD and/or IID are herein referred to as *dichotic* signals (although the term is sometimes used to refer to any stereo signal in which left and right ears are different).

Generation of a constant ITD or IID is very simple over headphones since it only requires that the source signal be delayed or scaled (respectively) at one ear. Just as with diotic signals, dichotic signals result in sources that appear to be located on an imaginary line inside the head, connecting the two ears. Varying the ITD or IID causes the lateral position of the perceived source to move toward the ear receiving the louder and/or earlier-arriving signal. For this reason, such sources are usually referred to as *lateralized* rather than *localized*.

Dichotic headphone displays are simple to implement, but are only useful for indicating whether a sound source is located to the left or right of a listener. On the other hand, when multiple sources are lateralized at different locations (using different ITD and/or IID values), some binaural unmasking can be obtained (see section 3.6.8).

The left and right signals of commercial stereo recordings generally contain simple ITD and IID cues in direct sounds, but also contain reverberation and echoes. When these signals are played over headphones, sources are usually lateralized, but actually may seem more realistic than other signals due to reverberation.

4.1.3 Spatialized Audio

Using signal-processing techniques, it is possible to generate stereo signals that contain most of the normal spatial cues available in the real world. In fact, if properly rendered, spatialized audio can be practically indistinguishable from free-field presentation (Langendijk & Bronkhorst, 2000). When coupled with a head-tracking device, spatialized audio provides a true virtual auditory interface. Using a spatialized auditory display, a variety of sound sources can be presented simultaneously at different directions and distances. One of the early criticisms of spatialized audio was that it was expensive to implement; however, as hardware and software solutions have proliferated, it has become feasible to include spatialized audio in most systems. Spatialized audio solutions can be fit into any budget, depending on the desired resolution and number of sound sources required. Most HMDs are currently outfitted with headphones of sufficient quality to reproduce spatialized audio, making it relatively easy to incorporate spatialized audio in an immersive VE system.

4.1.3.1 Head-Related Transfer Functions (HRTFs). In order to simulate any source somewhere in space over headphones, one must simply play a stereo headphone signal that recreates at the eardrums the exact acoustic waveforms that would actually arise from a source at the desired location. This is generally accomplished by empirically measuring the transfer functions that describe how an acoustic signal at a particular location in space is transformed as it travels to and impinges on the head and ears of a listener. Then, in order to simulate an arbitrary sound source at a particular location, the appropriate transfer functions are used to filter the desired (known) source signal. The resulting stereo signal is then corrected to compensate for transfer characteristics of the display system (for instance, to remove any spectral shaping of the headphones) and presented to the listener.

The pairs of spatial filters that describe how sound is transformed as it impinges on a listener are known as *head-related transfer functions* (HRTFs). HRTFs describe how to simulate the direct sound reaching the listener from a particular position, but do not generally include any reverberant energy. Empirically measured HRTFs vary mainly with the direction from head to source, but also vary with source distance (particularly for sources within reach of the listener). For sources beyond about a meter away, the main effect of distance is to change the overall gain of the HRTFs. In the time domain, the HRTF pair for a particular source location provides the pressure waveforms that would arise at the ears if a perfect impulse were presented from the spatial location in question. Often, HRTFs are represented in the frequency domain by taking the Fourier Transform of time domain impulse responses.

HRTFs contain most of the spatial information present in real-world listening situations. In particular, ITD and IID are embodied in the relative phase and magnitude (respectively) of the linear filters for the left and right ears. Spectral cues and source intensity are present in the absolute frequency-dependent magnitudes of the two filters.

Figure 4.2 shows two HRTF pairs from a human subject in the time domain (left side of figure) and in the frequency domain (magnitude only, right side of figure). All panels are for a source at azimuth 90 and elevation 0. The top two panels show the HRTF for a source very close to the head (15 cm from the center of the head). The bottom two panels show the HRTF for a source 1 meter from the head. In the time domain, it is easy to see the interaural differences in time and intensity, while the frequency domain representation shows the spectral notches that occur in HRTFs, as well as the frequency-dependent nature of the interaural intensity difference. The IIDs are larger in all frequencies for the nearer source (top panels), as expected. In the time domain, the 1 m source must traverse a greater distance to reach the ears than the near source, resulting in additional time delay before the energy reaches the ears (note time onset differences in the impulse responses in the left top and left bottom panels).

4.1.3.2 Room Modeling. HRTFs generally do not include reverberation or echoes, although it is possible to measure transfer functions (know as *room transfer functions*) that incorporate the acoustic effects of a room. While possible, such approaches are generally not practical because such filters vary with listener and source position in the room as well as the relative position of listener and source to produce a combinatorially large number of transfer functions. In addition, such filters can be an order of magnitude longer than traditional HRTFs, increasing both computational and storage requirements of the system.

There has been substantial effort devoted to developing computational models for room reverberation (e.g., see discussion in Shinn-Cunningham, Lehnert, Kramer, Wenzel, & Durlach, 1997). The required computations are quite intensive; in order to simulate each individual echo, one must calculate the distance the sound wave has traveled, how the waveform was transformed by every surface on which it impinged, and the direction from which it is arriving at the head. The resulting waveform must then be filtered by the appropriate anechoic HRTF based on the direction of incidence with the head.

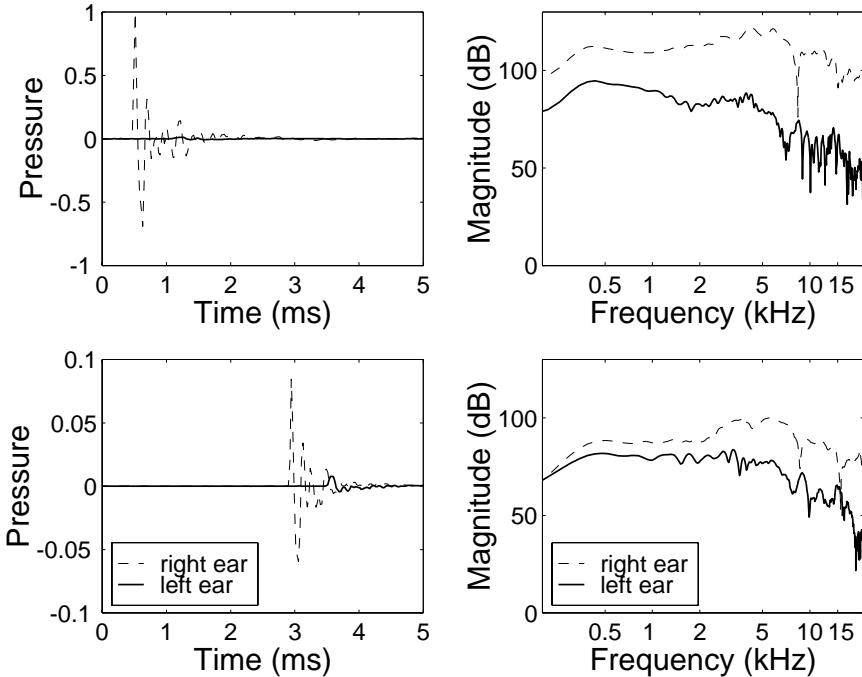

FIG. 4.2. Time domain (left panels) and magnitude spectra (right panels) representations of anechoic HRTFs for a human subject. All panels show a source at 90 azimuth, 0 elevation. Top panels are for a source at 15 cm, bottom panels for a source at 1 m.

If one looks at the resulting echoes as a function of time from the initial sound, the number of echoes in any given time slice increases exponentially with time (since the number of echoes grows exponentially with time as each echo impinges on multiple surfaces to effectively create new sources). At the same time the level of each individual echo decreases rapidly, both due to energy absorption at each reflecting surface and increased path length from source to ear. Many simulations only “spatialize” a small number of the loudest, earliest-arriving echoes, and then add random noise that dies off exponentially in time (uncorrelated at the two ears) to simulate later arriving echoes that are dense in time and arriving from essentially random directions. Even with such simplifications, the computations necessary to generate “realistic” reverberation (particularly in a system that tries to account for movement of a listener) can be overwhelming (e.g., see Shinn-Cunningham et al., 1997).

Figure 4.3 shows the room impulse response at the right ear for a source located at 45 azimuth, 0 elevation, and distance of 1 meter. This impulse response was measured in a moderate-size classroom in which significant reverberant energy persists for as long as 450 milliseconds. The initial few ms of the response are shown in the inset. In the inset, the initial response is that caused by the sound wave that travels directly from the source to the ear. The first reflection is also evident at the end of the inset, at a much reduced amplitude. In the main figure, the decay of the reverberant energy can be seen with time.

Development of tractable reverberation algorithms for real-time systems is an ongoing area of research. The extent to which listeners are sensitive to interaural and spectral details in reverberant energy is also not well understood and requires additional research. Nonetheless, there is clear evidence that inclusion of reverberation can have a dramatic impact on the subjective realism of a virtual auditory display and can aid in perception of source distance.

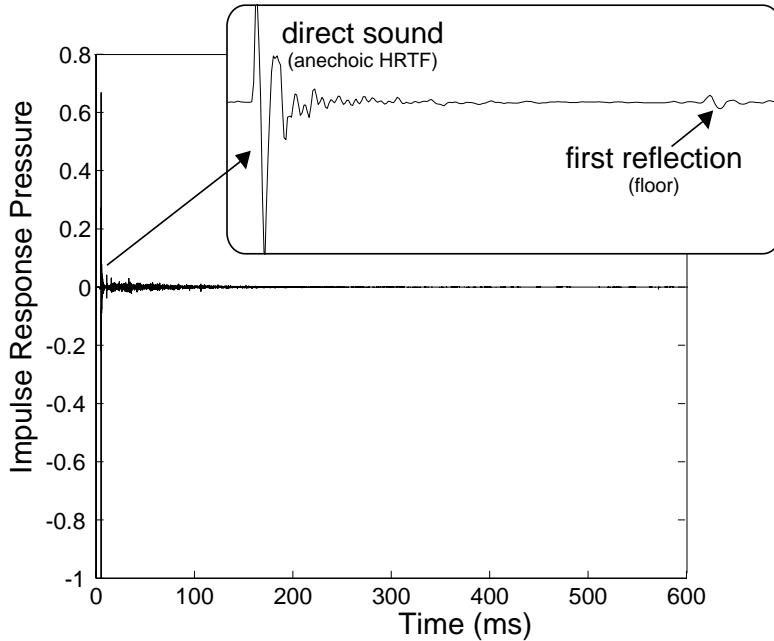

FIG. 4.3. Impulse response at the right ear for a source at 45 azimuth, 0 elevation, and distance 1 m in a standard classroom. Inset shows first 10 ms of total impulse response.

4.1.3.3 Practical Limitations On Spatialized Audio. While in theory, HRTF simulation should yield stimuli that are perceptually indistinguishable from natural experience, a number of practical considerations limit the realism of stimuli simulated using HRTFs. Measurement of HRTFs is a difficult, time-consuming process. In addition, storage requirements for HRTFs can be prohibitive. As a result, HRTFs are typically measured only at a single distance, relatively far from the listener, and at a relatively sparse spatial sampling. Changes in source distance are simulated simply by scaling the overall signal intensity. Because the HRTFs are only measured for a finite number of source directions at this single source distance, HRTFs are interpolated to simulate locations for which HRTFs are not measured. While this approach is probably adequate for sources relatively far from the listener and when some inaccuracy can be tolerated, the resulting simulation cannot perfectly recreate spatial cues for all possible source locations (Wenzel & Foster, 1993). Individual differences in HRTFs are very important for some aspects of sound source localization (particularly for distinguishing front/back and up/down). However, most systems employ a standard set of HRTFs that are not matched to the individual listener. Unfortunately, using these “nonindividualized” HRTFs reduces the accuracy and externalization of auditory images, but still results in useful performance increases (Begault & Wenzel, 1993). A great deal of ongoing research is focused on developing ways to tailor HRTFs to an individual listener without explicitly measuring HRTFs for that individual. For instance, researchers are exploring a variety of HRTF compression schemes in which individual differences are encoded in a small number of parameters that can be quickly or automatically fit to an individual (e.g., see Kistler & Wightman, 1991; Middlebrooks & Green, 1992). Nonetheless, many “typical” systems cannot simulate source position along a torus of confusion because they do not use individualized HRTFs.

The most sophisticated spatialized audio systems use trackers to measure movement of a listener and update the HRTFs in real time to produce appropriate dynamic spatial cues. The use of head tracking dramatically increases the accuracy of azimuthal localization (Sorkin,

Kistler, & Elvers, 1989). However, time lag in such systems (from measuring listener movement, choosing the new HRTF, and filtering the ongoing source signal) can be greater than 100 ms. While the binaural system is sluggish, the resulting delay can be perceptible. Real-time systems are also too complex and costly for some applications. Instead, systems may compute signals off-line and either ignore or limit the movement of the listener; however, observers may hear sources at locations inside or tethered to the head (i.e., moving with the head) with such systems.

Many simulations do not include any echoes or reverberation in the generated signals. Although reverberation has little impact (or degrades) perception of source direction, it is important for distance perception. In addition, anechoic simulations sound subjectively artificial and less realistic than do simulations with reverberation.

4.2 Simulation Using Speakers

The total acoustic signal reaching each ear is simply the sum of the signals reaching that ear from each source in an environment. Using this property, it is possible to vary spatial auditory cues (e.g., ITD, IID, and spectrum) by controlling the signals played from multiple speakers arrayed around a listener. In contrast with headphone simulations, the signals at the two ears cannot be independently manipulated; i.e., changing the signal from any of the speakers changes the signals reaching both ears. As a result, it is difficult to precisely control the interaural differences and spectral cues of the binaural signal reaching the listener to mimic the signals that would occur for a real-world source. However, various methods for specifying the signals played from each loudspeaker exist to simulate spatial auditory cues using loudspeakers.

To reduce the variability of audio signals reaching the ears, careful attention should be given to speaker placement and room acoustics. If speaker systems are not properly placed and installed in a room, even the best sound systems will sound inferior. Improperly placed speakers can reduce speech comprehension, destroy the sense of immersion, and dramatically reduce bass response (Holman, 2000). This is especially true when dealing with small rooms. If the system is installed properly, there will be a uniform (flat) frequency response at the listening area.

One example of a four speaker system (two front and two surround) is described in an International Telecommunications Union (ITU) recommendation and places speakers at ± 30 degrees in front of the listener and at ± 110 degrees behind the listener (ITU-R BS.775-1). It is further recommended that the signals emanating from the two surround channels be decorrelated to increase the sense of spaciousness. Correlated mono signals may give a sense of lateralization rather than localization. If a subwoofer is used, it is usually placed in front of the room. Placing the subwoofer too close to a corner may increase bass response, but may result in a muddier sound. The subwoofer should be moved to achieve the best response in the listening area. Unfortunately, speaker placement will vary depending on the dimensions and shape of the room, as well as the number of speakers employed. If the system is mobile, the sound system will have to be readjusted for every new location, unless the simulation incorporates its own enclosure. If the simulation will be housed in different sized rooms, the audio system (amplifiers and speakers) must have enough headroom (power) to accommodate both large enclosures as well as small. When possible, acoustical tile and diffusers should be employed where appropriate to reduce reverberation and echoes.

4.2.1 Nonspatial Display

Many systems use free-field speakers in which each speaker presents an identical signal. Such systems are analogous to diotic headphone systems; although simple to develop, these

displays (like diotic headphone displays) provide no spatial information to the listener. Such systems can be used when spatial auditory information is unimportant and when segregation of simultaneous auditory signals is not critical. For instance, if the only objects of interest are within the visual field and interference between objects is not a concern, this kind of simplistic display may be adequate.

4.2.2 Stereo Display

The analog of the dichotic headphone display presents signals from two speakers simultaneously in order to control the perceived laterality of a “phantom” source. For instance, simply varying the level of otherwise identical signals played from a pair of speakers can alter the perceived laterality of a phantom source. Most commercial stereo recordings are based on variations of this approach.

Imagine a listener sitting equidistant from two loudspeakers positioned symmetrically in front of the listener. When the left speaker is played alone, the listener hears a source in the direction of the left speaker (and ITD and IID cues are consistent with a source in that leftward direction). When the right speaker is played alone, the listener hears a source in the direction of the right speaker. When identical signals at identical levels are played from both speakers, each ear receives two direct signals, one from each of the symmetrically placed speakers. To the extent that the listener’s head is left-right symmetric, the total direct sound in each ear is identical, and the resulting percept will be of a single source at a location that gives rise to zero ITD and zero IID (e.g., in the listener’s median plane). Varying the relative intensity of otherwise identical signals played from the two speakers causes the gross ITD and IID cues to vary systematically, producing a phantom source whose location between the two speakers varies systematically with the relative speaker levels (e.g., see Bauer, 1961; Zurek & Shinn-Cunningham, under review 1997).

This simple “panning” technique produces a robust perception of a source at different lateral locations; however, it is nearly impossible to precisely control the exact location of the phantom image. In particular, the way in which the perceived direction changes with relative speaker level depends upon the location of the listener with respect to the two loudspeakers. As the listener moves outside a restricted area (the “sweet spot”), the simulation degrades rather dramatically. In addition, reverberation can distort the interaural cues, causing biases in the resulting simulation. Nonetheless, such systems provide some information about source laterality.

4.2.3 Lessons from the Entertainment Industry

The ability to generate an accurate spatial simulation using loudspeakers increases dramatically as the number of speakers used in the display increases. With an infinite number of speakers around the listener, one would simply play the desired signal from the speaker at the desired location of the source to achieve a “perfect” reproduction. Panning between multiple pairs of speakers (for instance, speakers arrayed in front of and behind the listener) is often used to improve spatial simulations using loudspeakers.

These Surround Sound technologies are primarily seen in the entertainment industry and are implemented via a variety of formats. Surround Sound systems find their genesis in a three-channel system created for the movie *Fantasia* in 1939. Fantasound speakers were located in front of the listener at left, middle, and right. The “surround” speakers consisted of approximately 54 speakers surrounding the audience and carried a mixture of sound from the left and right front speakers (i.e., it was not true stereo; Garity & Hawkins, 1941).

Currently, the most common Surround Sound format is the 5.1 speaker system, in which speakers are located at the left, middle, and right in front of the listener, and left and right

behind the listener. The so-called 0.1 speaker is a subwoofer. The middle speaker, located in front of the listener, reproduces most of the speech information to the listener. Typical 5.1 Surround formats are Dolby Digital Surround and Digital Theater Systems (DTS).

Newer Surround Sound formats include Dolby Digital Surround EX, which is a 6.1 speaker system (adding a center speaker behind the listener). A 10.2 system is now on the horizon (Holman, 2000). In the future, even greater numbers of speakers and more complex processing are likely to become standard. However, it is important to note that adding additional speakers may be detrimental to producing a sense of immersion, especially in a small room. As the number of speakers increases, explicit care must be taken to assure that the sound field in the room is diffuse enough that the speakers themselves are not obtrusive. If the user notices the speakers in the room, the illusion of reality will be destroyed. To negate this possibility, extreme care must be taken to account for room acoustics, speaker design and placement, and the location of the listener in the room (Holman, 2000).

4.2.4 Cross-talk Cancellation and Transaural Simulations

More-complex signal-processing schemes can also be used to control spatial cues using loudspeakers. In such approaches, the total signal reaching each ear is computed as the sum of the signals reaching that ear from each of the speakers employed. By considering the timing and content of each of these signals, one can try to reproduce the exact signal desired at each ear.

The earliest such approach attempted to recreate the sound field that a listener would have received in a particular setting from stereo recordings taken from spatially separated microphones. In the playback system, two speakers were positioned at the same relative locations as the original microphones. The goal of the playback system was to play signals from the two speakers such that the total signal at each ear was equal to the recorded signal from the nearer microphone. To the extent that the signal from the far speaker was acoustically cancelled, the reproduction would be accurate. Relatively simple schemes involving approximations of the acoustic alterations of the signals as they impinged on the head were used to try to accomplish this “cross-talk cancellation.”

As signal-processing approaches have been refined and knowledge of the acoustic properties of HRTFs improves, more sophisticated algorithms have been developed. In particular, it is possible to calculate the contribution of each speaker to the total signal at each ear by considering the HRTF corresponding to the location of the speaker. The total signal at each ear is then the sum of the HRTF-filtered signals coming from each speaker. If one also knows the location and source of the signal that is to be simulated, one can write equations for the desired signals reaching each ear as HRTF-filtered versions of the desired source. Combining these equations yields two frequency-dependent, complex-valued equations that relate the signals played from each speaker to the desired signals at the ears. To the extent that one can find and implement solutions to these equations, it is possible (at least in theory) to recreate the desired binaural signal by appropriate choice of the signals played from each speaker. The problem with such approaches is that the simulation depends critically on the relative location of the speakers and the listener. In particular, if the listener moves his head outside of the sweet spot, the simulation degrades rapidly. It can be difficult to compute the required loudspeaker signals and the computations are not particularly stable, numerically. To the extent that the HRTFs used in the equations are not matched to the listener and reverberation distorts the signals reaching the ears, the derived solutions are even less robust.

Head trackers can be used in conjunction with multispeaker simulations in order to improve the simulation. However, this requires that computations be performed in real time and significantly increases the cost and complexity of the resulting system.

In general, it is possible to generate relatively realistic phantom sources using multiple loudspeakers whose lateral position changes with changes in the speaker waveforms. More complex simulations in which spectral cues are simulated are often too difficult to include.

5. DESIGN CONSIDERATIONS

5.1 Hardware

Despite the importance of audio cues in human existence, there are relatively few platforms available for easily implementing spatial audio into virtual environments. The most common platforms used today for implementing spatial audio in research and VE are the AuSim GoldServer, Lake Huron, and Tucker Davis Technologies PD-1 Power SDAC and expander.

The AuSim GoldServer is based on the original acoustetron II design pioneered by Crystal River Engineering (CRE; Wenzel, Wightman, & Foster, 1988). Although the original acoustetron II is no longer commercially available, AuSIM acquired the rights to the device and is now producing boxes and replacement parts for the original CRE devices. AuSIM also claims that their new product line will not only fill the niche for VE applications, but will also provide a more flexible research tool than its predecessor (William L. Chapin, personal communication, April, 2000). A typical system will cost between \$12,000 and \$18,000 and claims to be relatively easy to integrate into a variety of VE applications. AuSim also produces a system for collecting customized HRTPs.

Hailing from Australia, Lake Technology offers a variety of hardware and software systems using either headphones or speakers. On the hardware side, the Huron System is a multiple DSP system that will present multiple sound sources to multiple listeners using positional tracking. The Huron can be configured using multiple speakers or headphones. Combined with an extensive set of software development tools, the Huron System is another good option for integrating sound in virtual environments. For instance, the software package Multiscape is advertised to be able to create a multiple user interactive auditory VE complete with geometric rooms with interconnecting doors. Finally, in cooperation with Dolby, Lake has recently helped develop, and now supports, headphone systems that simulate Dolby 5.1 Surround Sound.

The Tucker-Davis Technologies (TDT) PD-1 Power SDAC system is primarily a research tool. However, with some creative programming, it too can be used as a sound server for simulations (Shilling et al., 2000). The PD-1 combines up to 27 DSPs, allowing researchers to create complex spatial audio scenarios including numerous reflections and incorporating head tracking. It also provides real-time convolution, allowing the researcher to convolve "live" signals.

A software solution currently under development for research in spatial sound is Sound Lab (Wenzel, Miller, & Abel, 2000). Sound Lab (SLAB) is designed to run on a regular personal computer (PC) platform and provides low-level control of a variety of signal processing functions, including the number of reflections, number of filter taps, and positions of reflections. No special purpose hardware is required for the software to run. In addition to allowing normal HRTF processing and inclusion of reflections, the software allows for manipulation of acoustic radiation patterns, spherical spreading loss, and atmospheric absorption. Preliminary analysis of the dynamic performance of SLAB shows it achieves a very low 24 ms latency on a 450 MHz Pentium II, although the latency would be larger for a more complex acoustic model. At this time, SLAB continues to be developed.

5.2 Defining the Auditory Environment

When creating the auditory portion of a virtual environment, careful attention should be placed on what is absolutely essential for the task. The adage of motion picture sound designers, "see it, hear it" (Holman 1997; Yewdall, 1999), is also valid for designing audio for virtual

environments. The sense of immersion experienced in a movie theater is a carefully orchestrated combination of expertly designed sound effects and skillfully applied auditory ambiances. It is also interesting to note that “realistically” rendered sound is often perceived as emotionally flat in motion pictures. Sound effects are often designed as exaggerated versions of reality to convey emotion or to satisfy the viewers’ expectations of reality (Holman, 1997). Sound design in VE needs to balance the need for accurate reproduction with the need to make the user emotionally involved in a synthetic environment. When dealing with issues of emotionality in VE, sound should be considered as synonymous with emotion.

On the hardware side, a simple sound card solution may be adequate if spatialized audio and fidelity are not paramount. However, if there are multiple sound sources and/or a multiuser interface, an audio server such as the AuSIM Acoustetron or the Lake Huron System may be necessary. Just as photos and films of the visual environment are taken during the development process, it is a good idea to make audio recordings, including sound level measurements, when developing an auditory interface.

One of the current efforts in the Virtual Environments in Training Technology (VETT) program sponsored by the Office of Naval Research (see chap. 43, this volume) is to develop a systematic approach for obtaining baseline data concerning the content of an auditory environment. In addition to cataloguing the different sounds in a real environment, it is also important to systematically measure the intensity of sounds being experienced by the listener. In this manner, the VE developer has a detailed reference with which to compare the real world auditory environment with the virtual auditory environment. Two systems are currently being evaluated. The first system uses a portable Sony TCD-D8 DAT recorder coupled with Sennheisser microphone capsules (see Fig. 4.4, left). To produce a crude spatialized recording, the microphone capsules are inserted into an observer’s auditory meatus (ear canal). In this manner, a complete spatialized recording can be made of the auditory environment, completely externalized with azimuth and elevation cues. The second system (see Fig. 4.4, right) is more robust, using a larger set of microphones produced by Core Sound, which can clip to a set of eyeglasses to produce a binaural recording. However, since the microphones are not inside the ear canals, this system will not include spectral cues. Although pinnae cues cannot be utilized, the latter system has more robust construction and will be more tolerant of extreme conditions, especially if recordings are made outdoors. Both systems can be clipped to a belt and will be used in conjunction with a real-time logging and event analyzer (CEL 593). The complete data set, including sound recordings and sound measurements, will be stored on CDROM for ease of use. Digital recordings also allow for spectral analyses to be conducted on specific auditory stimuli contained on tape so that synthesized versions of those stimuli can be constructed. If

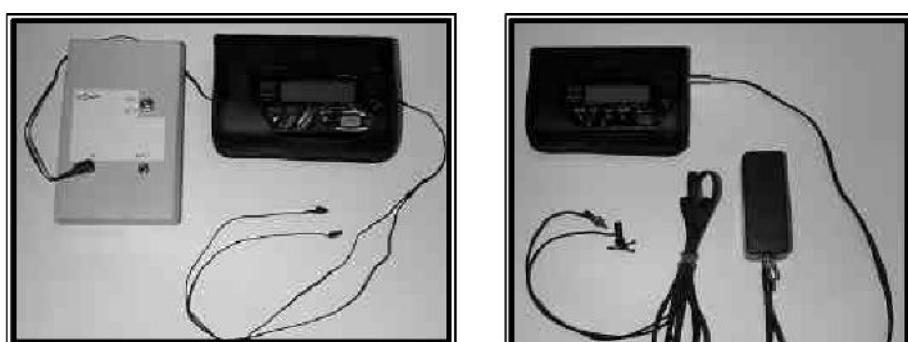

FIG. 4.4. Two portable systems for making binaural recordings. On the left is a system using microphone capsules placed in the auditory meatus using Sennheisser microphone capsules (Tucker Davis Technologies). On the right is a binaural recording system from CORE Sound.

concussive or low-frequency sounds need to be catalogued, microphones with wider frequency ranges should be employed.

Given the wide dynamic range involved with recording sounds ranging from concussive events to footsteps and the necessity that recordings be absolutely clean and accurate, the best solution may be to rely on professionals for making appropriate recordings. Different combinations of microphones and recording equipment produce vastly differing sound quality. Choosing the appropriate combination for a particular application is still more of an art than a science. In addition, there are many high-quality commercially available sound libraries for obtaining a wide variety of sound effects and ambiences (Holman, 1997; Yewdall, 1999).

5.3 How Much Realism Is Necessary?

Much of the research devoted to developing and verifying virtual display technology emphasizes the subjective realism of the display (see chap. 40, this volume); however, this is not the most important consideration for all applications. In some cases, signal processing that improves realism actually interferes with the amount of information a listener can extract. For instance, inclusion of echoes and reverberation can significantly increase the perceived realism of a display and improve distance perception. However, echoes can degrade perception of source direction. For applications in which information about the direction of a source is more important than the realism of the display or perception of source distance, including echoes and reverberation may be ill advised.

In headphone-based systems, realism is enhanced with the use of individualized HRTFs, particularly in the perception of up/down and front/back position. Ideally, HRTFs should also be sampled in both distance and direction at a spatial density dictated by human sensitivity. Thus, while the most “realistic” system would use individualized HRTFs that are sampled densely in both direction and distance, most systems use generic HRTFs sampled coarsely in direction and at only one distance.

If a particular application requires a listener to extract three-dimensional spatial information from the auditory display, HRTFs may have to be tailored to the listener to preserve directional information and reverberation may have to be included to encode source distance. On the other hand, if a particular application only makes use of one spatial dimension (for instance, to indicate the direction that a blind user must turn), coarse simulation of ITD and IID cues (even without detailed HRTF simulation) is probably adequate.

If information transfer is of primary importance, it may be useful to present acoustic spatial cues that are intentionally distorted so that they are perceptually more salient than more “realistic” cues. For instance, it may be useful to exaggerate spatial auditory cues to improve auditory resolution; however, such an approach requires that listeners are appropriately trained with the distorted cues (Shinn-Cunningham et al., 1998a).

The processing power needed to simulate the most realistic virtual auditory environment possible is not always cost-effective. For instance, the amount of computation needed to create realistic reverberation in a VE may not be justifiable when source distance perception and subjective realism are not important. Other acoustic effects are often ignored in order to reduce computational complexity of an acoustic simulation, including the nonuniform radiation pattern of a realistic sound source, spectral changes in a sound due to atmospheric effects, and Doppler shift of the received spectrum of moving sources. The perceptual significance of many of these effects is not well understood; further work must be done to examine how these factors affect the realism of a display, as well as what perceptual information such cues may convey.

In command-and-control applications (see chap. 43, this volume), the goal is to maximize information transfer to the human operator; subjective impression (i.e., realism) is unimportant. In these applications, both technological and perceptual issues must be considered to achieve

this goal. If nonverbal warnings or alerts are created, the stimuli must be wideband enough to be localizable. In addition, stimuli should be significantly intense to be at least 15 dB above background noise level. Stimulus onset should be fairly gradual so as not to be excessively startling to the user. In many instances, one may want the stimuli to be aesthetically pleasing to the user. As can be imagined, creating acceptable spatialized auditory displays is no trivial chore and should involve formal evaluations to ensure perceptual accuracy and system usability. For applications in which speech is the main signal of interest, basic interaural cues are important for preserving speech intelligibility, particularly in noisy, multisource environments. On the other hand, there is probably little benefit gained from including the detailed frequency-dependence of normal HRTFs. In entertainment applications (see chap. 55, this volume), cost is the most important factor; the precision of the display is unimportant as long as the simulation is subjectively satisfactory. For scientific research (see chap. 53, this volume), high-end systems are necessary in order to allow careful examination of normal spatial auditory cues. In clinical applications (see chaps. 49 and 50, this volume), the auditory display must only be able to deliver stimuli that can distinguish listeners with normal spatial hearing from those with impaired spatial hearing. Such systems must be inexpensive and easy to use, but there is no need for a perfect simulation.

1. INTRODUCTION

Haptics is concerned with information acquisition and object manipulation through touch. Haptics is used as an umbrella term covering all aspects of manual exploration and manipulation by humans and machines, as well as interactions between the two, performed in real, virtual, or teleoperated environments. Haptic interfaces allow users to touch, feel, and manipulate objects simulated by virtual environments (VEs) and teleoperator systems (Salisbury & Srinivasan, 1992). The keyboard, mouse, and trackball are familiar, passive, haptic interfaces that sense a user's hand movements. Although they apply forces on the user's hand upon contact and consequently provide tactful sensation, the forces are not under program control. Active haptic interfaces, such as desktop robots and exoskeletal gloves with force feedback, are more sophisticated devices that have both sensors and actuators. In addition to transducing position and motion commands from the user, these devices can present controlled forces to the user, allowing him or her to feel virtual objects as well as control them. This chapter focuses on such devices.

This is an exciting time for the field of haptics. Within approximately 10 years of significant research activity, commercial efforts have brought simple, active haptic interfaces into mass production. Research efforts on a range of more sophisticated devices have intensified. The success of these endeavors depends on finding application tasks where haptics adds significant value and, from a design viewpoint, on achieving an optimal balance between the human haptic ability to sense object properties, fidelity of the interface device in delivering the appropriate mechanical signals, and computational complexity in rendering the signals in real time. Accordingly, this chapter discusses the usefulness of haptic displays in virtual environments (section 2), the human haptic system (section 3), and current interface hardware (section 4). Algorithms for estimating and rendering force feedback are covered in chapter 6 of this volume. VE-assisted teleoperation is treated specifically in chapter 48 of this volume.

Locomotion interfaces, which may actively display forces to the user, are covered in chapter 11 of this volume. Previous overviews of this field can be found in Burdea (1996), Srinivasan (1995), Youngblut, Johnson, Nash, Wienclaw, and Will (1996), and Srinivasan and Basdogan (1997).

2. ADVANTAGES OF ACTIVE HAPTIC INTERFACES

The gap between performance in the world and in a simulation is familiar to most computer users. In the real world, the placement, orientation, and scaling of a rectangle can be indicated in one quick gesture using the thumb and index fingers of both hands, and a rubber band to mark the perimeter. In a simulation (e.g., MacDraw) the same process must be performed in three steps using a mouse, requiring about 10 times longer (Fitzmaurice, Balakrishnan, Kurtenbach, & Buxton, 1999). A similar gap exists in VEs, both in terms of physical realism and task performance. For example, the phrase *virtual reality* typically conjures an image of a user with one passive VR glove that senses joint angles of a few fingers and position/orientation of the hand, through which the user can convey his or her intentions to the computer. However, in tasks such as surgical simulation or virtual sculpting, the glove would be inadequate. Two-way communication between the user and the computer enabled by force feedback would be absolutely necessary in order to simulate the “feel” of the organs or the clay as they are manipulated. In contrast to vision and hearing, haptics is the only modality that permits this bidirectional information transfer between the user and virtual environment. Current excitement in developing haptic interfaces arises from applications like these, and others like those listed below (from Srinivasan & Basdogan, 1997):

- *Medicine*: surgical simulators for medical training; manipulating micro and macro robots for minimally invasive surgery; remote diagnosis for telemedicine; aids for the disabled such as haptic interfaces for blind users (see chaps. 47–51, this volume).
- *Entertainment*: video games and simulators that enable the user to feel and manipulate virtual solids, fluids, tools, and avatars (see chap. 55, this volume).
- *Education*: giving students the feel of phenomena at nano, macro, or astronomical scales; “what if” scenarios for nonterrestrial physics; experiencing complex data sets (see chaps. 45–46, this volume).
- *Industry*: integration of haptics into CAD systems such that a designer can freely manipulate the mechanical components of an assembly in an immersive environment (see chaps. 52–54, this volume).
- *Graphic Arts*: virtual art exhibits, concert rooms, and museums in which the user can login remotely to play the musical instruments, and to touch and feel the haptic attributes of the displays; individual or cooperative virtual sculpting across the Internet.

The need for active haptic interfaces clearly depends on the task at hand, and can be classified as follows:

1. Active haptic interfaces are absolutely required for some tasks: Many medical procedures (for example, administering epidural anesthesia, palpating for cancerous lumps) are intrinsically haptic tasks. Haptic displays are required to simulate such tasks for training, because sensing of forces arising from tool-tissue interaction is critical for success. Another intrinsically haptic VE task is testing the ease of manual assembly of complex mechanisms before they are manufactured (Nahvi, Nelson, Hollerbach, & Johnson, 1998). In addition, active haptic

interfaces make VEs accessible to visually impaired users. Current VEs are almost entirely visual, therefore inaccessible to the roughly 0.75 million visually impaired users in the United States. The United States Congress has called for “every-citizen interfaces to the country’s information infrastructure” (National Research Council, 1997). As VEs become more common in education and industry, it will be interesting to see whether the Americans with Disabilities Act is extended from the real environment to include virtual worlds.

2. Active haptic interfaces can improve a user’s sense of presence: Haptic interfaces with 2 or fewer actuated degrees of freedom are now mass-produced for playing PC video games, making them relatively cheap (about \$100 at the time of this writing), reliable, and easy to program. Although the complexity of the cues they can display is limited, they are surprisingly effective communicators. For example, if the joystick is vibrated when a player crosses a bridge (to simulate driving over planks) it can provide a landmark for navigation, and signal the vehicle’s speed (vibration frequency) and weight (vibration amplitude). Haptic cues have also been developed to augment graphical user interfaces to windows operating systems, both Microsoft Windows (Immersion, 2000) and Linux/Unix (Miller & Zeleznik, 1999). Free source code for haptic effects for desktops and games are available. Most manufacturers of general-purpose, active interfaces also sell haptic authoring software. A few examples are the Ghost Toolkit for the Phantom (SensAble Technologies, 2000), Immersion Studio for the FeelIt mouse (Immersion, 2000), and the VirtualHand Studio for the CyberGrasp force feedback glove (Virtual Technologies, Inc., 2000). Just one haptic interaction (for example, handling a real plate in a VE) can significantly improve a user’s expectations about the solidity and weight of all objects in a VE (Hoffman, 1998).

3. Active haptic interfaces can improve performance by providing natural constraints: In VEs, selecting and repositioning objects without haptic cues can be surprisingly difficult. Without force feedback, a user trying to set a simulated coffee mug down on a simulated table top is likely to merely push the mug through it. To overcome these difficulties, force-free interaction metaphors have been developed. For a review see Mine, Brooks, and Sequin (1997). The names of these metaphors generally suggest how they work (e.g., “extender grab,” “spring widget,” “virtual chopsticks”). Although these methods appear adequate for many tasks, they usually demand more visual attention than the same action would in the real world. A haptic interface is a more straightforward solution that may reduce the visual attention required of the user. Force feedback also can improve accuracy and rate of spatial input. For example, during a virtual a pick-and-place task force feedback cut positioning errors in half while speeding performance by about 20% (Noma, Miyasato, & Kishino, 1996).

4. Active haptic interfaces can reduce “information clutter”: Unlike speakers and video monitors, haptic displays don’t generally clutter a user’s environment with unnecessary information. A good example of this property is a pager set to vibrate rather than beep. This haptic display provides only the right message (“You have a page”), to the right person (the owner), at the right time. This specificity is likely to become more important as embedded processors make more real-world objects intelligent and active. The same considerations suggest that haptic displays may reduce information clutter in VEs of increasing complexity.

3. HUMAN HAPTIC SYSTEM

In the real world, whenever an individual touches an object, forces are imposed on the skin. The net forces as well as the posture and motion of various limb segments are conveyed to the brain as *kinesesthetic* information (the term *proprioceptive* is approximately equivalent; see endnote 2 in chap. 7, this volume), conveyed by multiple sources such as receptors in the joints, tendons,

and muscles. This is the means by which the coarse properties of objects, such as large shapes and springlike compliances that require hand or arm motion in probing them, are sensed. In addition, the spatial and temporal variations of the force distributions within the contact region on the skin are conveyed as *tactile* information by several types of receptors embedded in the skin. Fine texture, small shapes, softness, and slipping of surfaces are felt through the tactile sensors. The temperature of the skin, which, in turn, is related to the temperature and thermal properties of the object, is also sensed through specialized tactile sensors.

In addition to the tactile and kinesthetic sensory subsystems, the human haptic system consists of the motor system that enables active exploration or manipulation of the environment and a cognitive system that can link sensations to perception and action. In general, a tactful image is composed of both tactile and kinesthetic sensory information, and is controlled by motor commands based on the user's intention. Because of the large number of degrees of freedom, multiplicity of the subsystems, spatially distributed heterogeneous sensory receptors, and the sensorimotor nature of haptic tasks, the human haptic abilities and limitations that prescribe the design specifications of haptic interfaces are difficult to quantify.

Haptic interfaces in VE or teleoperation systems receive the intended motor-action commands from the human and display tactful images to the human. A successful haptic interface represents a good match between the human haptic system and hardware for sensing and display. The primary input-output variables of the interfaces are displacements and forces, including their spatial and temporal distributions. Haptic interfaces can therefore be viewed as generators of mechanical impedances that represent a relationship between forces and displacements (and their derivatives) over different locations and orientations on the skin surface at each instant of time. In contact tasks involving finite impedances, either displacement or force can be viewed as the control variable, and the other is a display variable, depending on the control algorithms employed. However, consistency among free-hand motions and contact tasks is best achieved by viewing the position and motion of the hand as the control variable, and the resulting net force vector and its distribution within the contact regions as the display variables.

Because the human user is sensing and controlling the position and force variables of the haptic interface, the performance specifications of the interface are directly dependent on human abilities. In a substantial number of simple tasks involving active touch, one of the tactile and kinesthetic information classes is fundamental for discrimination or identification, whereas the other is supplementary. For example, in the discrimination of length of rigid objects held in a pinch grasp between the thumb and the forefinger (Durlach, Delhorne, Wong, Rabinowitz, & Holherbach, 1989), kinesthetic information is fundamental, whereas tactile information is supplementary. In such tasks, sensing and control of variables such as fingertip displacements are crucial. In contrast, for the detection of surface texture or slip, tactile information is fundamental, whereas kinesthetic information is supplementary (Srinivasan, Whitehouse, & LaMotte, 1990). Here, the sensing of spatiotemporal force distribution within the contact region provides the basis for inferences concerning contact conditions and object properties. Both classes of information are clearly necessary and equally important in more complex haptic tasks.

Detailed reviews of the human haptic system are available, focusing on position sense (Clark & Horch, 1986), skin sensitivity (Sherrick & Cholewiak, 1986), and perception (Loomis & Lederman, 1986). In this section a brief overview focused on issues relevant to haptic interfaces is provided. Sections 3.1 and 3.2 are excerpted from Srinivasan (1995) and summarize briefly the psychophysical results available on human haptic abilities in real environments at two levels: (1) sensing and control of interface variables and (2) perception of contact conditions and object properties. These results are also gathered in tables in the Appendix of this chapter. Although humans can feel heat, itch, pain, and so forth, through sensory nerve endings in

the skin, these sensations are not discussed here because the availability of practical interface devices employing them is unlikely in the near future. This section concludes by emphasizing some features of the human haptic system that can provide guidance for haptic interface design (see section 3.3).

3.1 Sensing and Control of Interface Variables

3.1.1 Limb Position and Motion

A large variety of psychophysical experiments have been conducted concerning the perception of limb position and motion (Clark & Horch, 1986; Jones & Hunter, 1992). It has been found that humans can detect joint rotations of a fraction of a degree performed over a time interval of the order of a second. The bandwidth of the kinesthetic sensing system has been estimated to be 20 to 30 Hz (Brooks, 1990). It is generally accepted that human sensitivity to rotations of proximal joints is higher than that of more distal joints. The just noticeable difference (JND) is about 2.5 degrees for the finger joints, 2 degrees for the wrist and elbow, and about 0.8 degrees for the shoulder (Tan, Srinivasan, Eberman, & Cheng, 1994). In locating a target position by pointing a finger, the speed, direction, and magnitude of movement, as well as the locus of the target, can all affect accuracy. In the discrimination of length of objects by the finger-span method (Durlach et al., 1989; Tan, Pang, & Durlach, 1992), the JND is about 1 mm for a reference length of 10 mm, and increases to 2 to 4 mm for a reference length of 80 mm, thus violating Weber's law (i.e., JND is not proportional to the reference length). In the kinesthetic space, psychophysical phenomena such as anisotropies in the perception of distance and orientation, apparent curvature of straight lines, non-Euclidean distance measures between two points, and others have been reported. For reviews, see Fasse, Kay, and Hogan (1990), Hogan, Kay, Fasse, and Mussa-Ivaldi (1990), and Loomis and Lederman (1986).

Investigations of the human ability in controlling limb motions have typically measured human tracking performance with manipulanda having various mass, spring, and damping characteristics (Brooks, 1990; Jones & Hunter, 1992; Poulton, 1974; Sheridan, 1992). The differential thresholds for position and movement have been measured to be about 8% (Jones & Hunter, 1992). Human bandwidth for limb motions is found to be a function of the mode of operation: 1 to 2 Hz for unexpected signals; 2 to 5 Hz for periodic signals; up to 5 Hz for internally generated or learned trajectories; and about 10 Hz for reflex actions. For a review see Brooks (1990).

3.1.2 Net Forces of Contact

When a person contacts or presses objects through active motion of the hand, the contact forces are sensed by both the tactile and kinesthetic sensory systems. Overall contact force is probably the single most important variable that determines both the neural signals in the sensory system, as well as the control of contact conditions through motor action. It appears that the JND for contact force is 5% to 15% of the reference force value over a wide range of conditions involving substantial variation in force magnitude, muscle system, and experimental method, provided that the kinesthetic sense is involved in the discrimination task (Jones, 1989; Pang, Tan, & Durlach, 1991; Tan et al., 1992). In closely related experiments exploring human ability to distinguish among objects of different weights, a slightly higher JND of about 10% has been observed. For reviews see Clark and Horch (1986) and Jones (1986). An interesting illusion first observed in the late 19th century by Weber and reviewed more recently (Sherrick & Cholewiak, 1986) is that cold objects feel heavier than warm ones of equal weight. In experiments involving grasping and lifting of objects using a two-finger pinch

grasp (Johansson & Westling, 1984) it has been shown that individuals have exquisite control over maintaining the proper ratio between grasping and lifting forces (i.e., the orientation of the contact force vector) so that the objects do not slip. However, when tactile information was blocked using local anesthesia, this ability deteriorated significantly because individuals could not sense contact conditions such as the occurrence of slip and hence did not apply appropriate compensating grasp forces. Thus, good performance in tasks involving contact requires the sensing of appropriate forces, as well as using them to control contact conditions. The maximum controllable force that can be exerted by a finger pad is about 100 N, and the resolution in visually tracking constant forces is about 0.04 N or 1%, whichever is higher (Srinivasan & Chen, 1993; Tan, Srinivasan, Eberman, & Cheng, 1994).

3.2 Perception of Contact Conditions and Object Properties

Although humans experience a large variety of tactile sensations when touching objects, these sensations are really combinations of a few building blocks or primitives. For simplicity, normal indentation, lateral skin stretch, relative tangential motion, and vibration are the primitives for conditions of contact with an object. Surface microtexture, shape (mm size), and compliance can be thought of as the primitives for the majority of object properties perceived by touch. The human perception of many of these primitives is through tactile information conveyed by mechanoreceptors in the skin.

Considerable research effort has been invested on psychophysics of vibration perception and electrocutaneous stimulation using single or multiple probes. For a review see Sherrick and Cholewiak (1986). These studies are mostly directed at issues concerned with tactile communication aids for individuals who are blind, deaf, or deaf and blind, areas that are beyond the scope of this chapter. A comprehensive list of references describing such tactile displays can be found in Kaczmarek and Bach-y-Rita (1993) and Reed, Durlach, and Braida (1982). In designing these devices, human perceptual abilities in both temporal and spatial domains are of interest. The human threshold for the detection of vibration of a single probe is about 28 dB (relative to 1 μm peak) for 0.4 to 3 Hz. It decreases at the rate of -5 dB/octave for 3 to 30 Hz, and decreases further at the rate of -12 dB/octave for 30 to about 250 Hz, after which the threshold increases for higher frequencies (Bolanowski, Gescheider, Verrillo, & Checkosky, 1988; Rabinowitz, Houtsma, Durlach, & Delhorne, 1987). Spatial resolution on the finger pad, as measured by the localization threshold of a point stimulus, is about 0.15 mm (Loomis, 1979), whereas the two-point limen is about 1 mm (Johnson & Phillips, 1981).

To answer questions concerning perception and neural coding of roughness or spatial resolution, precisely shaped rigid surfaces consisting of mm-sized bar gratings (Lederman & Taylor, 1972; Morley, Goodwin, & Darian-Smith, 1983; Phillips & Johnson, 1981a, 1981b; Sathian, Goodwin, John, & Darian-Smith, 1989), embossed letters (Phillips, Johnson, & Browne, 1983; Phillips, Johnson, & Hsiao, 1988), or Braille dots (Darian-Smith, Davidson, & Johnson, 1980; Lamb, 1983a, 1983b) have been used in psychophysical and neurophysiological experiments. For a review see Johnson and Hsiao (1992). The perception of surface roughness of gratings is found to be solely due to the tactile sense and is dependent on groove width, contact force, and temperature but not scanning velocity (Loomis & Lederman, 1986). Some of the salient results on the perception of slip, microtexture, shape, compliance, and viscosity are given below. Humans can detect the presence of a 2 μm high single dot on a smooth glass plate stroked on the skin, based on the responses of Meissner-type rapidly adapting fibers (RAs; LaMotte & Whitehouse, 1986; Srinivasan, Whitehouse, & LaMotte, 1990). Moreover, humans can detect a 0.075 μm high grating on the plate, owing to the response of Pacinian corpuscle fibers (LaMotte & Srinivasan, 1991). Among all the possible representations of the shapes

of objects, the surface curvature distribution seems to be the most relevant for tactile sensing (LaMotte & Srinivasan, 1993; Srinivasan & LaMotte, 1991). Human discriminability of compliance of objects depends on whether the object has a deformable or rigid surface (Srinivasan & LaMotte, 1995). When the surface is deformable, the spatial pressure distribution within the contact region is dependent on object compliance, and hence information from cutaneous mechanoreceptors is sufficient for discrimination of subtle differences in compliance. When the surface is rigid, kinesthetic information is necessary for discrimination, and the discriminability is much poorer than that for objects with deformable surfaces. For deformable objects with rigid surfaces held in a pinch grasp, the JND for compliance is about 5% to 15% when the displacement range is fixed, increases to 22% when it is roved (varied randomly), and can be as high as 99% when cues arising out of mechanical work done are eliminated (Tan et al., 1992; Tan, Durlach, Shao, & Wei, 1993). Using a contralateral-limb matching procedure involving the forearm, it has been found (Jones & Hunter, 1992) that the differential thresholds for stiffness and viscosity are 23% and 34%, respectively. It has been found that a stiffness of at least 25 N/mm is needed for an object to be perceived as rigid by human observers (Tan et al., 1994). See the tables in the Appendix for a summary of these results.

3.3 Aspects of the Human Haptic System That Have Special Relevance to VE Hardware

A few aspects of the human haptic system that pertain to the design of haptic interface hardware deserve special attention. The following points are addressed:

1. A haptic precision gradient suggests that interface hardware deployed at distal body segments (e.g., fingertips) provides more benefit than interface hardware deployed proximally (e.g., shoulder).
2. A perceptual emphasis on transient stimuli suggests that users may tolerate considerable drift errors in haptic display hardware.
3. The human tendency to move the preferred hand with respect to the nonpreferred hand (rather than the world) suggests that two-handed interfaces offer significant advantages over one-handed.
4. The wide range of information transfer rates for different methods of manual communication suggests the importance of developing efficient “haptic languages” for interaction with virtual environments.

3.3.1 Distal to Proximal Gradient in Precision

Given the importance of the fingertips for manipulation, it is reasonable to use them as a reference for describing more proximal body segments. Viewed this way, one finds a consistent gradient in performance, such that the skin and segments closer to the fingertip can be sensed and controlled more precisely than those closer to the trunk. This trend holds for detecting indentation of the skin and fingertip displacement, resolving position targets and rate of information transfer.

Gradient in tactile resolution: On the distal half of the fingertip humans can sense slow indentations of about 20 microns, sense vibrations (~ 250 Hz) of about 0.1 microns, distinguish separate points until they are within about 1 mm, and sense translations as small as 0.15 mm. At more proximal points on the limbs and trunk, sensitivity in all of these categories is poorer. For example, on the upper arm, vibration amplitude must be about 10 times larger to be detected, and slowly applied forces must be about 2 times larger. This distal to proximal gradient generally holds, but the tongue and lips are a notable exception. See Sherrick and Cholewiak (1986) for a review.

Gradient in detecting movement: A similar precision gradient is observed in detecting fingertip displacement. See Clark and Horch (1986) for a review. If the fingertip is moved passively at the speed humans normally use for pointing, then a displacement of about 0.3 mm can be detected if movement is constrained to the distal finger joint. If the movement is constrained to the elbow joint, detection requires about twice as much fingertip displacement (0.6 mm), and at the shoulder, twice as much again (1.2 mm; Hall & McCloskey, 1983). Thus, in terms of linear displacement of the fingertip, the distal segments again show higher sensitivity.

Gradient in resolving position targets: If participants are asked to discriminate or reproduce fingertip locations, they can typically distinguish about three targets when movement is constrained to 70 degrees of flexion of the middle joint of the index finger (Clark, Larwood, Davis, & Deffenbacher, 1995). This makes each target about 25 mm wide (one third of the corresponding range of fingertip displacement). Although participants can distinguish more targets over the angular range of motion of the more proximal joints, this precision does not compensate for the increased displacement of the fingertip these joints permit. Thus, flexion of the most proximal index finger joint allows participants to resolve fingertip targets about 40 mm wide, the wrist about 70 mm, the elbow about 100 mm, and the shoulder about 80 mm (Clark et al., 1995). Again, more distal segments generally show higher precision.

Gradient in pointing speed: If participants actively point with the limb, they can specify about 4.2 to 4.5 bit/sec using the finger joints with a tool held in a pen grasp (Balakrishnan & MacKenzie, 1997). If movement is constrained to a more proximal joint (wrist abduction), the rate decreases by about 30%, to about 4 bit/sec. Other studies report the same trend with far steeper gradients. An extreme example is Langolf (1976), in which they report 38 bit/sec with fingers only, 23 bit/sec with wrist and fingers, and 10 bit/sec with shoulder and elbow. The neck is estimated to provide only about 4 bit/sec (Card, Mackinlay, & Robertson, 1991). One suspects that this gradient is due to the increasing rotary inertia of limbs as the axis of rotation is shifted proximally, and also due to the fact that the human body seems to have more precise sensing and control hardware deployed at the distal body segments. In this case, more distal segments show higher rates of information transfer.

Implications for haptic interfaces: Since the bandwidth of human motor performance typically limits bandwidth of haptic input devices (Card et al., 1991), these results suggest that interfaces that sense finger movement may allow users to perform more quickly than they can with interfaces that only sense movement of the palm or arm. Human-computer interaction (HCI) developers have had mixed success with attempts to speed spatial input by including the fingers (Balakrishnan & MacKenzie, 1997; Zhai, Milgram, & Buxton, 1996).

A second consequence of the haptic precision gradient is that the quality of simulations is not degraded unduly when forces that ought to be grounded in the world are grounded on more proximal segments of the body. (See section 3.3.2 for a more detailed explanation of force grounding). CyberGrasp illustrates this body-grounded approach. This device renders forces on the fingertips that mimic what a user would experience handling objects in the real world. However, forces are grounded on the back of the hand, so the device fails to render appropriate torques about the wrist, elbow, or shoulder joints. Still, it provides a satisfactory haptic simulation, probably because it addresses the distal body segments (fingers), where the haptic system has greatest sensitivity. Experiments (Richard & Cutkosky, 1997) show that just rendering fingertip forces (i.e., grounding force on the middle phalanx) provides cues that lead participants to stop at virtual walls with penetration depths comparable to those achieved by world-grounded haptic interfaces that display appropriate torques around all joints.

3.3.2 *Perceptual Importance of Change*

Broadly speaking, haptic sensors in skin and muscle perform like systems of second order or higher. That is, the response of the sensor depends on both rate and magnitude of stimulus. Perhaps because haptic input emphasizes higher time derivatives, the precision of human haptic output also depends strongly on time. Over short intervals (< 1 sec), fine displacements can be sensed and controlled. However, over longer intervals (1 sec to 1 min) the haptic system alone does not generally notice or correct for substantial position errors (> 1 cm of fingertip displacement; Clark & Horch, 1986).

This emphasis on higher time derivatives is also apparent in the difference between the small, rapid displacements of a passive limb that can just be detected, and the 10- to 100-fold larger errors in actively reproducing pose of the same limb. The shoulder joint illustrates the trend. Here a fingertip displacement of about 1.2 mm can be detected (Hall & McCloskey, 1983), but for participants to reproduce target positions reliably with the shoulder, the targets at the fingertip must be about 70 times wider (80 mm; Clark, Larwood, Davis, & Deffenbacher, 1995).

Implications for haptic interfaces: This laxity in absolute position sensing may offer the haptic interface designer some leverage. For example, many active interfaces can probably be recentered at 1 to 10 mm/sec (up to a few centimeters) without attracting a user's attention or degrading the quality of the interaction. This could help compensate for the limited workspace of many devices.

3.3.3 *Bimanual Frame of Reference*

Humans naturally perform many manual tasks by setting a frame of reference with the nonpreferred hand (e.g., positioning a piece of paper) and then operating the preferred hand in this frame (e.g., writing on the paper; Guiard, 1987). This preference also affects the precision of a user's performance with haptic interfaces. For positioning tasks, errors of the preferred hand are typically about twofold smaller relative to the nonpreferred hand (~ 50 mm) than they are relative to the world (~ 100 mm; Mine, Brooks, & Sequin, 1997). It is not yet clear how much of this improvement is simply due to subtracting out sway of the torso and how much is due to the participant's experience with this sort of manipulation in the real world. Regardless of the source of improvement, the effect is robust. Participants can perform spatial input in about half as much time (Hinckley, Pausch, & Proffitt, 1997) when the preferred hand operates in the frame of the nonpreferred hand. These results suggest that two-handed interfaces offer about a two-fold improvement in speed and accuracy.

3.3.4 *Factors That Determine Rates of Information Transfer*

Coordination of movement: Since inertia of the limbs limits the rate of motor production to less than 5 Hz, and the precision of motor output typically limits information transfer to a few bits per joint, rapid information transfer depends on coordination of multiple joints. Work thus far (Zhai & Milgram, 1998) has shown that humans performing a one-handed 6 degree-of-freedom (DOF) docking task tend to set position of a grasped object first (simultaneously adjusting 3 DOF), and then specify orientation separately (simultaneously setting 3 more DOF). In these experiments, the haptic interface paradigm (position versus force input to the computer) did not have much effect on this basic division of labor. However, these efforts have provided some useful tools for haptic interface development—generic techniques for measuring how well humans can specify different kinematic parameters simultaneously. Advances in HCI require finding these kinematic parameters, and developing hardware that can transduce them.

Codes for information transfer: When a motor activity is more complicated than just pointing, the code used to transmit information has a large effect. The same fingers that are used to send Morse code at about 3 bit/sec can be used to type at about 14 bit/sec, transmitting information about 2,000-fold faster. See Appendix for information transfer rates for different modes of manual communication. Coding is comparably important for manual reception of information. Advances in HCI require finding rich codes for haptic input and output that users can learn quickly and easily.

4. CURRENT HARDWARE

In performing tasks with a haptic interface, the human user conveys desired motor actions by physically manipulating the interface, which, in turn, displays tactal sensory information to the user by appropriately stimulating his or her tactile and kinesthetic sensory systems. Thus, in general, haptic interfaces can be viewed as having two basic functions: (1) to measure the positions and contact forces (and time derivatives) of the user's hand (or other body parts) and (2) to display contact forces and positions (or their spatial and temporal distributions) to the user. Among these position (or kinematic) and contact force variables, the choice of which ones are the motor action variables (i.e., inputs to the computer) and which are the sensory display variables (i.e., inputs to the human) depends on the hardware and software design as well as the tasks for which the interface is employed. Typically, the user's hand position is sensed by the interface and contact forces computed by rendering algorithms are displayed to the user.

A primary classification of haptic interactions with real environments or VEs that affects interface design can be summarized as follows: (1) free motion, in which no physical contact is made with objects in the environment; (2) contact involving unbalanced resultant forces, such as pressing an object with a finger pad; (3) contact involving self-equilibrating forces, such as squeezing an object in a pinch grasp. Depending on the tasks for which a haptic interface is designed, some or all of these elements will have to be adequately simulated by the interface. For example, grasping and moving an object from one location to another involves all three elements. The design constraints of a haptic interface are strongly dependent on which of these elements it needs to simulate. Consequently, the interfaces can be classified according to whether they are force-reflecting or not, as well as by what types of motions (e.g., how many degrees of freedom) and contact forces they are capable of simulating.

An alternative but important distinction in haptic interactions with real environments or VEs is whether an object is touched, felt, and manipulated directly or with a tool. Which of these two types of interactions is supposed to be simulated seriously affects the complexity in the design of a haptic interface. Note that an ideal interface, designed to provide realistic simulation of direct haptic exploration and manipulation of objects, would be able to simulate handling with a tool as well. Such an interface would measure the position and posture of the user's hand, display forces to the hand, and make use of a single hardware configuration (e.g., an exoskeleton with force and tactile feedback) that could be adapted to different tasks by changes in software alone. For example, displaying forces on the fingers and palm when they were in proper position for grasping a hammer would simulate wielding this tool. However, the large number of degrees of freedom of the hand, extreme sensitivities of cutaneous receptors, together with the presence of mass, friction, and limitations of sensors and actuators in the interface make such an ideal impossible to achieve with current technology. In contrast, an interface in the form of a tool handle, for which reconfigurability within a limited task domain is achieved through both hardware and software changes, is quite feasible. Thus, one of the basic distinctions among haptic

interfaces is whether they attempt to approximate the ideal exoskeleton or employ the tool-handle approach.

Another distinction concerning haptic interfaces has to do with whether the device “grounds” forces on the body or on the world. A “body grounded” device, such as a hand exoskeleton, is capable of simulating some forces (e.g., the resistance of a tennis ball to squeezing with the thumb and forefinger), but cannot simulate all forces (e.g., the torque about the user’s shoulder due to the weight of the ball). In principle, a “world grounded” device, such as a desktop robot could simulate both types of forces, but is generally not portable. User performance with the two types of force grounding have been compared for some tasks (Richard & Cutkosky, 1997) and found roughly equivalent.

4.1 Current Technology

Compared to audio (see chap. 4, this volume) and video (see chap. 3, this volume) hardware, haptic interface hardware for VEs is in an early stage of development. Many of the devices available today have been motivated by needs predating those of VE technology. Simple position/motion-measuring systems have long been employed to provide control inputs to the computer. These have taken many forms, such as those that involve contact with the user without controlled force display (e.g., keyboards, computer mice, trackballs, joysticks, passive exoskeletal devices) and those that measure position/motion without contact (e.g., optical and electromagnetic tracking devices). Applications motivating development of these devices have ranged from the control of equipment (e.g., instruments, vehicles) to biomechanical study of human motion (e.g., gait analysis, time and motion studies).

The early developments in force-displaying haptic interfaces were driven by the needs of the nuclear energy industry and others for remote manipulation of materials (Sheridan, 1992). The force-reflecting teleoperator master arms in these applications were designed to communicate to the operator information about physically real tasks. The recognition of the need for good-quality force displays by early researchers (Goertz, 1964; Hill, 1979) continues to be relevant to today’s VE applications. However, the dual challenges of making free motion feel unimpeded but making virtual surfaces feel stiff requires hardware with low friction, low apparent inertia, and very high bandwidth. Although Sutherland’s (1965) pioneering description of VEs included force-reflecting interfaces, development of practical devices has proven difficult.

A wide variety of devices are under development in companies and universities worldwide. A rough breakdown of major types of haptic interfaces that are currently available or being developed is as follows:

1. Ground-based devices
 - Joysticks, mice, steering wheels, flight yokes
 - Tool-based (pen or instrument)
2. Body-based devices
 - Flexible (gloves and suits worn by user)
 - Exoskeletal (jointed linkages affixed to user)
3. Tactile displays

4.1.1 *Ground-Based Devices*

Joysticks are probably the oldest of these technologies and were originally conceived to control aircraft. Even the earliest of control sticks, connected by mechanical wires to the flight surfaces of aircraft, unwittingly presented force information about loads on flight surfaces

to pilots. In general, these devices may be passive (i.e., not force reflecting), as in joysticks used for cursor positioning, or active (i.e., force reflecting), as in many of today's modern flight-control sticks. Many ground-based devices are now commercially available:

1. Force-reflecting joysticks are now commercially available in a wide range of prices and capabilities. Low-cost devices (\$100–\$1,000) with 2 actuated DOF are targeted primarily toward video games (Microsoft Sidewinder, Immersion Impulse Stick, I-Force). Devices with more DOF are produced in smaller quantities, generally have higher precision, and cost more (\$1,000–\$10,000). Joysticks with 3 actuated DOF include the Immersion Impulse Engine 3000 and Cybernet PER-Force 3DOF. More dof are available in the Cybernet PER-Force Handcontroller (6 DOF). Force-reflecting mice with 2 actuated DOF are also commercially available at low cost (e.g., Immersion FeelIt mouse, about \$100). The video-game industry has also led to mass production of steering wheels with 1 actuated DOF, and flight yokes with 2 actuated DOF.

2. Pen-based force-reflecting interfaces are now mass-produced for general-purpose work. The Phantom (from SensAble Technologies) is a popular commercial desktop interface that comes in a variety of sizes, with either 3 or 6 actuated DOF. At the time of this writing, units are in the price range of about (\$13,500–\$61,000).

3. Force-reflecting surgery simulators are also in mass production. The Immersion Laparoscopic Impulse Engine drives the tips of surgical tools to simulate laparoscopic procedures. It offers 3 actuated DOF (5 sensed) for about \$9,000. The Freedom-7 (with 7 actuated DOF) appears to be near market. Dedicated telesurgery systems (e.g., the Intuitive Surgical daVinci system) incorporate multiple hand-masters with 4 to 7 DOF per hand, but full force-feedback has not yet been implemented. The current price range is about three quarters to a million dollars.

These devices represent the commercial fruition of decades of research on teleoperation hand masters. For reviews of this field see Jacobus, Riggs, Jacobus, and Weinstein (1992), Meyer, H. L. Applewhite, and Biocca (1992), Brooks (1990), McAfee and Fiorini (1991), Honeywell, Inc. (1989), and Okamura, Smaby, and Cutkosky (2000). For reviews of the ergonomics of hand controllers (shape, switch placement, motion and force characteristics, etc.) see Brooks and Bejczy (1985). For a review of actuator technologies see Hollerbach, Hunter, and Ballantyne (1992) and chapter 11 (this volume).

Notable applications of force-reflecting hand controllers to VEs include project GROPE at the University of North Carolina (Brooks, Ouh-Young, & Batter, 1990). In this simulator, the Argonne Mechanical Arm (ARM), and more recently the Phantom, were used successfully for force reflection during interactions with simulations of molecule docking. Haptic interactions with data from a scanning tunneling microscope have also been simulated (Taylor, 1994). The MIT Sandpaper is a 3-DOF joystick that is capable of displaying virtual textures (Minsky, Ouh-Young, Steele, Brooks, & Behensky, 1990). In Japan, notable desktop master manipulators have been built at Tsukuba University (Iwata, 1990; Noma & Iwata, 1993), ATR Laboratories in Kyoto (Noma et al., 1996), and Tokyo Institute of Technology (Walairacht, Koike, & Sato, 2000). At the University of British Columbia, high-performance hand controllers have been developed by taking advantage of magnetic levitation technology (Salcudean, Wong, & Hollis, 1992). At McGill University, the 2-DOF Pantograph has been developed for desktop applications, and the Freedom 7 has been developed for surgical simulation (Hayward, Gregorio, Astley, Greenish, & Doyon, 1997; Ramstein & Hayward, 1994). In conjunction with MPB technologies, the Freedom 6S hand controller has also been developed (MPB, 2000). PER-Force hand controllers were developed in conjunction with NASA

(Cybernet, 2000). The Phantom (Massie & Salisbury, 1994) was developed at MIT. Hand controllers that provide dynamically reprogrammable passive constraints have been developed at Northwestern University (Colgate, Peshkin, & Wannasuphprasit, 1996) and Grenoble University (Troccaz-J & Delnondedieu-Y, 1996). A hand controller with very high peak stiffness has been developed at the University of Washington (Adams, Klowden, & Hannaford, 2000).

One of the most complex force-reflecting devices built to date is the Dexterous Teleoperation System Master designed by Sarcos, Inc., in conjunction with the University of Utah's Center for Engineering Design and the Naval Ocean Systems Center (NOSC). Although it is primarily ground-based, by having attachment points at the forearm and upper arm of the user it has the advantages of an exoskeleton, such as a large workspace comparable to that of the human arm. This device utilizes high-performance hydraulic actuators to provide a wide dynamic range of force exertion at relatively high bandwidth on a joint-by-joint basis for 7 DOF. Another high-performance force-reflecting master is a ground-based system for teleoperated eye surgery built by Hunter, Lafontaine, Nielsen, Hunter, & Hollerbach (1990). At Harvard, a planar manipulator has been developed to study precision teleoperation with a pinch grasp between the thumb and the index finger (Howe, 1992).

4.1.2 Body-based Devices

Body-based devices fit over and move with the limbs or fingers of the user. Because they are kinematically similar to the arm and hands that they monitor and stimulate, they have the advantage of the widest range of unrestricted user motion. As position-measuring systems, body-based devices (gloves, suits, etc.) are relatively inexpensive and comfortable to use. A few of the more common commercially available gloves include the VTI CyberGlove, and the iReality 5th glove. Depending on the manufacturer and model, these typically resolve 5 to 23 DOF to approximately 1 degree. The FakeSpace Pinch Glove takes a different approach, detecting contact between the tips of two or more digits.

Body-based devices with rigid exoskeletons afford force display and slightly more accurate pose sensing, typically at the expense of greater bulk. For a review of the design issues in exoskeletal devices see Shimoga (1992). At the time of this writing, one force reflecting exoskeleton is in mass production (the VTI CyberGrasp). Research on body-based force reflecting hand exoskeletons has been ongoing for decades. See Okamura et al. (2000) for a review. Some current designs are notable. The Rutgers Portable Dextrous Master (Burdea, Zhuang, Roskos, Silver, & Langrana, 1992; Fabiani, Burdea, Langrana, & Gomez, 1996), is a light, simple exoskeleton that grounds fingertip forces on the palm rather than the back of the hand. A light, cable-based, 2-DOF, body-grounded hand controller (HapticGEAR) for immersive VEs has been developed at Tokyo University (Hirose, Ogi, Yano, & Kakehi, 1999). A force-reflecting hand master that senses and controls fingertip position (but not joint angles) is under development at Johnson Space Center (Sinah, Endsley, Riggs, & Millspaugh, 1999). Regardless of the exact mechanical design, providing force feedback with body-based hand controllers remains a difficult problem, placing great demands on minimizing actuator size to make the control bandwidth of the device commensurate with human haptic capabilities.

4.1.3 Tactile Displays

While the display of net forces is appropriate for coarse object interaction, investigators have also recognized the need for more detailed displays within the regions of contact. In particular, the display of tactile information (e.g., force distributions for conveying information

on texture and slip), though technically difficult, has long been considered desirable for remote manipulation (Bliss & Hill, 1971).

Very crude tactile displays for VEs are now in mass production. The Aurora Interactor uses a voice coil to display vibration through a vest or seat cushion. CyberTouch, by VTI, is another vibrotactile transducer made to mount on the backs of the fingers. A 1.25-inch diameter vibrotactile transducer has been developed by Engineering Acoustics, Inc., and applied to the torso for a situational awareness display (Raj, McGrath, Rochlis, Newman, & Rupert, 1998). The Displaced Temperature Sensing System from CM Research displays temperature changes to the fingertip. Although they are not designed expressly for VE applications, electromechanical Braille cells are also commercially available (American Foundation for the Blind, 2000) and are being actively developed (Petersen, 2000).

Research on tactile display systems in the last two decades has been motivated in part by efforts to convey visual and auditory information to deaf and blind individuals (Bach-y-Rita, 1982; Reed et al., 1982), and more recently to simulate tissue palpation during minimally invasive surgery (Howe, Peine, Kontarinis, & Son, 1995; Moy, Singh, Tan, & Fearing, 2000a).

Many of these displays have the general appearance of pin or balloon arrays, often with an antialiasing membrane between the pins and fingertip skin. A variety of actuators have been employed, including DC solenoids (Friskin-Gibson, Bach-Y-Rita, Tompkins, & Webster, 1987), shape memory alloys (Howe et al., 1995), compressed air (Moy, Wagner, & Fearing, 2000b), piezoelectric vibrators (Chanter & Summers, 2000), and electrorheological fluids (Monkman, 1992). Also under development are micromachined tactile displays that stimulate skin with tangential tactors (Ghodssi, Beebe, White, & Denton, 1996), electrical current (Beebe, Hymel, Kaczmarek, & Tyler, 1995), or tangential force due to electrostatic attraction (Tang & Beebe, 1998). A review of principles and technical issues in vibrotactile and electro-tactile displays can be found in Kaczmarek and Bach-y-Rita (1993) and Shimoga (1992).

Some interesting alternatives to the rectangular array are under development. Researchers have developed an array of concentric rings that simulates compliant surfaces by controlling the rate at which the skin contact area spreads as normal force is applied to the display (Ambrosi, Bicchi, De Rossi, & Scilingo, 1999). A "grasp blob" is also under development (Aldridge, Carr, England, Meech, & Solomonides, 1996). This device consists of a grasped, fist-sized bag that can be depressurized rapidly, compacting the particles within it into a solid mass.

4.2 Hardware Summary

Computer keyboards, mice, and trackballs are the simplest haptic interfaces and are being widely used to interact with computers. Position-sensing gloves and exoskeletons without force reflection are also available on the market but are used mainly for research purposes. Among the force-reflecting desktop devices, joysticks, mice, small robots, and surgical simulators are commercially available. Force-reflecting exoskeletons are harder to design for adequate performance, and only a few are commercially available. Tactile displays offer particularly difficult design challenges because of the high density of receptors in the skin to which they must apply the stimulus. Basic (1-DOF) tactile stimulators are now available for VEs, whereas tactile arrays for VEs are still in development.

5. FUTURE WORK

Design specifications for haptic interfaces depend on the biomechanical, sensorimotor, and cognitive abilities of humans. Therefore, multidisciplinary studies involving biomechanical and psychophysical experiments together with computational models for both are needed in

order to have a solid scientific basis for device design. Perhaps to a lesser extent, neurophysiological studies concerning peripheral and central neural representations and the processing of information in the human haptic system will also aid in design decisions concerning the kinds of information that need to be generated and how these should be displayed. A major barrier to progress from the perspectives of biomechanics, psychophysics, and neuroscience has been the lack of robotic stimulators capable of delivering a large variety of stimuli under sufficiently precise motion and force control.

5.1 Hardware Development

For the foreseeable future, it appears progress in haptics will be limited by the development of new actuator hardware. It is now clear that active interfaces with two and perhaps three DOF are commercially sustainable. It remains to be seen whether devices with 4 or more active DOF eventually become general purpose computer peripherals or remain limited to specialized applications like surgical simulation.

Hardware for displaying distributed forces on the skin remains an especially challenging problem. Exploration of novel technologies is needed for quantum improvements in miniature rotary and linear actuators. Shape memory alloys (SMAs), piezoelectrics, microfluidics, and other microelectromechanical systems (MEMS) for tactile display all warrant further investigation. Mechanical flexibility is another major challenge in the development of general-purpose wearable tactile displays. The human skin is a dynamic environment subject to bumps, scratches, and deformations due to flexion of the body segments. To put an array of actuators on it in a package that does not break or encumber an active user may require methods for manufacturing or embedding actuator arrays in flexible substrates, a challenge MEMS technology is only beginning to address.

5.2 Methods of Stimulation

The right balance of complexity and performance in system capabilities is generally task dependent. In particular, the fidelity with which tactal images have to be displayed, and motor actions have to be sensed by the interface depends on the task, stimulation of other sensory modalities, and interaction between the modalities. Experimenting with available haptic interfaces, in conjunction with visual and auditory interfaces, is necessary to identify needed design improvements. Design compromises and tricks for achieving the required task performance capabilities or telepresence (immersion) need to be investigated (see chaps. 21, 22, and 40, this volume). One of the tricks might be the use of illusions (such as visual dominance) to fool the human user into believing a less than perfect multimodal display (DiFranco, Beauregard, & Srinivasan, 1997; Srinivasan, Beauregard, & Brock, 1996). Techniques such as filtering the user's normal tremor or the use of sensory substitution within a modality (e.g., the use of tactile display to convey kinesthetic information) or among different modalities (e.g., visual display of a force) need to be developed to overcome limitations of devices and limitations of the human user, perhaps to achieve supernormal performance. To tackle the ever-present time delays, efficient and reliable techniques for running model-based and real-time controls concurrently are needed.

5.3 Evaluation of Haptic Interfaces

Evaluation of haptic interfaces is crucial to judge their effectiveness and to isolate aspects that need improvement. However, such evaluations performed in the context of teleoperation have been so task-specific that it has been impossible to derive useful generalizations and to

form effective theoretical models based on these generalizations. There is a strong need to specify a set of elementary manual tasks (basis tasks) that can be used to evaluate and compare manual capabilities of a given system (human, robotic, VE) efficiently. Ideally, this set of basis tasks should be such that (1) knowledge of performance on these tasks enables one to predict performance on all tasks of interest and (2) it is the minimal set of tasks (in terms of time consumed to measure performance on all tasks in the set) that has this predictive power (Durlach, personal communication, 1990).

In this void, some tasks have become de facto standards, including point-to-point movements (i.e., Fitts' task, Balakrishnan & MacKenzie, 1997), target selection (Card et al., 1991), and docking (Zhai, Milgram, & Drascic, 1993), measured in terms of mean completion time, RMS error, and information transfer rates. For basic input devices like joysticks and mice, a task-based ISO9000 standard has been proposed (Douglas, Kirkpatrick, & MacKenzie, 1999). However, it is not clear how well these measurements extrapolate to devices intended for tasks more complicated than pointing.

Some progress has been made in developing a standard set of physical measurements for devices (e.g., workspace, degrees of freedom, force range, precision, etc.). A standard set of physical measurements is proposed by Hayward and Astley (1996). Although these physical measurements are clearly necessary, at this point in the development of haptic interfaces they are probably not sufficient to guide device development. For example, a device might perform brilliantly at displaying shoulder torque (a physical measurement), but if this parameter is not very effective at helping the user complete many tasks or feel immersed the device may not really be "good." Measures of the relative perceptual importance of force and position cues at different body sites during different tasks are also required in order to ascertain what stimuli are worth displaying to the user.

TABLE 5.1
Mechanical Properties of Human Upper Limb

Degrees of Freedom

Shoulder	4 (shrug, flexion, abduction, rotation)
Elbow	2 (flexion, pronation)
Wrist	2 (flexion, pronation)
Each digit	4 (abduction + 3 flexions)
Bandwidth of motor system ¹	
Unexpected signals	1–2 Hz
Periodic signals	2–5 Hz
Reflex actions	10 Hz
Minimum hand closure time	0.09 seconds
Fingertip forces ²	
Typical pinch grip	1–10 N
Controllable	Up to 100 N
Control resolution	0.05 to 0.5 N
Grasp force range	50–500 N

¹(Brooks, 1990).

²(Tan et al., 1994).

TABLE 5.2
Mechanical Impedance of Human Upper Limb

<i>Passive elbow</i> ¹		
	Up to 2 Hz	~ 0.02 (N · m)/rad)
	10 Hz	~ 0.1 (N · m)/rad)
	100 Hz	~ 5 (N · m)/rad)
	1000 Hz	~ 100 (N · m)/rad)
<i>Lumped response of index finger pad and segments</i>		
	“Relax” ²	0.14–0.4 N/mm
	“Resist force as much as possible” ²	0.30–0.86 N/mm
	Straight ³	0.8–2.2 N/mm
	Flexed ³	0.4–2.0 N/mm
<i>Lumped response of finger pad and digits during pen grasp</i> ²		
	“Relax”	0.34–1.25 N/mm
	“Resist force as much as possible”	0.79–2.41 N/mm
<i>Lumped response of finger pad to pseudo-static plate indentor</i> ⁴		
Physiologic range of finger pad indentation		~ 3 mm
Stiffness at initial contact (0–1 mm)		~ 0.1 N/mm
Upon further indentation (1–2 mm)		~ 0.4 N/mm
Upon further indentation (2–3 mm)		~ 1.0 N/mm
Indentations > 3 mm		10–100 N/mm

¹(Jones, Hunter, Lafontaine, Hollerbach, & Kearny, 1991).

²(Buttolo, 1996) Measured 30 ms after start of force ramp at 0.1–0.5 N/s. Stiffness of pen grasp is six- to sevenfold greater than index finger alone. Precision of position control improves two- to threefold.

³(Milner & Franklin, 1995).

⁴(Gulati & Srinivasan, 1996).

TABLE 5.3
Tactile Sensation¹

<i>Indentation threshold</i>		
Static	20 μm , 0.3 mN/mm ²	
10 Hz	10 μm	
250 Hz	0.1 μm	
<i>Feature detection</i>		
Texture	0.075 μm (improvement due to lat scanning)	
Single dot	2 μm	
Normal force when detecting features	0.4–1.1 N (typical), 0.3–4.5 N (observed range)	
<i>Temporal resolution</i>		
Time between successive taps	10 ms	
Bandwidth sensed	0–1000 Hz	
Reaction time	70 ms to 500 ms (reflexive slip to threshold detection)	
<i>Spatial resolution</i>		
Lateral localization	0.15 mm	
Lateral 2-point limen	1 mm at fingertip	
<i>Hot/cold</i>		
Detection threshold for temperature change	0.01°C/s	
Reaction time	300–900 ms	
Persistent hot	> 40°, (pain > 48°)	
Persistent cold	< 20°, (pain < 15°)

TABLE 5.4
Active Touch Including Tactile,
Kinesthetic, and Motor Systems¹

<i>Parameter</i>	<i>(JND)</i>
Length	10% or less
Velocity	10%
Acceleration	20%
Force	7%
Compliance	8% (rigid surface, piano key)
Compliance	3% (deformable surface, rubber)
Viscosity	14%
Mass	21%
Rigidity perception	25 N/mm or greater

¹For source details see Beauregard, Srinivasan, and Durlach (1995) and Chen and Srinivasan (1998)

TABLE 5.5
Information Transfer Rates Through the Hands¹

<i>Method for manual production</i>	<i>Rate (bits/sec)</i>
Morse code	1.8–3.6
Handwriting	3.5–7 (estimated)
Finger spelling	7–11
Typing	7.2–14.4
Court stenography	13.5–27
Signing with ASL	15–30

<i>Method for manual reception</i>	
Kinesthetic Morse code	0.9–1.4
Tactual reception of finger spelling	8.1–?
Tactual reception of spoken English (Tadoma)	11.2–22.5
Tactual reception of ASL	11.7–23.4

1. INTRODUCTION

The goal of *haptic rendering* is to enable a user to touch, feel, and manipulate virtual objects through a haptic interface. With the introduction of high-fidelity haptic devices (see chap. 5, this volume), it is now possible to simulate the feel of even fine surface textures on rigid complex shapes under dynamic conditions. Starting from the early 1990s, significant progress has occurred in our ability to model and simulate haptic interactions with three-dimensional (3-D) virtual objects in real time (Salisbury & Srinivasan, 1997; Srinivasan & Basdogan, 1997). The rapid increase in the number of workshops, conference sessions, community web pages, and electronic journals on haptic displays and rendering techniques* indicates growing interest in this exciting new area of research called *computer haptics*. Just as computer graphics is concerned with synthesizing and rendering visual images, computer haptics is the art and science of developing software algorithms that synthesize computer generated forces to be displayed to the user for perception and manipulation of virtual objects through touch. Various applications of computer haptics have been developed in the areas of medicine (e.g., surgical simulation, telemedicine, haptic user interfaces for blind people, rehabilitation of patients with neurological disorders; see chaps. 47–51, this volume), entertainment

(e.g., 3-D painting, character animation, morphing and sculpting; see chap. 55, this volume), mechanical design (e.g., path planning and assembly sequencing; see chap. 54, this volume), and scientific visualization (e.g., geophysical data analysis, molecular manipulation; see chap. 53, this volume). More applications are anticipated as devices and rendering techniques improve and computational power increases. This chapter will primarily focus on fundamental concepts of haptic rendering, with some discussion of implementation details. Although, it is impossible to cite all relevant work within the constraints of this chapter, an attempt has been made to cover the major references. Given that current technology is mature for net force and torque feedback (as in tool usage in the real world) and not tactile feedback (as in actual distribution of force fields on the skin during contact with real objects), the discussion is restricted to techniques concerning the former. In general, the concepts discussed in the chapter include: (1) *haptic interaction paradigms*, which define the nature of the “haptic cursor” and its interaction with virtual objects; and (2) *object property display algorithms*, which enable rendering of surface and material properties of objects and their behavior through repeated use of the haptic interaction paradigm.

2. PRINCIPLES OF HAPTIC RENDERING: OBJECT SHAPE

Typically, a haptic rendering algorithm is made of two parts: (a) collision detection; and (b) collision response (see Fig. 6.1). As a user manipulates the probe of a haptic device, the new position and orientation of the haptic probe are acquired and collisions with virtual objects are detected (i.e., *collision detection*). If a collision is detected, interaction forces are computed using preprogrammed rules for *collision response* and conveyed to the user through the haptic device to provide him or her with the tactual representation of 3-D objects and their surface details. Hence, a haptic loop, which updates forces around 1 kHz (otherwise, virtual surfaces feel softer, or, at worst, instead of a surface it feels as if the haptic device is vibrating), includes at least the following function calls:

- `get_position (vector and position); // position and/or orientation of the end effector`
- `calculate_force (vector and force); // user-defined function to calculate forces`
- `send_force (vector force); // calculate joint torques and reflect forces back to the user`

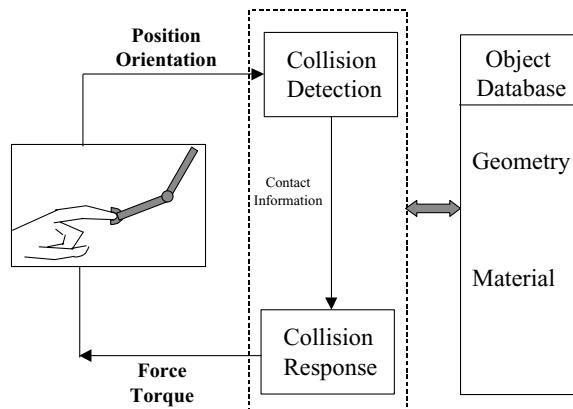

FIG. 6.1. A haptic interaction algorithm. Typically made of two parts: (a) collision detection; and (b) collision response. The haptic loop seen in the figure requires an update rate of around 1 kHz for stable force interactions. Computationally fast collision detection and response techniques are required to accommodate this requirement.

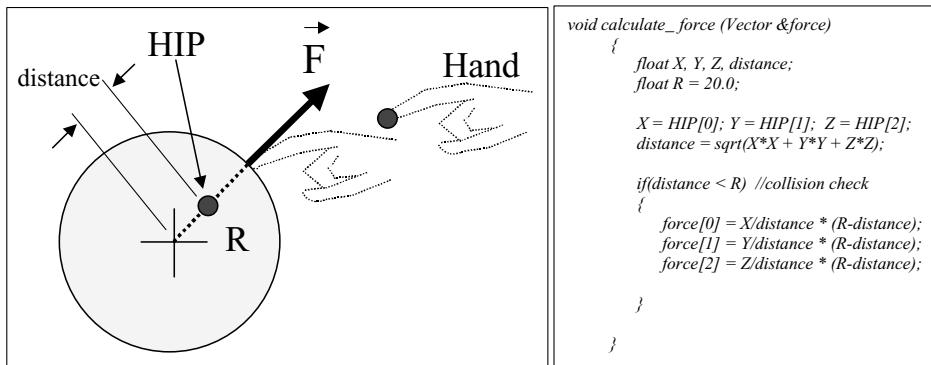

FIG. 6.2. Haptic rendering of a 3-D sphere in virtual environments. (The software code presented on the right-hand side calculates the direction and the magnitude of the reaction force for the sphere discussed in the example. The sphere has a radius of 20 units and is located at the origin of a 3-D virtual space.)

To describe the basic concepts of haptic rendering, consider a simple example, haptic rendering of a 3-D frictionless sphere, located at the origin of a 3-D virtual space (see Fig. 6.2). Assume that the user can only interact with the virtual sphere through a single point, which is the end point of the haptic probe, also known as the *haptic interaction point* (HIP). In the real world, this is analogous to feeling the sphere with the tip of a stick. As the 3-D space is freely explored with the haptic probe, the haptic device will be *passive* and will not reflect any force to the user until a contact occurs. Since the virtual sphere has a finite stiffness, HIP will penetrate into the sphere at the contact point. Once the penetration into the virtual sphere is detected and appropriate forces to be reflected back to the user are computed, the device will become *active* and reflect opposing forces to the user's hand to resist further penetration. The magnitude of the reaction force can easily be computed by assuming that it is proportional to the depth of penetration. Assuming no friction, the direction of this force will be along the surface normal as shown in Fig. 6.2.

As it can be seen from the example given above, a rigid virtual surface can be modeled as an elastic element. Then, the opposing force acting on the user during the interaction will be:

$$\vec{F} = k \Delta \vec{x}$$

where k is the stiffness coefficient and $|\Delta \vec{x}|$ is the depth of penetration. Whereas keeping the stiffness coefficient low would make the surface perceived soft, setting a high value would make interactions unstable by causing undesirable vibrations. Figure 6.3 depicts changes in force profile with respect to position for real and virtual walls. Since the position of the probe tip is sampled digitally with a certain frequency during the simulation of a virtual wall, a "staircase" effect is observed. This staircase effect leads to energy generation (see the discussions and suggested solutions in Colgate & Brown, 1994, and Ellis, Sarkar, & Jenkins, 1996).

Although the basic recipe for haptic rendering of virtual objects seems easy to follow, rendering of complex 3-D surfaces and volumetric objects requires more sophisticated algorithms than the one presented for the sphere. The stringent requirement of updating forces around 1 kHz leaves very little CPU time for computing collisions and reflecting forces back to the user in real time when interacting with complex shaped objects. In addition, the algorithm given above for rendering of a sphere considered only "point-based" interactions (as if interacting with objects through the tip of a stick in the real world), which is far from what our hands are capable of in the real world. However, several haptic rendering techniques have been developed recently to simulate complex touch interactions in virtual environments (reviewed

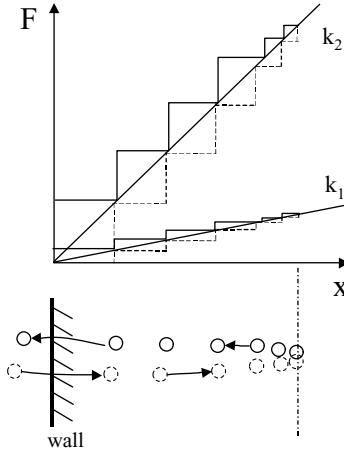

FIG. 6.3. Force-displacement curves for touch interactions with real and virtual walls. In the case of real walls, the force-displacement curve is continuous. However, a “staircase” effect is seen when simulating touch interactions with a virtual wall. This is due to the fact that haptic devices can only sample position information with a finite frequency. The difference in the areas enclosed by the curves that correspond to penetrating into and out of the virtual wall is a manifestation of energy gain. This energy gain leads to instabilities as the stiffness coefficient is increased (compare the energy gains for stiffness coefficients k_2 and k_1). On the other hand, a low value of the stiffness coefficient generates a soft virtual wall, which is not desirable either.

in Hollerbach & Johnson, 2001; Salisbury & Srinivasan, 1997; Srinivasan & Basdogan, 1997). The existing techniques for haptic rendering with force display can be distinguished based on the way the probing object is modeled: (1) a point (Adachi, Kumano, & Ogino, 1995; Avila & Sobierajski, 1996; Ruspini, Kalarov, & Khatib, 1997; Ho, Basdogan, & Srinivasan, 1999; Zilles & Salisbury, 1995); (2) a line segment (Basdogan, et al., 1997; Ho et al., 2000); or (3) a 3-D object made of a group of points, line segments, and polygons (McNeely et al., 1999). The type of interaction method used in simulations depends on the application.

In point-based haptic interactions, only the end point of the haptic device (i.e., the HIP) interacts with virtual objects (Fig. 6.4b). Each time a user moves the generic probe of the haptic device, the collision detection algorithm checks to see if the end point is inside the virtual object. If so, the depth of indentation is calculated as the distance between the current HIP and the corresponding surface point, also known as the *ideal haptic interface point* (IHIP; also called god-object, proxy point, or surface contact point; see Fig. 6.5). For exploring the shape and surface properties of objects in VEs, point-based methods are probably sufficient and could provide users with similar force feedback as what they would feel when exploring objects in

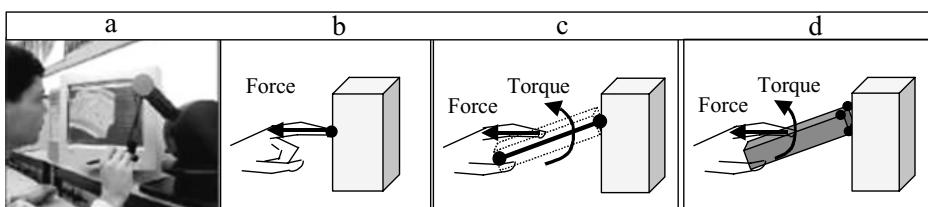

FIG. 6.4. Existing interaction methods for haptic rendering with force display can be distinguished based on the way the probing object is modeled: (b) a point; (c) a line segment; and (d) a 3-D object.

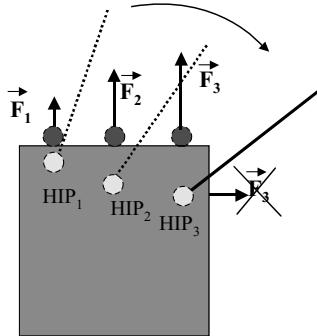

FIG. 6.5. A haptic rendering algorithm that is based on point interactions must calculate the IHIP for a given HIP at each rendering cycle. (IHIP can be considered as the surface point of the object with which the tool or finger would be in contact. The computation of this point relies on contact history. In the figure, for example, ignoring contact history and always choosing the closest point on the object surface as the new IHIP for a given HIP would make the user feel as if he is pushed out of the object as HIP moves from point 2 to point 3.

real environments with the tip of a stick. Using a point-based rendering technique, polyhedrons (Ho et al., 1999; Rusconi et al., 1997; Zilles & Salisbury, 1995). NURBS (Stewart, Chen, & Buttolo, 1997; Thompson, Johnson, & Cohen, 1997), implicit surfaces (Salisbury & Tarr, 1997), and volumetric objects (Avila & Sobierajski, 1996) have been successfully rendered. Point-based methods, however, are not capable of simulating more general *tool-object* interactions that involve single or multiple objects in contact with the tool at arbitrary locations of the tool. In such a context, both forces and torques displayed to the user need to be independently computed.

In ray-based interactions, the generic probe of the haptic device is modeled as a line segment whose orientation is taken into account, and collisions are checked between the finite line and objects. This approach enables the user to touch multiple objects simultaneously. In addition to forces, torque interactions can be simulated, which is not possible with point-based approaches (see Fig. 6.4c). Ray-based rendering can be considered as an approximation to long tools and as an intermediate stage in progress towards the full interaction between a 3-D cursor and 3-D objects. Also, if the geometric model of the probing object can be simplified to a set of connected line segments, then the ray-based rendering technique can be used and will be faster than simulation of full 3-D object interactions. For example, haptic interactions between a mechanical shaft and an engine block have been successfully simulated (Ho et al., 2000), as well as the interactions between laparoscopic surgical instruments and deformable objects (Basdogan, et al. 1998; Basdogan, Ho, & Srinivasan, 2001) using multiple line segments and the ray-based rendering technique. However, if the probing object has a complex geometry and cannot be easily modeled using a set of line segments, simulation of 6 degrees of freedom (DOF) object-object interactions has to be considered.

Simulation of haptic interactions between two 3-D polyhedra is desirable for many applications, but this is computationally more expensive than point-based and ray-based interactions (see Fig. 6.4d). Although a single point is not sufficient for simulating force and torque interactions between two 3-D virtual objects, a group of points, distributed over the surface of a probing object, has been shown to be a feasible solution. For example, McNeely et al. (1999) simulated touch interactions between the 3-D model of a teapot and a mechanical assembly.

Irrespective of the interaction method used, a haptic rendering algorithm must include both collision detection and collision response computations (see Fig. 6.1). Although collision detection has been extensively studied in computer graphics (Cohen, Lin, Manocha, & Ponamgi,

1995; Hubbard, 1995; Gottschalk, Lin, & Manocha, 1996; Lin, 1993), existing algorithms are not designed to work directly with haptic devices to simulate touch interactions in virtual environments. Moreover, merely detecting collisions between 3-D objects is not enough for simulating haptic interactions. How a collision occurs and how it evolves over time (i.e., *contact history*) are crucial factors (see the discussion in Fig. 6.5 on contact history) in haptic rendering to accurately compute the interaction forces that will be reflected to the user through a haptic device (Ho et al., 1999; Ho, Basdogan, & Srinivasan, 2000).

Although collision detection algorithms developed in computer graphics cannot be used in haptics directly, several concepts developed for fast collision detection can be ported to haptics. For example, haptic rendering algorithms can easily take advantage of: (1) space partitioning techniques (i.e., partitioning the space that encloses the object into smaller subspaces in advance for faster detection of first contact); (2) local search approaches (i.e., searching only the neighboring primitives for possible new contacts); and (3) hierarchical data structures (i.e., constructing hierarchical links between the primitives that make up the object for faster access to the contacted primitive). In addition to these improvements, a client–server model has to be considered to synchronize visual and haptic displays for achieving faster update rates. Using multithreading techniques, for example, one can calculate the forces at 1 kHz in one thread while updating the visual images at 30 Hz in another thread (Ho et al., 1999). If the forces cannot be computed at 1 kHz, a numerical scheme can be developed to extrapolate the new forces based on the previously computed ones to maintain the constant update rate of 1 kHz for stable interaction (Basdogan, 2000; Ellis, Sarkar, & Jenkins, 1996).

3. RENDERING OF SURFACE DETAILS: SMOOTH SHAPES, FRICTION AND TEXTURE

Quite frequently, it is desirable to display object surfaces as smooth and continuous, even when an underlying polyhedral representation is employed. In computer graphics, for example, illumination models are used to compute the surface color at a given point of a 3-D object (Foley, van Dam, Feiner, & Hughes, 1995). Then, shading algorithms are applied to shade each polygon by interpolating the light intensities (Gouraud shading) or surface normals (Phong shading). Shading algorithms make the shared edges of the adjacent polygons invisible and provide the user with the display of visually smooth surfaces (Watt & Watt, 1992). One can integrate a similar approach into the study of haptics to convey the feel of haptically smooth object surfaces (Basdogan et al., 1997; Fukui, 1996; Morgenbesser & Srinivasan, 1996; Ruspini et al., 1997). By using the *force-shading* technique suggested by Morgenbesser and Srinivasan (1996), force discontinuities can be reduced and the edges of polyhedral object can be made to feel smoother. To implement force shading with polygonal surfaces (Basdogan et al., 1997), the surface normal at each vertex is precomputed by averaging the surface normals of neighboring polygons, weighted by their neighboring angles. During real-time computations, the collision point that divides the contacted triangle into three subtriangles is first detected. Then the surface normal (\vec{N}_s) can be calculated at the collision point by averaging the normals of the vertices (\vec{N}_t) of the contacted polygon, weighted by the areas A_i of the three subtriangles:

$$\vec{N}_s = \frac{\sum_i^3 A_i \vec{N}_i}{\sum_i^3 A_i}$$

Haptic simulation of surface details such as friction and texture significantly improves the realism of virtual worlds. For example, friction is almost impossible to avoid in real-life

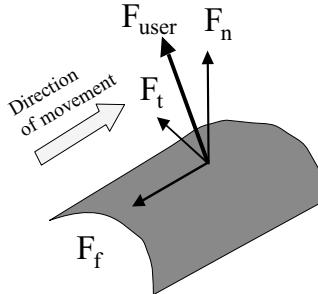

FIG. 6.6. Forces acting on the user ($F_{user} = F_n + F_t + F_f$) during the haptic simulation of friction and textures. (The normal force can be computed using a simple physics-based model such as Hooke's law ($F_n = k \Delta x$, where $|\Delta x|$ is the depth of penetration of the haptic probe into the virtual surface). To simulate coulomb friction, a force is created ($F_f = \mu F_n$, where μ is the coefficient of friction) that is opposite to the direction of the movement. To simulate textures, the magnitude and direction of the normal force vector are changed using the gradient vector of the texture field at the contact point.

and virtual surfaces without friction feel “icy-smooth” when they are explored with a haptic device. Similarly, most surfaces in nature are covered with some type of texture that is sensed and distinguished quite well by our tactile system (Srinivasan, Whitehouse, & LaMotte, 1990). Haptic texture is a combination of small-scale variations in surface geometry and its adhesive and frictional characteristics. However, displaying detailed geometry of textures would be computationally too expensive. Instead, both friction and texture can be simulated by appropriate perturbations of the reaction force vector computed using nominal object geometry and material properties. The major difference between friction and texture simulation via a haptic device is that the friction model creates only forces tangential to the nominal surface in a direction opposite to the probe motion, while the texture model can generate both tangential and normal forces in any direction (see Fig. 6.6).

Salcudean and Vlaar (1994) and Salisbury, Brock, Massie, Swarup, & Zilles, (1995) simulated static and dynamic friction such that the user feels the stick-slip phenomenon when the stylus of a haptic device is stroked over the surface of an object. By changing the mean value of the friction coefficient and its variation, more sophisticated frictional surfaces, such as periodic ones (Ho et al., 1999), and various grades of sandpaper (Green & Salisbury, 1997) can be simulated as well.

Haptic perception and display of textures in VEs require a thorough investigation, primarily because the textures in nature come in various forms. Luckily, graphics texturing has been studied extensively, and researchers can draw from that experience to simulate haptic textures in virtual environments. For example, bump mapping is a well-known technique in graphics for generating the appearance of a nonsmooth surface by perturbing surface normals. Blinn (1978) initially proposed this technique as a method of graphically rendering 3-D bumps for modeling clouds. His formulation depends on parameterization of the surface. Although the surface parameterization techniques have some advantages, they may generate uneven bump textures on the surface of complex shapes. Max and Becker (1994) suggested a direct method of mapping that does not require a transformation from global to parametric space. They developed a formulation that is purely based on the original surface normal and the local gradient of the height field that generates bumps on the surface of an object. Max and Becker utilized this technique to generate bumps on cloud contour surfaces. We used the same approach and perturbed the direction and magnitude of the surface normal (\vec{N}_s) to generate bumpy or textured surfaces that can be sensed tactually by users in virtual environments (Basdogan et al., 1997). The perturbed surface normals (\vec{M}) can be computed using the

following formulation:

$$\vec{M} = \vec{N}_s - \nabla h + (\nabla h \cdot \vec{N}_s) \vec{N}_s$$

$$\nabla h = \frac{\partial h}{\partial x} \hat{i} + \frac{\partial h}{\partial y} \hat{j} + \frac{\partial h}{\partial z} \hat{k}$$

where, $h(x,y,z)$ represents the texture field function and ∇h is the local gradient vector. One of the earliest methods of texture rendering that uses the force perturbation concept with a 2-DOF haptic device was developed by Minsky, Ming, Steele, Brook, & Behensky (1990). The formulation given above extends this concept to 3-D surfaces. In general, haptic texturing techniques can be classified into two parts: image-based and procedural.

3.1 Image-based Haptic Texturing

This class of haptic texturing deals with constructing a texture field from two-dimensional (2-D) image data. In computer graphics, digital images are wrapped around 3-D objects to make them look more realistic. While a graphical texture consists of 2-D texels with only color or gray scale intensities, a haptic texture should consist of texels with a height value. To display image-based haptic textures, the two-stage texture mapping technique of computer graphics (Bier & Sloan, 1986; Watt & Watt, 1992) can be followed. The first stage in this technique is to map the 2-D image to a simple intermediate surface such as a plane, cube, cylinder, or sphere. The second-stage maps the texels from the intermediate surface to the object surface. Following this stage, one can easily access the height value at any point on the object surface. In addition, the gradient vector at any point can be estimated using a finite difference technique and interpolation scheme. Then, the force perturbation concept described above can be used to display image-based haptic textures (see Ho et al., 1999, for implementation details).

3.2 Procedural Haptic Texturing

The goal of procedural haptic texturing is to generate synthetic textures using a mathematical function. The function usually takes the coordinate (x,y,z) as the input and returns the height value and its gradient as the output. For example, several investigators have implemented the well-known noise texture (Ebert et al., 1994; Perlin, 1985) to generate stochastic haptic textures (Basdogan et al., 1997; Fritz & Barner, 1996; Siira & Pai, 1996). Fractals are also appropriate for modeling natural textures since many objects seem to exhibit self-similarity (Mandelbrot, 1982). The fractal concept has been used in combination with other texturing functions, such as Fourier series and pink noise in various frequency and amplitude scales, to generate more sophisticated surface details (Ho et al., 1999). Similarly, several types of other graphical textures can be converted to haptic textures. For example, Ho et al. (1999) implemented haptic versions of reaction–diffusion textures (Turk, 1991; Witkin & Kass, 1991), spot noise (Wijk, 1991), and cellular texture (Worley, 1996).

4. RENDERING OF DEFORMABLE OBJECTS

Graphical display of deformable objects has been extensively studied in computer graphics. With the addition of haptic feedback, deformable objects have gained a new characteristic. Now, deformable models need to estimate not only the direction and amount of deformation of each node of an object but also the magnitude and direction of interaction forces that will be reflected to the user via a haptic device.

One way to categorize deformation techniques is according to the approach followed by researchers to deform surfaces: *geometry*- or *physics-based* deformations. In geometry-based

deformations, the object or surrounding space is deformed, based purely on geometric manipulations. In general, the user manipulates vertices or control points that surround the 3-D object to modify the shape of the object. In contrast, physics-based deformation techniques aim to model the physics involved in the motion and dynamics of interactions. These models simulate physical behavior of objects under the effect of external and internal forces. Geometry-based deformation techniques are faster and are relatively easier to implement, but they do not necessarily simulate the underlying mechanics of deformation. Hence, the emphasis is on visual display and the goal is to make deformations more easily controllable and appear smooth to the user. Physics-based approaches, although necessary for simulating realistic behavior of deformable objects, are computationally expensive and not always suitable for real-time applications due to current limitations in computational power. In general, hybrid approaches that take advantage of both worlds seem to work well for many real-time applications.

Geometry- and physics-based deformation techniques used to render force-reflecting deformable objects can be further subgrouped as follows (see Basdogan, 1999, 2000, for more details):

1. Geometry-based Deformation Models

- *Vertex-based*: The vertices of the object are manipulated to display the visual deformations. The reaction force can be modeled using Hooke's law, where depth of penetration can be computed based on the current and home positions of the vertex that is closest to the contact point. For example, in displaying soft tissue deformations graphically, polynomial functions that fit experimental data on finger pad deformation (Srinivasan, 1989) were used to remap the vertices of other organs (Basdogan, Ho, Srinivasan, Small, & Dawson, 1998).

- *Spline-based*: Instead of directly transforming the vertices of the object, control points are assigned to a group of vertices and are manipulated to achieve smoother deformations. The concept of free-form deformation was originally suggested by Sederberg and Parry (1986) and extended by Hsu, Hughes, & Kaufman (1992) to direct free-form manipulation. The extension of this technique to haptic display of deformable objects with applications in medical simulation (Basdogan et al., 1998), computer-aided design (CAD), and haptic sculpting (Dachille, Qin, Kaufman, & El-sana, 1999; Edwards & Luecke, 1996) can be found in the literature. Here, the key advantages of using force feedback are to increase intuition, control deformations, and support implementation of various constraints.

2. Physics-based Deformation Models

In comparison to geometry-based models, interaction forces are always part of the computation in physics-based models, and the developer does not need to consider a separate model for computing forces.

- *Particle-based*: Particle systems consist of a set of point masses, connected to each other through a network of springs and dampers, moving under the influence of internal and external forces (see Witkin, Barraff, & Kass, 1998, for implementation details). In this model, each particle is represented by its own mass, position, velocity, and acceleration. This technique has been used extensively by computer graphics researchers in simulation of soft tissue and cloth behavior (Cover et al., 1993; Lee, Terzopoulos, & Waters, 1995; Ng & Grimsdale, 1996). Swarup (1995) demonstrated the implementation of this technique to haptic simulation of deformable objects.

- *Finite element-based*: The volume occupied by a 3-D object is divided into finite elements, properties of each element are formulated, and the elements are assembled together to study deformation states for the given loads (Bathe, 1996). Due to the limited computational power that is available today, modeling simplifications have to be made to implement real-time finite element method with haptic displays

(see Cotin, Delingette, & Ayache, 1999; James & Pai, 1999, for static computations; see Basdogan et al., 2001, for dynamic computations). For example, De and Srinivasan (1999) have proposed a modeling approach in which organs are viewed as thin walled structures enclosing a fluid, thereby converting the 3-D problem into an effectively 2-D one (see also Balaniuk & Costa, 2000). In Basdogan et al. (2001), to compute dynamical deformations and interaction forces, a modal analysis approach was implemented such that only the most significant vibration modes of the object were selected. In this study, interactions between two deformable objects were also incorporated, one finite element based and the other particle based. Basdogan (2001) has also recently proposed the spectral Lanczos decomposition method to obtain explicit solutions of the finite element equations that govern the dynamics of deformations. Both methods (modal analysis and spectral Lanczos decomposition) rely on modeling approximations but generate dynamical solutions that are computationally much faster than the ones obtained through direct numerical integration techniques.

- *Meshless methods:* Because of the complexities of mesh generation and consequent constraints imposed on the computations, a meshless numerical technique called the method of finite spheres has recently been applied to physics-based soft-tissue simulation (De, Kim, & Srinivasan, 2001).

In earlier studies, a loose coupling between force and displacement computations has been proposed to take advantage of human perceptual limitations (Basdogan et al., 1998). In this approach, vertex-based or spline-based approaches have been used to generate smooth visual deformations, whereas interaction forces were computed and reflected to the user based on a simple spring and a damper model between the new and home positions of the contact point. Because human perception of position and motion is dominantly influenced by visual cues in interacting with objects (Srinivasan, Beauregard, & Brock, 1996), the loose coupling between force and displacement computations was not readily sensed by users during simulations (see Model A in Fig. 6.7). However, this architecture is limited to simulation of geometric-based deformations (e.g., sculpting and animation). Since force and displacement computations are

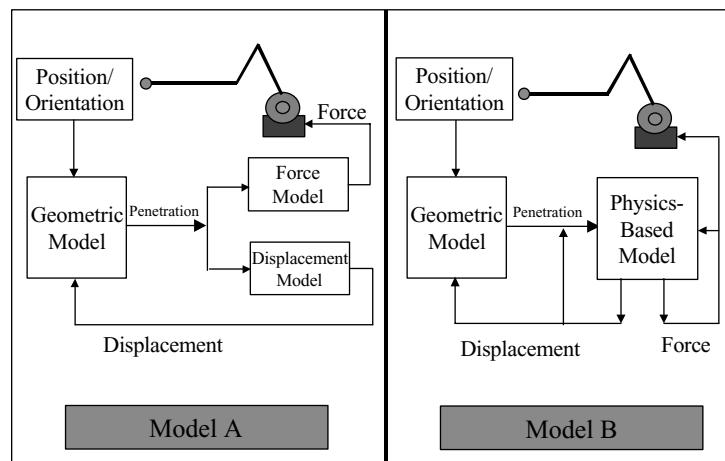

FIG. 6.7. Computational architectures for simulating force-reflecting deformable objects in virtual environments. In model A, force and displacement computations are loosely coupled. In model B, the physics-based model generates forces and displacements simultaneously, which are then fed back to the model to generate new values. Although this architecture is computationally expensive to implement, it is more comprehensive than architecture A (Basdogan, 1999).

usually tightly coupled in more physically based systems, a closed-loop architecture has to be developed to solve the equations that govern the physics of deformable behavior (see Model B in Fig. 6.7). In this architecture, forces and displacements computed in the previous cycle are continuously supplied back to the physics-based model to generate new values in the next cycle.

5. RENDERING OF DYNAMIC OBJECTS

Simulating haptic interactions with 3-D objects that translate and rotate over time is another challenge, which becomes computationally quite intensive if objects collide with each other, as well as with the haptic probe in real time. Dynamic equations have to be solved and the state of each object has to be updated at each iteration (see Fig. 6.8). Techniques to calculate forces and torques based on principles of rigid body dynamics (Baraff, 1994) and impulse mechanics (Mirtich & Canny, 1995; Mirtich, 1996) have been developed for graphical simulation of floating multiple objects. Latimer (1997) discusses the extension of these techniques to the haptics domain, whereas Colgate and Brown (1994) and Adams and Hannaford (1998) address the stability issues.

To describe the basic concepts of haptic interaction with dynamic objects, consider an example (see Fig. 6.8a). Assume that interactions are point-based again such that the user controls the dynamics of a floating object via only the tip point of the haptic probe. The new position and orientation of the object can be calculated using equations that govern the dynamics of rigid body motion. These equations can be solved in real time using a numerical

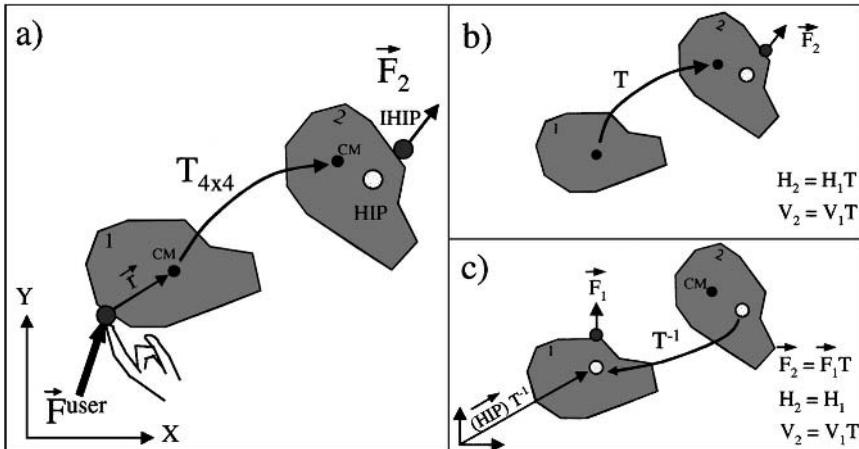

FIG. 6.8. Modeling point-based haptic interactions with a floating rigid object in virtual environments. (In the figure, T is the transformation matrix, \vec{F}_2 represents the force acting on the user through a haptic display, H and V represent the haptic and visual coordinates of the object respectively. Here, two different methods for computing the interaction forces when the object is transformed from State 1 to State 2 are discussed. Figure (b) describes a method in which both haptic and visual coordinates are updated and collisions are detected with the new haptic coordinates of the object to compute the new interaction force (\vec{F}_2) at State 2. In Figure (c), only visual coordinates are updated. First, HIP is multiplied with the inverse of the transformation matrix and collisions are detected with the original haptic coordinates. Then, the reaction force (\vec{F}_1) is computed relative to the original coordinates and then multiplied with the T matrix ($\vec{F}_2 = \vec{F}_1 \cdot T$) to include the effects of transformation. Although both methods (b and c) are valid and return the same interaction force (\vec{F}_2) at the end, the method described in Figure (c) is computationally less expensive than the one described in Figure (b), because the haptic coordinates of the object are not required to be updated at each iteration when the object is transformed to a new state.)

integration method, such as Euler integration, to update the state of the object at each cycle of the haptic loop:

Constants:	Initial Conditions:	Integration over interval Δt :	Update Auxillary Quantities:
I_{body}^{-1}, M	$\vec{v}_t=0.0$ $\vec{p}_t=0.0$ $R_t=0.0$ $L_t=0.0$ $\vec{\omega}_t=0.0 = I_{body}^{-1} \vec{L}_{t=0.0}$	$\vec{v}_{t+\Delta t} = \vec{v}_t + \Delta t(M^{-1} \vec{F}_{user})$ $\vec{p}_{t+\Delta t} = \vec{p}_t + \Delta t \vec{v}_{t+\Delta t}$ $R_{t+\Delta t} = R_t + \Delta t \omega^* R_t$ $\vec{L}_{t+\Delta t} = \vec{L}_t + \Delta t \vec{T}_{user}$ where: $\omega^* = \begin{bmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{bmatrix}$	$I_{t+\Delta t}^{-1} = R_t I_{body}^{-1} R_t^T$ $\vec{\omega}_{t+\Delta t} = I_{t+\Delta t}^{-1} \vec{L}_{t+\Delta t}$

where, \vec{F}_{user} and \vec{T}_{user} represent the total force and torque acting on the object, \vec{v} and \vec{p} represent the linear velocity and position vectors and $\vec{\omega}$ and \vec{L} are the angular velocity and momentum vectors. In addition, R , M , and I are the rotation, mass and inertia matrices of the object respectively and Δt is the sampling time (e.g. $\Delta t = 0.001$ seconds if the haptic loop is updated at 1 kHz). The total force acting on the object (\vec{F}_{user}) is calculated based on the depth of penetration of the haptic probe into the object. The torque acting on the object will be the cross product of \vec{r} and \vec{F}_{user} vectors (see Fig. 6.8). The details of the formulation and the computation of mass and inertia matrices can be found in Baraff (1997).

Since the position and orientation of the object change at each time step, the updated coordinates of the object should be used to detect collisions with the new coordinates of the HIP. However, it would be computationally too expensive to update the object database at each time step to detect collisions with the new HIP. A better strategy is to compute everything relative to the original coordinates and then apply the effects of transformation later (see the description in the legend for Fig. 6.8).

6. RECORDING AND PLAYING-BACK HAPTIC STIMULI

The concept of recording and playing back haptic stimuli (MacLean, 1996) to the user has some interesting applications. For example, the user equipped with a desktop haptic device may touch and feel the prerecorded textures of a car seat that is advertised by a car company over the Internet (this concept is similar to downloading a movie file and playing it on screen). In another application, preprogrammed haptic devices can be used in neuro-rehabilitation (see chaps. 49 and 50, this volume) to improve the motor-control skills of patients with neurological disorders by displaying prerecorded haptic trajectories (Krebs et al., 1998). In both of these examples, the user will be a passive participant of the system, though he or she may have some control over the device. As the user holds the end-effector of the device gently, the device guides his or her hand along prerecorded shapes or paths.

To describe the concept of haptic “playback,” consider a simple example. Assume that the goal is to program a haptic device such that it will display a square shaped frame to a passive user. Here, programming of a haptic device as a typical closed-loop control problem is considered. Although this is a well-studied problem in robotics, the following practical issues appear when it is implemented with haptic devices:

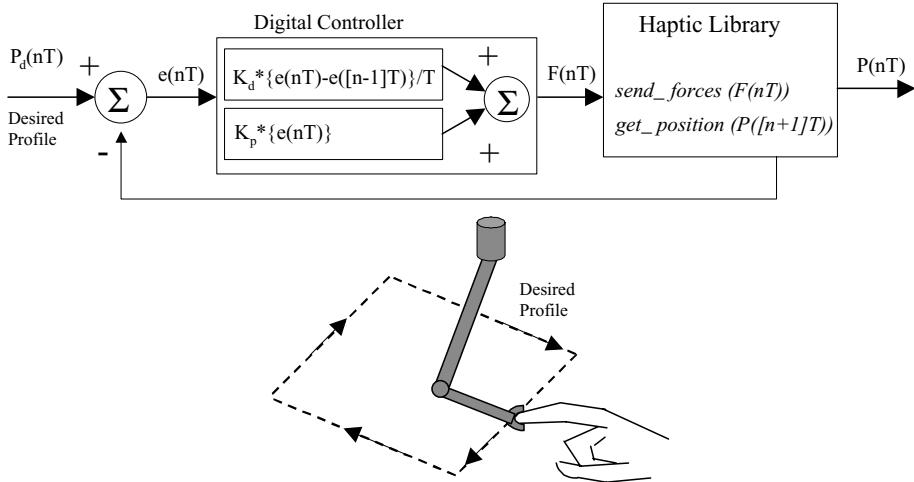

FIG. 6.9. Digital servo loop for commanding the haptic device to play prerecorded haptic stimuli (a frame in this example). P , e , and F represent position, error, and force vectors respectively. K_d and K_p are derivative and proportional control gains.

- Haptic devices are typically “open-loop” systems. The user manipulates the end-effector of the robot to control the end position, but the dynamics of interactions are not governed by the principles of closed-loop control systems. In other words, you need to design your own controller to command your haptic device to play back prerecorded haptic stimuli.
- Unless you build your own haptic device and do not purchase from a manufacturer, you most likely do not know the kinematics (e.g., mass and length of each link) and dynamic properties (e.g., friction, performance of motors) of your device exactly. Haptic devices, sold by a manufacturer, usually come with a library that includes function calls for acquiring position and orientation of the end-effector and for sending force commands to motors (see section 2). Hence, the goal is to use these function calls to control the movements of the haptic device and navigate from one point to another in 3-D space while compensating for positional errors. One can design a controller to achieve this goal (see Fig. 6.9; we use a PD controller to track the desired profile).

It is possible to play back prerecorded forces to the user even when the user is actively interacting with the environment by using, visual cues. Dang, Annaswamy, & Srinivasan (2001) have developed an epidural injection simulator in which a training feature is the capability to display an expert’s path and forces to a novice in two ways. The expert’s path is displayed visually either as a “tunnel” through which the novice could traverse or as a cursor moving along the prerecorded path that the trainee needs to follow closely to feel the prerecorded forces continuously.

7. SHARED HAPTICS: HAPTIC INTERACTION BETWEEN NETWORKED USERS

Another potentially promising area is haptic interaction among a group of users sharing the same VE over a network (see chaps. 16 and 44, this volume). Since the haptic loop requires a high update rate of around 1 kHz for stable interactions, and changes in the visual scene will require frequent update of the haptic database, developing a network protocol that can provide sufficient bandwidth with minimum latency to a group of distributed users is a quite challenging

problem. For shared environments to be effective in performing collaborative tasks that involve haptic feedback, several network architectures have been proposed (Buttolo, Oboe, & Hannaford 1997; Wilson, Kline-Schoder, Kenton, & Hogan, 1999), and physics-based models that simulate haptic interactions among users have begun to be developed (Basdogan et al., 2000). Because of network time delays, the difficult nature of some collaborative tasks, and lack of knowledge on user abilities and behaviors, the problem of developing a universal model for shared haptics could be too complex. For example, it is obvious that time delays during the transfer and processing of data may easily result in unstable forces and can be harmful to the user (see chap. 41, this volume). Similarly, participants could follow several different strategies to manipulate virtual objects during the execution of a task if an interaction model is established. For example, one could talk about *sequential* versus *simultaneous* types of haptic manipulations. It is even possible to make one user “stronger” than the other (Basdogan et al., 2000). Since limited knowledge in this area makes it almost impossible to integrate all these features into a single interaction model, the type of model selected to simulate haptic interactions between participants in shared environments depend, at this stage, on the collaborative task itself. For example, a simple physics-based model has been developed to simulate haptic interactions between participants (Basdogan et al., 2000). In this model, each participant manipulates his or her own cursor through a stylus attached to the force feedback device placed next to his or her seat. When the participant manipulates the stylus of the haptic device with his or her dominant hand, the cursor moves in 3-D space so that the manipulated object translates or rotates depending on the task. In our experiments, a spring-damper model ($F = k\Delta p + b\Delta \dot{p}$, where F is the force exerted by the user on the ring that is felt by his or her remote partner, k and b are the spring and the damping coefficients, and Δp is the displacement of the participant’s cursor) was used to control the impedance of interactions between participants and between the participant’s cursor and the ring in the scene (see Fig. 6.10). This model simply

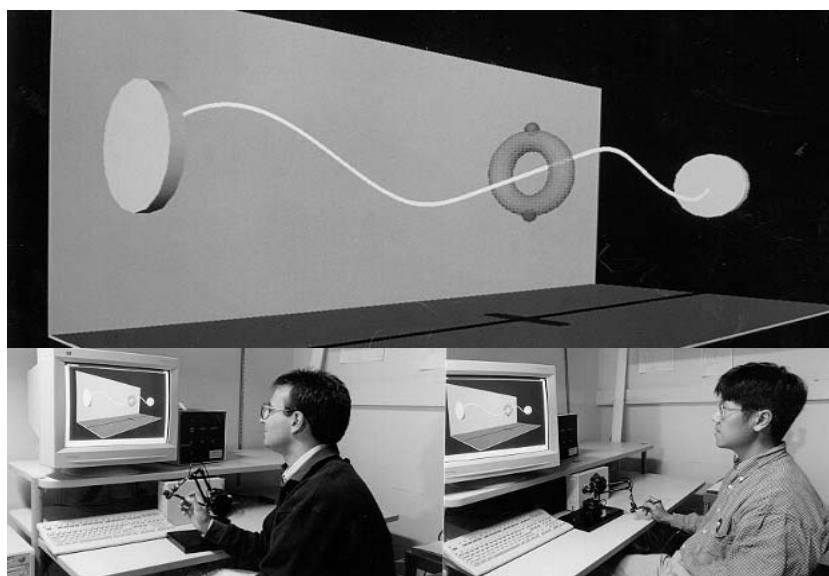

FIG. 6.10. We developed a shared VE setup that enables two people, at remote locations, to interact with each other through visual and haptic displays. An experiment was designed to investigate the role of haptics in collaborative manipulation. In our experiment, participants were asked to hold and move a ring on a wire in a collaborative manner, as depicted in this figure. To eliminate time delays due to network connections, we bifurcated the signals from a single host and displayed it on two separate monitors and haptic interfaces.

simulates the translational movements of the ring on a wire and pulling and pushing forces between the participants. Hence, if a participant pulls or pushes his own cursor the remote partner feels the forces. Visually, however, the ring remains rigid (i.e., no deformation of the ring is displayed graphically). The rotation of the ring due to unbalanced forces applied by the participants was prevented to make the task easier. Moreover, only “simultaneous” haptic interactions were supported such that the ring did not move if both participants did not apply sufficient forces to the ring at the same time.

8. SUMMARY AND FUTURE

Computer haptics is concerned with the development of software algorithms that enable a user to touch, feel, and manipulate objects in VEs through a haptic interface. It primarily deals with the computation of forces to be displayed to the user in response to user's actions. The demands placed on it depend on the capabilities and limitations of the interface hardware, computational engine, and user, together with the needs of the task to be accomplished. Current haptic interface technology is mature for net force and torque feedback, as in tool usage in the real world. Consequently, current haptic rendering algorithms have been developed mainly for simulating net forces and torques of interaction and give users the feeling of touching and manipulating objects through a stick or a rigid thimble. Point-based rendering, which views the haptic cursor as a point in computing point-object interaction forces, was developed first and is widely used. This was followed by ray-based rendering, which computes line-object interaction forces and torques. More recently, limited success has been achieved in simulating 3-D object-object interactions in which one of the objects is viewed as a collection of points. Using these haptic interaction paradigms, real-time haptic display of shapes, textures, and friction of rigid and deformable objects has been achieved. Haptic rendering of dynamics of rigid objects, and to a lesser extent, linear dynamics of deformable objects, has also been accomplished. Methods for recording and playing back haptic stimuli, as well as algorithms for haptic interactions between multiple users in shared VEs, are beginning to emerge.

In the future, capabilities of haptic interface devices are expected to improve primarily in two ways: (1) improvements in both desktop and wearable interface devices in terms of factors such as inertia, friction, workspace volume, resolution, force range, and bandwidth; (2) development of tactile displays to simulate direct contact with objects, including temperature patterns. These are expected to result in multifinger, multihand, and even whole body displays, with heterogeneous devices connected across networks. Even with current rapid expansion of the capabilities of affordable computers, the needs of haptic rendering with more complex interface devices will continue to stretch computational resources. Currently, even with point-based rendering, the computational complexity of simulating the nonlinear dynamics of physical contact between an organ and a surgical tool, as well as surrounding tissues is very high. Thus there will be continued demand for efficient algorithms, especially when the haptic display needs to be synchronized with the display of visual, auditory, and other modalities (see chap. 21, this volume). Similar to graphics accelerator cards used today, it is quite likely that repetitive computations will need to be done through specialized electronic hardware, perhaps through parallel processing. Given all the complexity and need for efficiency, in any given application the central question will be how good the simulation needs to be to achieve a desired goal.

1. INTRODUCTION

This chapter describes various methods for eliciting perceptions of body acceleration. The focus of discussion is on the “user’s requirements” for perceiving acceleration in a virtual environment (VE). The most direct means for eliciting an acceleration perception in a VE is by using a real acceleration stimulus that is meant to mimic critical aspects of the “virtual acceleration” perception being conveyed. A rudimentary understanding of human vestibular function is necessary in order to employ physical acceleration effectively as part of a virtual environment. This chapter provides an introduction to the “vestibular channel” of the VE stimulus and details different methods for exploiting knowledge about the vestibular modality to elicit perceptions of self-motion, self-tilt, and self-entry into unusual force environments. The authors compare physical acceleration of the user to other methods, such as visually induced illusions of self-motion or illusions of self-motion induced by locomotion without displacement (as occurs on treadmills). The authors conclude that the most compelling perceptions of body acceleration in VEs will be achieved through mutually enhancing combinations of vestibular, visual, and somesthetic stimuli. A particularly effective approach will be to use acceleration stimuli that duplicate the real acceleration profiles being simulated, but to do so in a different environment from the (virtual) environment where the user perceives himself to be located.

2. “USER REQUIREMENTS” FOR PERCEIVING BODY ACCELERATION

2.1 Purpose and Scope of This Chapter

The purpose of this chapter is to introduce various methods for eliciting acceleration perceptions. The acceleration perceptions one can elicit in a VE are not limited to feelings of velocity or displacement through space. Since gravity is one type of acceleration (according to Einstein’s stated equivalence of inertial and gravitational force; see de Broglie, 1951), the perception of unusual G-forces on one’s body qualifies as an acceleration perception. One might wish to elicit a perception of altered G-force in order to simulate travel in a high performance vehicle or into a nonterrestrial gravity environment.

Acceleration simulations that are designed correctly could be used to create experiences outside the user’s immediate, veridical experience (e.g., training in a simulator building), but appropriate to the VE (e.g., flying in the cockpit of a high-performance airplane). Acceleration simulations need not be produced solely by VEs that elicit illusory perceptions of self-motion (such as occur when viewing a moving visual surround); they can be produced by actual body accelerations (such as occur with a “moving-base” simulator) or actual locomotions (such as on a treadmill—see Appendix A). The purpose of an acceleration simulation is to elicit a perception of acceleration appropriate to the VE being created by whatever combination of illusory or real motion is most effective.¹ It would be wrong to think that an acceleration display is only “virtual” when it does not employ an acceleration stimulus. Certainly no one would argue that a visual display is only virtual when it does not stimulate the retina with light. Similarly, the feeling of “virtual acceleration” refers not to the means by which the acceleration perception is generated, but rather to the resulting perceptual event created.

During normal daily activities, the integration of multimodal sensory information is critical to a human’s appreciation of his motion, his position, and the forces acting on his body. The perception of body acceleration involves most of the senses, including vision, audition, vestibular sensation, and somesthesia (which refers to cutaneous, muscle, and joint receptors).² Similarly, during simulated activities, the aforementioned sensory modalities can be exploited to elicit the perception of acceleration. For example, the motion of large visual fields around the user is known to act upon the vestibular nucleus (and associated structures) and thereby to induce a compelling illusion of self-motion (Dichgans & Brandt, 1978). A visually induced illusion of self-motion is commonly referred to as “vection.”³ Vection can be considered an acceleration perception that indirectly implicates vestibular involvement. The use ofvection as a means for simulating self motion in a VE is treated in detail in chapter 23 (this volume).

Just as visual stimuli can provide acceleration cues, so can somesthetic stimuli. For example, walking in place (as on a treadmill) can be exploited to enhance the perception of locomotion through a virtual display and can induce compensatory eye movements not unlike those elicited by real body motion (chap. 38, this volume; also see Bles, 1979; Brandt, Büchele, & Arnold, 1977; Lackner & DiZio, 1988). Like visualvection, walking in place can be considered an acceleration simulation. Some locomotion simulation devices are listed in Appendix A. The use of locomotion devices in VE is treated in detail in chapter 11 of this book.

The primary focus of the present chapter will be to describe the user requirements that must be met to elicit acceleration perceptions via information presented in the vestibular channel of a virtual environment. The most direct means for creating an acceleration perception in a VE is by using a real acceleration stimulus that is meant to mimic critical aspects of the acceleration scenario being simulated. This can be accomplished by allowing the user to move through a real space that serves as an ambient context for the virtual environment (see section 3.2 below) or by the use of moving simulators, centrifuges, and other acceleration

devices (examples are provided in Appendix A). All of these “real-motion” methods tend to stimulate the vestibular organs, which are specifically evolved to transduce head acceleration. The vestibular modality should be exploited by VE designers to induce feelings of acceleration when they are desirable and to avoid feelings of acceleration when they are undesirable, yet are required because of the logistic constraints of the simulator and the space within which it operates. For example, “moving-base” simulators often employ a subthreshold motion stimulus during relatively quiescent periods in the simulation. This is done to slowly reposition the user and ready the motion platform to achieve the desired acceleration profile the next time a strong acceleration perception is required as part of the simulation. In discussing the vestibular channel in VEs, the essential qualities of the stimulus (acceleration) and the receptor (the vestibular end organs) will be briefly introduced. The authors will then introduce ways in which the vestibular system can be exploited to create, prevent, or modify acceleration perceptions.

2.2 Necessary Prerequisites of an Effective Simulation

To understand the simulation of a perception, one must start with a basic knowledge of how that perception is formed in the natural world. To understand how perceptions are formed, one must begin with the stimulus, i.e., the qualities in the physical world that are detected by the sensory system of interest. For example, the amplitude and frequency of vibration of air molecules is sensed by the auditory modality and then perceived by the listener as loudness and pitch. Similarly, if one wishes to meet the user’s “visual requirements” with a display, one manipulates the intensity and wavelength of the light reaching the user’s eye so as to match the stimuli that would be received if the viewer were physically present inside the virtual world.

Manipulating the quality of the stimulus is only part of a simulation. It is equally important to understand the functioning and limitations of the sensory modalities one is stimulating to evoke a synthetic experience effectively. Sometimes it may not be possible or desirable to recreate the stimuli the user would receive if he were actually inside the virtual world. In cases where it is desirable but does not appear possible, a solution might be finessed by exploiting known principles of sensory functioning.

Information about the functioning of the vestibular system is presented in this chapter. Such information can be exploited to enhance feelings of acceleration. In any VE, certain system requirements must be met to generate an appropriate stimulus, while critical user requirements dictated by the functional properties of the user’s perceptual apparatus must be met for the VE to be compelling and effective. The acceleration stimulus and the functioning of the vestibular system will be the focus of the discussion below.

2.3 Introduction to the Acceleration Stimulus and Vestibular Receptors

The human vestibular modality is evolved to detect acceleration stimuli; it can do so in the absence of visual or somesthetic cues, but these cues are present most of the time. The sensory qualities to which the vestibular modality is sensitive include linear and angular accelerations due to self-motion and gravity. Linear and angular accelerations are detected by the otolith organs and the semicircular canals, respectively. These organs will be described below. For a detailed description, see Howard (1986, chap. 11).

The otolith organs of the inner ear detect linear accelerations of the head via the utricles and the saccules, and they also sense angular motion that produces changes in the angle of the earth’s gravity vector relative to the perceiver’s body. The otolith organs detect changes in the magnitude or direction of linear gravitoinertial force vectors via hair cell mechanoreceptors, which are embedded in gelatinous membranes containing tiny crystals of calcium carbonate

called otoconia. The otoconia are more dense than the surrounding medium and hence lag behind motions of the head very slightly due to their inertia, causing a corresponding deformation of the hair cells.

Three semicircular canals located in each inner ear code angular motion in three roughly orthogonal axes. The semicircular canals are fluid filled rings with a gelatinous structure called the cupula obstructing each ring. The gelatinous cupula is embedded with hair cells that are deformed when the cupula is itself deformed by very small changes in fluid pressure caused by angular acceleration of the semicircular canals.

Collectively, the semicircular canals and otolith organs make up the equilibrium organs of the nonauditory portion of the human labyrinth. The semicircular canals and otolith organs interact with one another (and with other sensory modalities) during the processing of complex stimuli involving simultaneous angular and linear acceleration. The mutual interaction of otoliths and canals explains why an individual's perception of self-tilt during "off-center" rotation (i.e., rotation around a central axis that is located at some radial distance from one's own body) facing tangentially forward initially lags behind the stimulus given by the rate of change in the direction of the resultant gravito-inertial force vector (Graybiel & Brown, 1950; Lawson, Mead, Chapman, & Guedry, 1995). This lag effect is likely attributable to "suppression" of the otolith system by the angular acceleration signal being processed and transmitted by the semicircular canals. Numerous other intralabyrinthine interactions can be identified (Guedry & Benson, 1978; Reason & Brand, 1975), as well as important interactions among the labyrinthine and nonlabyrinthine sensory modalities, including vision (Dichgans & Brandt, 1978), audition (Lackner, 1977), and somesthesia (Bles, 1979; Lackner & Graybiel, 1978).

The vestibular system is involved in several aspects of human functioning besides the perception of acceleration, including the reflexive control of gaze stabilization, head righting, postural equilibrium, coordinated locomotion, and certain reaching behaviors. Functioning vestibular organs are probably critical to the elicitation of unpleasant symptoms such as motion sickness (so named by Irwin in 1881) and "cybersickness" (see chap. 30, this volume; Stanney et al., 1998). A comprehensive explanation of vestibular function, neurovestibular pathways, or the psychophysics of vestibular perception is not necessary for the reader to gain a rudimentary grasp of the practical options available for eliciting acceleration perceptions in virtual environments. (Appendix B provides a list of recommended readings for those who wish to learn more about vestibular function and psychophysics.) The most practical options available for eliciting acceleration perceptions are evaluated below.

2.4 Current Options Available for Creating an Acceleration Perception

Most of the methods for creating the perception of displacement, velocity, acceleration, or abnormal G-force upon one's body are enumerated in this section. In section 3, the focus of discussion is narrowed to those few methods that will be most helpful to the creation of controlled acceleration perceptions within a virtual environment.⁴

2.4.1 Methods Involving Acceleration of the User

2.4.1.1 Real Physical Motion. The most obvious way to elicit the perception of dynamic body movement through a VE is by real physical motion of the user that is correctly perceived as such. Physical motion can be achieved "passively"⁵ with moving devices such as simulators, centrifuges, and real vehicles (see sections 3.2.1 and 3.2.3). Physical motion can also be achieved by allowing the user to walk through a real environment that serves as an ambient context for the VE (see section 3.2.2). Real motion is a very effective and controllable way to create acceleration perceptions in a VE, provided the VE customer can afford it

and the simulations are designed by individuals who understand the psychophysics of human acceleration sensations and the factors which give rise to motion induced discomfort.

2.4.1.2 Addition or Subtraction of Felt Body Weight. Physical acceleration of the user is not always perceived as such. Acceleration can lead to the perception of altered body weight instead. The external addition or subtraction of felt body weight during movement through space can be used to enhance the simulation of high-performance vehicles or nonterrestrial settings (Guedry, Richard, Hixson, & Niven, 1973; Guedry, 1974; Lackner & Graybiel, 1980).⁶

2.4.1.3 Illusions of Self-motion Associated With Acceleration Stimuli. Illusions of self-motion can accompany the cessation (or change in velocity) of certain real-motion stimuli, such as prolonged constant velocity self-motion (Guedry, 1974). This is a useful adjunct to method 2.4.1.1, above.

2.4.1.4 Constant Velocity Rotation Followed By Head Movement. Self-velocity perceptions can be produced by prolonged constant velocity rotation in one axis followed by a head movement in another, nonparallel axis (Guedry & Benson, 1978). This is a useful approach when the stimulus is relatively mild. Pronounced discomfort can arise among susceptible individuals making repeated head movements after prolonged body rotation, especially when body rotation occurs at high velocity. However, earth-referenced cues can lessen the unpleasant effects (Lawson, Guedry, Rupert, & Anderson, 1993; Lawson, Rupert, Guedry, Grissett, & Mead, 1997).

2.4.1.5 Static Body Tilt. Alterations in perceived orientation can be induced via static body tilt and the aftereffects thereof. This is a useful adjunct to other methods in this section, but simple body tilt by itself elicits effects that are restricted mostly to the visual modality (see section 4).

2.4.2 Methods Not involving Acceleration of the User

2.4.2.1 Visual Field Motion. Acceleration perceptions can be elicited via tilting visual frames of reference, continuous whole-field visual motions, and the aftereffects thereof (Dichgans & Brandt, 1978). This is a promising method if applied with a full knowledge of the psychophysics of human perception and the factors that give rise to visually induced discomfort (see chap. 30, this volume).⁷

2.4.2.2 Auditory Surround Motion. Acceleration perceptions can be elicited via motion of auditory surrounds and the aftereffects thereof (Lackner, 1977). This is a promising method, especially when used in conjunction with confirmatory body motion (see section 2.4.1) or visual motion (see section 2.4.2.1).

2.4.2.3 Tactile Surround Motion. Acceleration perceptions can be elicited via moving touch and pressure cues and the aftereffects thereof (Chapter 38, this volume; see also Brandt, Büchele, & Arnold, 1977; Lackner & Graybiel, 1977; Lackner & DiZio, 1984). This is a promising method, especially when used in conjunction with confirmatory information from other sensory modalities (see sections 2.4.1, 2.4.2.1, 2.4.2.2).

2.4.2.4 Voluntary Tactile/Kinesthetic Behaviors. Acceleration perceptions can be elicited by voluntary tactile/kinesthetic behaviors such as locomotion without displacement, stationary pedaling, or simulated “hand walking” (as well as the aftereffects of these behaviors),

as discussed in chapters 11 and 38 (this volume). (See also Brandt et al., 1977; Lackner & DiZio, 1988; Lackner & DiZio, 1993.) This is a most promising method, albeit limited to acceleration simulations involving limb movement.

2.4.2.5 Vibration of Localized Body Regions. Acceleration perceptions can be elicited by exploiting illusions of motion that accompany vibration of localized body regions. Vibration of skeletal muscles can elicit a variety of self-motion perceptions (Lackner & Levine, 1979; Levine & Lackner, 1979), as can vibration of the cranium (Lackner & Graybiel, 1974).⁸ These are potentially useful methods that may augment other methods.

2.4.2.6 Acoustic Vibrations. Specific acoustic vibrations appear to act upon the vestibular organs (Minor, Solomon, Zinreich, & Zee, 1998; Van Campen, Dennis, King, Hanlin, & Velderman, 1999). However, this is currently not a promising method for eliciting acceleration perceptions, due to unpleasant symptoms induced and due to the unknown long-term consequences to auditory and vestibular organs.⁹

2.4.2.7 Caloric Stimulation of Ear Canal. Caloric stimulation of the ear canal (National Research Council, 1992) can elicit a sensation of movement. This is an effective method that can be applied unilaterally, but it is somewhat invasive and unpleasant, and the specific motion perception is difficult to alter from moment to moment.

2.4.2.8 Direct Electrical Stimulation of Vestibular Nerve Fibers. Direct electrical stimulation of the vestibular nerve fibers is a very effective way to elicit movement sensations, but when done invasively (as in the animal model), it is not a promising method for general (nonprosthetic) use. However, low-intensity noninvasive stimulation of the mastoids may be a method for achieving controlled-velocity perceptions (Quarck, Etard, Normand, Pottier, & Denise, 1998).

2.4.2.9 Drug Treatments. Dysfunctions in a given vestibular labyrinth or imbalances in the normal interaction of the respective labyrinths (such as may result from inner ear infections, Menier's syndrome, or ototoxic drug treatments) can create feelings of movement. It would be unethical to intentionally produce such invasive effects by similar means because of the long-term adverse effects. The vestibular effects of certain drugs such as alcohol (Fetter, Haslwanter, Bork, & Dichgans, 1999) are reversible, but not pleasant or easily controllable. Moreover, such drugs produce unpleasant side effects and raise ethical and safety concerns.

2.4.2.10 Other Techniques. Eliciting vertigo via looking over a visual cliff (Brandt, 1999), via postural hypotension (Baloh & Honrubia, 1979), or via atmospheric pressure changes (Benson, 1988) is effective for producing nonspecific feelings of instability, dizziness, or falling, but is not conducive to controllable motion perceptions and would give rise to safety concerns for certain individuals.

2.4.3 Combining Different Methods for Eliciting Acceleration Perceptions

A controlled feeling of acceleration within a VE can be achieved via a judicious combination of the more promising stimuli listed above. It is well-known that when motions of the visual field (see section 2.4.2.1) correspond with real motions of the user (see section 2.4.1.), feelings of acceleration are enhanced (Young, Dichgans, Murphy, & Brandt, 1973, 1988).

Multimodal inputs act in concert to create acceleration perceptions in the natural world. Similarly, compelling perceptions of acceleration in VE should be elicited by the introduction of mutually enhancing combinations of multimodal stimuli. The most promising methods will predictably combine real passive or active vestibular acceleration stimuli (see section 2.4.1) with visual field motion (see section 2.4.2.1.), auditory surround motion (see section 2.4.2.2.), or tactile surround motion (see section 2.4.2.3.). Vestibular motion stimuli and perceptions are described below.

3. FOCUS ON THE VESTIBULAR CHANNEL FOR CREATING ACCELERATION PERCEPTIONS

The vestibular end organs are stimulated directly by many of the methods of eliciting acceleration perceptions covered in section 2.4 above, including physical tilt or motion of the user, the aftereffects of prolonged rotation, caloric stimulation, low-frequency auditory vibrations, vibrations to the cranium, vestibular diseases, and drug or alcohol effects impacting the end organs. Many other acceleration perceptions arise by stimulating the vestibular nucleus (and associated structures in the brainstem) without directly stimulating the vestibular end organs. Illusions of self-motion can arise indirectly as a result of viewing a moving visual field or hearing a moving auditory surround stimulus. Several of the methods for inducing acceleration perceptions without using a direct stimulus to the vestibular end organ are promising and should be explored. Even if many of them do not prove to be viable ways of eliciting consistent and controllable acceleration perceptions, they must be understood if VE designers are to create effective acceleration simulations that are not inadvertently corrupted by interference from competing stimuli.

The best acceleration simulations will coordinate a variety of vestibular and nonvestibular stimuli so that different cues confirm one another and mutually enhance the simulation. Three of the most promising methods for eliciting acceleration perceptions are: (1) physical motion of the user (either passively or actively produced); (2) whole-field visual displays that induce illusions of self-motion (chap. 23, this volume); and (3) locomotion devices that induce illusions of self-motion without physical displacement of the user through space (chap. 11, this volume). This review focuses upon the use of “real-motion” stimuli (category A). However, it is instructive to compare the acceleration perceptions arising from real motion to those arising from visual-motion stimuli (2) or walking in place (3). This comparison is especially useful when one considers the likelihood that these three methods will be employed in combination, because it allows the reader to see where each method excels and thus to imagine how the three methods can complement one another. If virtual displays are to meet the promise of their initial “virtual reality” hype and become fully immersive and effective, a careful combination of the advantages of each of the three methods listed in Table 7.1 will be necessary.

3.1 Acceleration Perceptions Involving the Vestibular Channel

An important step toward developing a good acceleration simulation involving the vestibular modality is to gain some familiarity with the various vestibular acceleration sensations that are possible and how each one is generated. A wide variety of acceleration perceptions can be elicited via stimulation of the vestibular system, some of which are illusory perceptions. Below some acceleration perceptions involving the vestibular modality are listed, with a brief description of the stimuli that can cause them.¹⁰ Most of the perceptions described below

TABLE 7.1
A Comparison of Three Methods for Eliciting
Acceleration Perceptions

- A. Passive or Active Body Acceleration (see sections 2.4.1 and 3.2, also Appendix A of this chapter)
- B. Visually Induced Illusory Self Motion (see section 2.4.2.1, also chapter 23, this volume)
- C. Illusory self Motion Induced by Locomotion without Displacement (see sections 2.4.2.4, Appendix A; chapters 11 & 38, this volume)

Points of Comparison	(A) <i>Real-Body Acceleration (Passive or Active)</i>	(B) <i>Visually Induced Illusory Self-Motion</i>	(C) <i>Illusory Self-Motion Induced by Locomotion Without Displacement</i>
<i>Situation Flexibility</i>			
Range of perceived situations that can be simulated.	A vast number of passive transportation stimuli in 6 degrees-of-freedom can be simulated, as well as active locomotion, e.g., walking through a real space that serves as a context for a virtual space (see section 3.2.2). The range of simulations is very wide, with cost and space the main limitations.	A moderate number of virtual accelerations of predictable and uniform trajectory can be simulated if the motion is of sufficient duration and velocity is not too high. This method does not work well for all degrees of freedom and it will not work to simulate movement in darkness.	A wide number of active or semi-passive locomotion behaviors can be simulated without moving through space. These include active crawling, walking, running, climbing, peddling, paddling, hand cranking, and hand-over-hand locomotion as well as semi-passive stepping in time with a moving surface.
<i>Isomorphism</i>			
When simulation is the goal of the VE, isomorphism implies: (a) Presenting similar multi-modal stimuli in the VE as would have been present during the real event. (b) Demonstrating the absence of VE side effects or aftereffects (unless they are present in the real stimulus).	The acceleration effect is nearly isomorphic when the simulation requires limited displacement. When the desired movement exceeds the feasible distance possible with the moving device, simulation quality suffers and head or arm movements are no longer isomorphic. Illusions can be exploited at times to enhance the simulation, or real vehicles can be employed instead (see section 3.2).	The visual aspect of self motion through the world can be reproduced faithfully for unidirectional motion at constant velocity, but the quality of the acceleration perception will not be isomorphic during changes in simulation velocity or direction, and during the user's own actions (e.g., head movements, reaching behaviors).	The characteristics of human stride and energy expenditure during treadmill locomotion are not identical to real locomotion. Nevertheless, this remains the most isomorphic way to simulate active locomotion within a small space.
<i>compellingness</i>			
Indicated by short latency to onset of self motion perception, by degree of "saturation" ofvection (perceived self-movement	Highly compelling, ranks first for vehicle motion simulation. Space required limits amplitude and duration of movement, however. When real vehicles are used for the simulation	Very compelling under the right circumstances. Does not work as well for rapidly changing or high velocity virtual motions. Rotationalvection works best for	Very compelling for the simulation of active locomotion in a limited space (especially when coupled with confirming visual motion information—see column B of this Table).

<p>without perceived surround motion), by high ratings of “presence,” and by the inability to discriminate real from virtual stimuli.</p>	<p>(see section 3.2), the effect will be very compelling. When space is available, body acceleration via real locomotion (see section 3.2.2) will be superior to treadmill locomotion.</p>	<p>constant velocity visual surround rotation < 90 deg/sec or when the axis of rotation of the visual display is aligned with the earth vertical. (See Boff & Lincoln, 1988, for further details.)</p>	
<p><i>Range of acceleration profiles possible</i></p>	<p>Range of perceived virtual velocities and accelerations possible.</p>	<p>Wide range of acceleration effects possible on moving devices, but effect duration is limited by the space within which the device operates. Simulation using real vehicles or active locomotion also requires a large space, but allows for additional acceleration simulations. When space is limited, perceived motion can be enhanced by vestibular illusions.</p>	<p>Works best at a moderate, constant velocity (e.g., below 90 deg/sec for rotationalvection). No theoretical limit on duration of stimulus, however.</p>
<p><i>Temporal fidelity</i></p>	<p>How well the perception tracks changes in stimulus velocity or direction.</p>	<p>Often immediate onset or recovery of acceleration perception with changes in stimulus. Perception stays in phase with the stimulus within normal frequencies of voluntary human motion. Vestibular illusions arise during passive motion outside the normal range.</p>	<p>Often delayed onset and will not readily follow sudden changes in the velocity of the visual stimulus.</p>
<p><i>Usefulness for simulating altered force environments</i></p>	<p>Ability to simulate altered gravitoinertial force environments, such as occur on other planets or during high performance flight.</p>	<p>The only method that can generate a non-terrestrial force environment to simulate extraplanetary travel or the G-forces felt by operators of high performance vehicles.</p>	<p>Can enhance the feeling of falling, but is not ideal for simulating non-terrestrial gravity or motion induced G-forces.</p>
			<p>Alone, no simulation of altered G is possible, but in conjunction with limb loading, body suspension, or certain cutaneous inputs, some subtle illusions may arise which are worth exploring.</p>

TABLE 7.1
(Continued)

<i>Points of Comparison</i>	<i>(A) Real-Body Acceleration (Passive or Active)</i>	<i>(B) Visually Induced Illusory Self-Motion</i>	<i>(C) Illusory Self-Motion Induced by Locomotion Without Displacement</i>
<i>Behavioral flexibility</i> Degree to which the user's activities must be artificially restricted for the virtual acceleration perception to be elicited and maintained.	User should not be freely locomoting inside of a moving device at more than 2 g without precautions. Head, eye, and limb motions can alter the acceleration percept. Head movements can produce adverse symptoms. Restrictions during simulations exploiting real vehicles or real locomotion are the same as when no simulation is being created.	Works best when the user's head and eyes are relatively still. Probably won't work as well when simulating real situations where the field of view is limited and the sight of one's own body is limited (e.g., a virtual simulation of a view through a tank periscope).	Works best when the locomotion is at constant velocity and in a predictable direction.
<i>Discomfort</i> How disturbing or "sickening" the method can be (see chap. 30, this volume, for details)	Certain stimuli can be very disturbing, but these effects can be partially diminished by helpful visual or somatosensory inputs (Lawson et al., 1993, 1994, 1997). Drowsiness is one of the most common symptoms, while nausea contributes most to degraded feelings of overall well-being (see chap. 30, this volume, for details on symptomatology). Fewer adverse effects expected when using real vehicles or real locomotion.	Certain stimuli can be fairly disturbing and effects can persist after cessation of stimulus. However, the user need only close his eyes to avoid the stimulus. Even with eyes open, sudden cessation of prolonged visual flow velocity is not likely to be as sickening as sudden cessation of prolonged self rotation. "Head symptoms" may be somewhat more common during visually induced motion discomfort (see chap. 30, this volume).	Few symptoms arise when walking at a constant speed on a treadmill during conditions of constant velocity visual flow, but symptoms may arise when treadmills walkers are exposed to variations in visual flow velocity (Durlach & Mavor, 1995, chap. 6, 1995).
<i>Other undesirable effects</i> Extent and nature of other undesirable side and aftereffects besides motion discomfort.	May include postural dysequilibrium, altered eye-hand coordination, altered vestibulo-ocular and cervical reflexes. Fewer problems expected when a real vehicle or real locomotion is used.	Similar symptoms as above and at left, but often of milder severity than for real motion stimuli. Additional oculomotor effects may arise.	Altered limb control and altered gate on exiting treadmill simulator, possibly other aftereffects as well.

TABLE 7.1
(Continued)

<i>Points of Comparison</i>	<i>(A) Real-Body Acceleration (Passive or Active)</i>	<i>(B) Visually Induced Illusory Self-Motion</i>	<i>(C) Illusory Self-Motion Induced by Locomotion Without Displacement</i>
<i>Expense of Building and Maintaining the Display.</i>	The average “virtual accelerator” will be relatively expensive. Some moving devices, real vehicles, or real-locomotion simulations will be able to take advantage of existing infrastructure.	The average “visual-only” display will tend to be relatively inexpensive. Existing computer display infrastructure can be leveraged readily. Programming expense is the main financial burden.	The average cost will be moderate. The range of costs is likely to be very wide, ranging from stepping in place or walking on a treadmill (inexpensive) to sophisticated locomotion devices mounted to each limb separately (expensive).
<i>Technical difficulty</i> How difficult the virtual displays are to design, build, and program.	A difficult approach if taken without prior knowledge of acceleration psychophysics. Will be most feasible when “piggy-backing” virtual displays onto existing motion-capable devices or real vehicles.	Although still an unsolved challenge, the visual motion approach will be relatively easy to design, build, test, and modify.	Not very difficult when using simple treadmills to simulate constant velocity walking in one direction, but complicated when attempting to simulate more sophisticated behaviors.
<i>Size</i> Space occupied by the display.	Large “footprint” required for most moving based simulators; very large footprint for centrifuge based devices. Extremely large space needed when using real vehicles or active locomotion through a real space used to mimic the virtual space.	Very small space needed if head mounted, relatively small space needed if visual stimulus surrounds entire body.	Small space needed for simple treadmills and foot mounted devices; moderate space needed for omnidirectional and tiltable treadmill surfaces or when incorporating suspension/weighting systems to attempt altered G simulation.
<i>Initial “Market Niche.”</i>	Costly government, sporting, and entertainment applications. Especially useful for simulations of high-performance land, air, and sea vehicles. Will also be marketed for high-budget situations involving active locomotion through a real space used to mimic a virtual space (see section 3.2.2). In entertainment applications, start-up costs will be defrayed by user fees.	Lower-budget personal and home applications. Note, however, that high-budget applications will not be complete without visual displays of high quality, and hence this method will always have a key role to play in the market.	Mid-range budget applications requiring prolonged active locomotion perceptions within a small real space. Higher budget applications will include all limbs and all motions (not just walking, running, or pedaling). Promising approach for marketing portable units to augment training of athletic skills and training for dangerous activities such as close quarters combat.

are especially salient when veridical information from nonvestibular modalities (e.g., helpful visual cues from the outside world) is absent.

3.1.1 Perception of Tilt

The simplest way of achieving the feeling of body tilt (i.e., misalignment with the earth vertical) in a VE is to physically tilt the user in the real world at the same speed and by the same amount. When this is not possible or the effect needs to be magnified, one can produce or enhance the feeling of tilt in various ways. An alternate way to produce a feeling of tilt is via the presence of a linear (including centripetal) acceleration vector not aligned with the gravitational acceleration vector. In a laboratory setting, stimuli for eliciting tilt perceptions include off-center rotation about the vertical axis (leading to a feeling of tilting away from the central axis of rotation) and horizontal linear oscillation at low frequency (leading to a feeling of tilting away from the gravity vector during each deceleration that must accompany a reversal in direction). In aerospace operations, strong accelerations of the aircraft (e.g., forward thrust during jet-assisted take-off) can induce a false perception of tilt known as the “somatogravic illusion” (Gillingham & Krutz, 1974). Similarly, an overall increase of the net $+G_z^{11}$ force (e.g., during a banking turn such as occurs in an aircraft) can cause a complex tilt sensation during head movement (known as the “G-excess effect”; see Chelette, Martin, & Albery, 1992; Guedry et al., 1973; Guedry & Rupert, 1991). Rolling back to the straight and level after a prolonged banking turn can cause a pilot to feel a false perception of tilt known as “the leans” (Gillingham & Krutz, 1974).¹² The feeling of self-inversion is a special case of perceived tilt. A perception of inversion can be induced in a VE by turning the user upside down, or it can be done by less direct means. Turning a user upside down in a VE could augment the “ground-based” simulation of the inversion illusion that occurs in aviation operations during $-G_z$ (usually combined with $+G_x$) accelerations (e.g., rapidly leveling off following a fast, steep climb), which is a special case of the somatogravic illusion. The same technique could be used to simulate the inversion illusions that can occur during the sudden removal of $+G_z$ that occurs upon transition to microgravity during parabolic flight or space flight (Nicogossian, Huntoon, & Pool, 1989).

3.1.2 Perception of Rotation

The simplest way to achieve a feeling of rotation (or other curvilinear motion) in a VE is to move the user in a rotating (or other curved) path that exactly duplicates the intended simulation. When an illusion of rotation is caused by rapid deceleration following prolonged unidirectional rotation in the darkness, it is called *after-rotation*. The after-rotation sensation involves a feeling of turning opposite to the direction of prior body rotation when the prior body rotation was passively generated, but when the body rotation is actively generated (by stepping around in a circle), the after-rotation illusion is diminished and can be felt in the same direction as prior rotation (Guedry et al., 1978).

When an illusion of rotation is caused by a sudden motion of the head in an axis not parallel to the central rotation axis of the body during prolonged rotation in the darkness, it is called a “Coriolis, cross-coupling” effect and is characterized by a feeling of head or self-velocity in a curved path that is predominantly¹³ orthogonal to the axes of both body and head rotation. The aforementioned (see section 3.1.1) feeling of tilt vis à vis gravity that arises from a purely linear acceleration (usually via low-frequency oscillation) in a horizontal plane is also a perception that has an angular component, because the resultant of acceleration due to gravity and due to horizontal movement creates a rotating gravitoinertial acceleration vector that is perceived as an angular change in the direction of “up” when earth-referenced visual cues are absent or fixed relative to the observer (Howard, 1986).

3.1.3 Perception of Translation

When users' actions within a VE require them to move in a straight line, one can move them through the physical world in exactly the same manner. However, given the limited size of most buildings housing VE displays, often it is desirable to create the illusion of moving in a straight path over a longer time and distance than is actually occurring. This magnified movement perception can be accomplished via the use of a centrifuge, albeit with the introduction of some angular acceleration. The centrifuge technique is especially useful when the device can minimize the undesirable consequences of angular acceleration by having the longest possible rotation radius and by allowing for strategic combinations of radial linear translation (toward or away from the center of rotation) and capsule-centered counterrotation (on-axis capsule rotation opposite to the direction of rotation of the central axis of the centrifuge) during the off-center rotation stimulus. (For an explanation of such complex stimuli, see Hixson, Niven, & Correia, 1966.)

3.1.4 Illusory Absence of Tilt

In this case, one has the illusion of remaining in one's former orientation vis à vis gravity when one has actually tilted. This can occur when the tilt stimulus is below the threshold of detection, which is about 2.1 degrees (Mann, Dauterive, & Henry, 1949, 1974). Tilt can also fail to be perceived when the subject remains aligned with the resultant gravitoinertial force vector during off-center rotation, such as occurs during a banking turn in an airplane (Gillingham & Krutz, 1974). Finally, a failure to detect tilting of the resultant gravitoinertial force vector can occur when the individual remains seated upright while rotating off-center at a very low velocity (wherein the threshold for stimulation given by the oculogravie illusion would suggest that a tilt of the resultant that is less than 1.1 degrees would be undetectable, according to Graybiel & Patterson, 1955).

3.1.5 Illusory Absence of Rotation

In this situation, one is moving in a curved path but has the illusion of moving in a straight path or of not moving at all. This effect can occur during off center rotation below the threshold of the semicircular canals. The minimum threshold for rotation sensation is around 0.44 dg/s^2 using verbal reporting of self rotation, but can be as low as 0.11 dg/s^2 when detection of the oculogyral illusion is used as the threshold measure (Clark & Stewart, 1968). Even when the rotation stimulus is above threshold, it is possible to fail to perceive a part of the rotation stimulus during off-center angular acceleration with the nose (x-axis) aligned with the resultant of the tangential and centripetal acceleration vectors (Guedry, 1992). A failure to perceive self-rotation can also occur after prolonged constant velocity rotation, because the elastic properties of the cupula of the semicircular canal will cause it to return to resting position during prolonged constant velocity rotation. The user will feel stationary in this situation if there are no veridical visual (or other nonvestibular) cues to inform him that he is still turning. Finally, failure to perceive rotation can occur when rotating with the longitudinal z-axis of the body orthogonal to gravity (e.g., rotating as if on a horizontal barbecue spit). One variation of this stimulus results in a feeling of orbital motion of the body about a central point, with little or no change in the direction one's face seems to point, and hence no felt rotation about one's own longitudinal z-axis (Lackner & Graybiel, 1977).

3.1.6 Illusory Absence of Translation

In this instance, one has the illusion of not moving in a straight line when one is doing so. This effect can be produced by linearly translating an individual (without tilting him out of his

former alignment vis-à-vis gravity) at a speed lower than the threshold of the otolith organs, which is about 6 cm/s^2 (Melville, Jones, & Young 1978, 1988), but may be slightly lower for subjects oriented sideways to the movement (i.e., translating along the y-axis, Melville et al., 1978; Travis & Dodge, 1928, 1988).

3.1.7 Perception of Increased Weight or G-forces

When driving a real vehicle such as a car or an airplane, one is subjected to G-forces during acceleration in various directions. However, in most current VE, these forces are absent during simulated driving or flying. This absence should be no surprise when one considers the simulation of a high-performance jet airplane. For example, one would need a simulator and a maneuvering space several hundred feet long to exactly reproduce the forces on a pilot's body during a catapult launch from an aircraft carrier. However, one can readily reproduce most of the perceptual aspects of a catapult launch from an aircraft carrier in a much smaller space by rotating the pilot off-center inside a centrifuge capsule while keeping his nose pointing into (i.e., his x-axis aligned with) the resultant of the tangential and centripetal acceleration vectors (Guedry, 1992). The predominant perception will be of rapid forward and upward acceleration while pitching back. Another way to produce the feeling of G-force during centrifugation is by exploiting the linear Coriolis acceleration that occurs when a body is moved radially in a rotating environment. Due to the inertia of the user's body, he or she will feel a sideways (tangentially directed) force act on the body during (actual) displacement either toward or away from the center of rotation.

3.2 Eliciting Acceleration Perceptions Via Isomorphic Motion Stimuli

Even the most careful orchestration of visual displays, locomotion devices, and man-moving machines will not provide an acceleration experience that can pass the Virtual Reality Turing Test (Barberi, 1992; Turing, 1950) for most of the synthetic experiences in a given VE's repertoire. However, there is a way of simulating real events that has the potential to generate isomorphic motion stimuli that elicit acceleration perceptions that are indistinguishable from reality. This method involves identically duplicating the real acceleration profiles being simulated, but doing so in an alternate location from the user's virtual location. This method is similar to the concept of augmented reality, wherein users see and move through a real environment while being able to view virtual information as well. However, the purpose of the type of augmented reality presently under consideration is not to provide additional information to a user who is otherwise engaged with the physical world. Rather, the goal is to provide a physical mock-up that serves as the ambient context for a synthetic event that would be difficult or impossible to experience in the physical world. What follows are several examples of potential future applications of isomorphic motion stimuli for enhancing flight training, law enforcement training, and sports training.

3.2.1 Examples of Real Acceleration to Enhance Aviation Mission Rehearsal

During advanced mission rehearsal, military aviators flying real jet aircraft would execute all the same maneuvers and actions as they would execute during a real combat mission, except they would fly in a designated friendly airspace. Thus, the flying would be real, but the targets, enemies, and ordnance would be simulated. Aviators would view simulated targets and simulated ground or air threats through virtual displays and neutralize them either through virtual representations of weapons systems or via live fire on veridical practice targets whose position in space coincides with the virtual image and virtual targeting information represented

to the pilot. Opponents could also be real, but remote (e.g., aviators from allied countries coordinating in the exercise from their own friendly air space, located thousands of miles away). Safety of the crew and allied ground troops would be ensured by simulating (or deactivating) ordnance in all situations involving close support of ground troops, and by close monitoring from the ground and from an onboard safety observer who is not part of the virtual environment. This approach would allow for more realistic, varied, and challenging practice than is possible with current simulators or small unit training exercises. It would also provide many of the training benefits of full-scale war games on a more frequent basis, and without the same amount of preparation time, cost, danger, environmental impact, or political visibility (useful in cases where demonstration of force is not a mission goal).

3.2.2 Examples of Real Locomotion Through Simulated Environments as Part of Police Training

Law enforcement officers serving on special weapons and tactics (SWAT) teams could go armed into a physical mock-up of a house and proceed to “clear” the armed and hostile criminals resisting within (e.g., as part of hostage crisis training). This simulation would be achieved via voluntary movement through the typical “fun house” or “Hogan’s Alley” (a custom-built practice area that looks like a regular building but has bullet resistant backstops all around to enhance the safety of live-fire practice), coupled with head-mounted “look through” visual displays wherein virtual criminals and innocent people (either computer simulations or real-but-remote users sharing the virtual environment) appear suddenly and either respond to certain key verbal commands or attempt to attack the officers with various simulated weapons. Simulation of “return fire” from moving virtual opponents could be dictated probabilistically as a miss or a hit to various parts of the officer’s body, based upon the officer’s speed and skill in moving through the simulation (e.g., his skill with “quartering techniques” when rounding corners or entering rooms, his use of cover and concealment) and his speed in neutralizing threats with adequate force (e.g., his coordination with other officers, his skill with nonlethal force alternatives, the accuracy and speed of his shooting), and the likely degree of threat posed by the sort of criminals encountered in the scenario being practiced (e.g., first time mugger vs. professional terrorist; sober vs. drug influenced suspect).

Simulation of return fire could also be based on tracking technology on the bodies and weapons of two opposing teams of officers moving through one virtual space but physically located in different practice areas. The simplest example would be the case where one officer is locomoting through the Hogan’s Alley and directing live fire against the virtual representation of another officer playing the role of a violent criminal in a different Hogan’s Alley. The approach described is merely an extension of the training simulations already in use to allow live fire against projected images of actors portraying criminals (<http://teams.drc.com/fast/index.html>) and simulated fire against live opponents (www.simuniton.ca/html/welcome_simuniton.html). As the most useful features of these existing techniques are enhanced by the new virtual display features mentioned above, more sophisticated and realistic simulations will emerge. This outcome will yield obvious advantages for the training of law enforcement personnel and for certain national defense applications involving infantry soldiers (chap. 43, this volume).

In the better training devices available currently, self-motion is suggested solely by the visual stimulus, and “movement” is scripted in advance (<http://teams.drc.com/fast/index.html>). Even in some current devices where movement is not scripted, the user’s navigation and visual reconnaissance may be accomplished via nonintuitive methods such as foot switches that initiate visual scene motion, the direction of which is then determined by head pointing (www.bdi.com/How_People_are_Using.html). One of the key features distinguishing future

individual (or small unit) combat simulations will be that body movement through the VE will be real and naturally accomplished.¹⁴

3.2.3 Examples of Real Acceleration as a Feature of Sports Simulations

In sports as disparate as automobile racing, rock climbing, gymnastics, kayaking, and golf, VE that allow physical movement through nearly identical real spaces will provide a valuable training tool for Olympic and professional athletes. For example, race car drivers routinely practice alone on tracks to familiarize themselves before a race. Using virtual displays, it will be possible for drivers to do their practice runs against simulated competitors represented on an otherwise transparent (“look through”) display while driving alone on a real track at a speed reduced just enough to keep the margins of exposure to monetary and personnel risk appropriate to the practice session. If the driver makes a driving error while maneuvering against a simulated (or real but remote) competitor, he will receive error feedback but will not suffer a dangerous and expensive car-to-car collision. This type of practice would form a bridge between lone practice on the track and live competition with other drivers.

3.3 Advantages and Limitations of Using Isomorphic Acceleration Stimuli

Real acceleration provides the most direct means for eliciting acceleration perceptions in VE and allows incredible flexibility and control concerning the types of accelerations perceptions that can be elicited at any given moment. Real acceleration that is isomorphic to the psychophysics of the VE should minimize the amount of interference a VE trainer creates regarding the transfer of psychomotor skills to a real situation. For example, if the airplane-based VE previously mentioned (see section 3.2.1) is designed and executed properly, it will be able to simulate a hazardous military combat mission over friendly air space, eliciting only those adaptive effects and aftereffects that occur during a comparable real flight.

The primary disadvantage of using real acceleration in VE is that this approach will require large and often costly practice spaces. In the case of military flight training, this concern is not insurmountable because the infrastructure for real flying (of simulated missions) is already in place. For police training, the infrastructure of “fun houses” is also in place among many of the larger agencies, although numerous software challenges remain in order to enhance realism and simulate the stress of actual operations. The cost associated with introducing real acceleration into VE training for the most popular professional or Olympic sports will probably be less of an impediment than it is for the military and law enforcement. However, the technical ease of implementation and the revenue available for implementation of “virtual acceleration” will be very different for different sports. For example, implementation of virtual acceleration training could be achieved readily for either automobile racing or whitewater kayaking, but would probably be implemented for automobile racing first (despite the fact that a larger practice area is necessary), because automobile racing has greater spectator and commercial support (and thus commands greater revenue). Also, virtual acceleration training during automobile racing can be accomplished on existing automobile tracks without substantive modifications to the track itself, whereas the simulation of whitewater kayaking requires the construction of a special recycling water course with programmable high-speed currents. Some sports will be very difficult to train for via real movement through virtual spaces. A good example would be equitation, which requires the mutual coordination of perception and action on the part of a horse and rider, each of whom has profoundly different user requirements.

4. VISUAL CONSEQUENCES OF ACCELERATION

This chapter is concerned with the perception of body acceleration. However, it should be noted that many acceleration stimuli can influence the perception of a visual display relative to the user. For example, simple body tilt in darkness can make it hard for an observer to set a line of light to align with the true earth vertical. The visual effects of acceleration stimuli include the following: the Müller (or "E") effect, the Aubert (or "A") effect (e.g., Bauermeister, 1964; Clark & Graybiel, 1963; Müller, 1916; Passey & Ray, 1950; Wade & Day, 1968), the oculogyral illusion (Graybiel & Hupp, 1946), the oculogravic illusion (Graybiel, 1952), the elevator illusion (Cohen, 1973; Whiteside, 1961), and the degradation of visual acuity that occurs when viewing a head fixed display while one's body is moving (Guedry, Lentz, Jell, & Norman, 1981).¹⁵ Thus, even when a user is being exposed to a simple tilt, the VE designer must take into account the interactions between visual inputs and vestibular and somatosensory inputs for any task requiring visual estimates of the orientation of objects within the virtual scene or any tasks requiring eye-to-hand coordination. Fortunately, many of these effects will be minimized by the presence of a whole-field visual stimulus (rather than a simple visual target presented in the darkness, as in most of the laboratory studies cited). This will be true especially when the visual stimulus provides veridical information about self-orientation (Lawson et al., 1997).

5. SUMMARY

The perception of acceleration encompasses feelings of self-motion through space and self-tilt relative to the upright. The feeling that one is being subjected to unusual forces (such as occur during high-performance flight or in nonterrestrial settings) also qualifies as an acceleration perception. The techniques for eliciting acceleration perceptions in future VEs will employ either real motion or illusory motion. Real motion methods will accelerate the VE user aboard a moving device such as a centrifuge or will allow his to drive or actively locomote (as appropriate) within a real space that serves as an ambient context for the virtual environment. Illusory motion methods will induce an illusion of body motion by moving a visual, auditory, or somesthetic surround stimulus relative to the user or by having the user locomote (without displacement) on a treadmill or like device. Each of these methods has advantages and disadvantages. The methods for inducing acceleration perceptions via real motion will tend to generate a wider range of simulations and be more effective. The methods involving illusory motion will require less money and space to implement. Methods employing real or illusory motion are not mutually exclusive. When a person moves through space while receiving visual, auditory, or somesthetic information that confirms the movement, the resulting movement perception will tend to be stronger than when only one self-movement cue is present in isolation. Thus, combining different cues to elicit acceleration perceptions will be advisable whenever it is feasible. Such multisensory cueing is exactly what takes place whenever the reader goes for a stroll through the real world.

APPENDIX A: ACCELERATION AND LOCOMOTION DEVICES: TECHNOLOGIES FOR ELICITING ACCELERATION PERCEPTIONS

This appendix lists some of the current acceleration and locomotion devices available nationally, including simulators, centrifuges, and treadmills. Man-rated acceleration devices represent a fairly mature technology that is costly to implement. Hence, when sophisticated acceleration simulations are needed, new VE display and navigation systems may seek to interface with older human-rated acceleration devices already in operation. A partial list of organizations in the United States housing large acceleration devices is provided below, in Section 1 of this Appendix. (Additional information can be found in Cronin, 1998; Rupert & Gadolin, 1993; & White, 1964).

Information about locomotion devices suitable for VE applications is provided in section 2 below. The technology for building locomotion devices is not yet mature. Such devices are not as costly to build as simulators and centrifuges, but they are not cheap either.

APPENDIX B: RECOMMENDED READINGS ON VESTIBULAR FUNCTION

1 Basic Introduction

For a general introduction to the perception of body position and movement via kinesthesia and vestibular sensation, the authors recommend the textbook by Ludel (1978).

2 General Scientific Review

Excellent scientific reviews on vestibular sensation were written by Howard (1986, chap. 11, from Boff et al.,) and by Guedry (1974). The chapter by Howard provides a lucid review of vestibular structure, dynamics, neural projections, and psychophysics, ranging afield of

vestibular modality as well. The comprehensive paper by Guedry focuses on psychophysics of vestibular sensation during a wide variety of stimulus situations. Other reviews of interest have been contributed Correia and Guedry (1978), Guedry and Correia (1978), Cohen and Keshner (1988), Keshner and Cohen (1989), and others.

3 Introduction to Spatial Orientation in Flight

Two of the more readable introductory papers written on spatial disorientation vis-à-vis aerospace operations were contributed by Benson (1988) and by Gillingham and Krutz (1974). An updated version of the spatial disorientation section in Gillingham and Krutz (1974) is available in Gillingham and Previc (1996). These papers introduce the common illusions associated with spatial disorientation in flight. The original paper by Gillingham and Krutz covers acceleration nomenclature and human cardiovascular and vestibular reactions to unusual accelerations, especially high-G. Gillingham and Krutz (1974) illustrate their points vividly with 47 figures and four tables. Another excellent resource is the U.S. Naval Flight Surgeon's Manual, which has been published in many editions. Chapter 8 of the 1968 manual (Guedry, 1968) is a thorough effort with a clinical slant. (Some general information about acceleration and vibration can be found in the most recent online version of the manual at www.vnh.org/FSManual/02/SectionTop.html.)

4 Detailed Research Compendia Including Coverage of Special Topic Areas

Many of the works in this section are special edition compilations of papers by various scholars, published as the proceedings of a conference. Works of note include *Sensing and Controlling Motion*, edited by Cohen, Tomko, and Guedry (1992), *Visual-Vestibular Interaction in Motion Perception and the Generation of Nystagmus*, by Henn, Cohen, and Young (1980), *The Vestibular System: Neurophysiologic and Clinical Research*, edited by Graham and Klemink (1987), *Mammalian Vestibular Physiology*, by Wilson and Melville-Jones (1979), and *Adaptive Mechanisms of Gaze Control*, by Berthoz and Melville-Jones (Vol. 1, 1985). The book by Cohen, Tomko, and Guedry is the most recent compendium mentioned above and covers a variety of topics on vestibular and sensorimotor function. The book by Henn, Cohen, and Young provides a succinct and well organized treatment of the neural substrate of human orientation and includes an appendix describing the major mathematical models of the era. The book edited by Graham and Klemink summarizes clinical and research findings concerning the structure, function, and disorders of the vestibular system, with special attention paid to testing, diagnosis, and research in weightlessness. Wilson and Melville-Jones discuss the peripheral and neuronal physiology of vestibular function, giving a lucid explanation of the biophysics of the peripheral end organs. Berthoz and Melville-Jones review oculomotor research relevant to the topic of adaptation of gaze control during sensory rearrangement. Other notable books include Cohen and Henn (1988), Arenberg (1993), Naunton (1975), and Marcus (1992). Of these, the book by Arenberg is the longest and the most recent, giving a thorough treatment of dizziness and balance disorders that would be a worthy alternative to Graham and Klemink (1987).

5 Works on Side Effects of Virtual Environments

Chapters 29 to 32 and 37 to 39 (this volume) discuss the signs and symptoms of exposure to VE and other synthetic experiences. Earlier sources for information on unpleasant vestibular side effects of VE include McCauley (1984), Casali (1985), Kennedy and Frank (1985), the

Advisory Group for Research and Development (1988), National Research Council technical report BRL-CR-629 (1990), Chien and Jenkins (1994), Durlach and Mavor (1995), Kolasinski (1995), Stanney, Mourant, and Kennedy (1998), and Stanney et al. (1998). An early issue of the journal *Presence* was dedicated to simulator sickness and cybersickness (Vol. 1, No. 3, 1992). In this issue, Pausch, Crea, and Conway (1992) contributed a literature review and several other authors contributed important papers that have shaped current thinking about cyber sickness. A comprehensive book on virtual environments was contributed by Durlach and Mavor (1995), which includes a discussion of acceleration perceptions and side effects in chapter 6.

6 A General Human-Factors Reference Work of Relevance to Spatial Orientation

The *Engineering Data Compendium: Human Perception and Performance*, is a multivolume set edited by Boff and Lincoln (1988). This compendium of human factors findings is not limited to spatial orientation, vestibular function, or simulation, but it has succinct sections devoted to each of these topics. It is a fine “one-stop” source of information on human perceptual function in all sensory modalities. The authors recommend it highly for anyone who anticipates doing research in human factors or allied fields.

ENDNOTES

¹ To be deemed effective, the VE should produce no adverse side effects that are not also caused by the real event being simulated. Most importantly, the VE should provide good transfer of skills learned in VE training to performance in the situation being simulated. Provided side effects are appropriate and transfer of training is satisfactory, it would be advantageous for the VE to elicit consistent and controllable acceleration perceptions that are difficult to distinguish from the real event being simulated. (The stated criteria for an effective VE apply to VE that attempt to simulate real situations; criteria for effectiveness must be modified for VE that do not attempt to simulate real situations.)

² The authors prefer terms such as *somesthesia* or *somatosensation* to refer to cutaneous, muscle, and joint receptors collectively, instead of the commonly used terms *proprioception* or *haptic*. The word *proprioception* includes the vestibular modality and hence should not be used synonymously with somesthesia. The word *haptic* is applied too ambiguously at present to be meaningful. *Haptic* usually refers to “active touch”, or cutaneous exploration of the world via manual exploration. This usage helps distinguish “active” from “passive” touch and presumably recognizes that manual exploration is informed by muscle and joint receptors as well as cutaneous receptors. However, the word *haptic* has come to be applied by the VE community to encompass information derived by manual exploration, locomotion, and even “passive” cutaneous sensations applied to the torso. For these reasons, it is difficult to understand what a particular researcher means when using the term *haptic*, unless the researcher provides his own definition.

³ The term *vection* is attributed to Tschermark, 1931, 1998.

⁴ The reviews recommended in Appendix B can provide the reader with additional ideas about how to simulate a perception of acceleration that is appropriate to the desired goal of a VE (see also Boff & Lincoln, 1988.).

⁵ Such real motion is “passive” in the sense that it is not generated primarily by the individual’s muscular efforts. However, the distinction between “passive” and “active” motion is more a continuum than a dichotomy, since driving a vehicle is less “passive” than riding as a passenger,

even though driving a vehicle could be considered an example of “passive acceleration.” Similarly, coasting downhill on a bicycle is fairly “passive,” while peddling a bicycle would be considered “active” acceleration. Both types of real acceleration (“active” and “passive”) are lumped together in section 2.4.1.1.

⁶ It is possible that whole-body acceleration perceptions can also be elicited by the aftereffects of carrying a load (or being partially suspended) for long periods of time within the normal terrestrial environment (i.e., at 1 g). However, the authors predict that the effects would be restricted mostly to changes in felt sense of force and a slight loss of position constancy of the visual environment.

⁷ In addition to continuous visual motion, classical visual object motion aftereffects and illusory object motion sensations are elicited by the phi phenomenon (see Matlin & Foley, 1992); this phenomenon could be exploited to enhance feelings of self-motion, though it does not appear to be studied for this application at present.

⁸ Note also that gently jiggling the eyeball (by pushing on the eyelid) elicits the perception that the visual world is jiggling (see Teuber, 1960; Stark & Bridgeman, 1983). Whereas this type of vibration does not elicit an illusion of self movement, it might be exploited to enhance synthetic perceptions of high-frequency body oscillation or ground shaking created by other means.

⁹ However, if reversible effects can be demonstrated, acoustic energy weapons are likely to be exploited for inducing temporary vertigo, disorientation, and nausea in conflict situations requiring less-than-lethal force.

¹⁰ A different method of categorizing acceleration stimuli and perceptions is presented in Boff and Lincoln (1988). For a detailed explanation of acceleration stimuli and acceleration perceptions, see Howard (1986, chap. 11); Benson (1988); Nicogossian, Huntoon, and Pool (1989); Guedry (1992); and Gillingham and Krutz (1974). An updated version of the spatial disorientation section in Gillingham and Krutz (1974) is available in Gillingham and Previc (1996). Many of the other works cited in this endnote are discussed in Appendix B (this chapter).

¹¹ Positive G_z refers to a downward force (caused by upward acceleration) in the longitudinal axis of the head and body. Negative G_z refers to an upward force (caused by downward acceleration) in the longitudinal axis. The three cardinal head axes used in vestibular research were established by Hixson et al. (1966) as follows: (1) the line corresponding with the z-axis is a dorsal–ventral (or cephalo–caudal line) traveling along the intersection of the midcoronal and midsagittal planes and is commonly called *yaw* (for angular acceleration about this axis) or *heave* (for linear acceleration within this axis); (2) the line corresponding with the x-axis is an anterior–posterior (or naso–occipital) line traveling along the intersection of the midsagittal and midhorizontal planes and commonly called *roll* (for angular acceleration) or *surge* (for linear acceleration). The y-axis is an interaural line traveling along the intersection of the midcoronal and midhorizontal planes and commonly called *pitch* (for angular acceleration) or *sway/side-slip* (for linear acceleration). This explanation suffices to define the cardinal axes used in this chapter; a diagram and full explanation of acceleration versus force nomenclature and of positive and negative signs given to linear and angular vectors is given in Hixson et al. (1966). The reader should note that the criteria therein differ slightly from aviation nomenclature regarding the positive direction assigned to the linear y-vector (+y projects from left ear in Hixson et al. [1996] and from right ear in aviation).

¹² Related phenomena such as the “graveyard spin,” “graveyard spiral,” and “giant hand phenomenon” are mentioned in the same review.

¹³ Some preliminary evidence (Lawson, 1995) suggests that the perception of velocity in this situation is not as simple as described in the text. The actual percept may contain an additional velocity perception in the same axis as the head movement. Thus, an x-axis head movement

toward the right shoulder following prolonged counterclockwise rotation in the vertical z-axis (seated upright) seems to produce an illusory sensation of forward pitch in the y-axis and also may produce an illusory sensation of rolling in the same direction as the head movement (x-axis).

¹⁴ The type of simulation described in this section could be made quite sophisticated and multi-sensory in ways not usually considered within the context of acceleration perceptions. For example, accelerations delivered to localized body parts could be employed to enhance the somesthetic aspects of the simulation. The somesthetic perception of weapons firing could be augmented via force feedback against the firearm to simulate recoil. This could be accomplished via a small off-center mass driven in an arc by an electric motor that is mounted on the weapon frame (and set in motion by trigger pull). Similarly, an acceleration to the chest of the officer could simulate a fraction of the force generated by a pistol shot impacting the officer's ballistic vest. This could be accomplished by small mechanical or pneumatic pistons under the officer's vest.

¹⁵ The aforementioned illusions are not described herein because they fall outside the theme of this chapter. For a brief description, see chapter 3, this volume. For a full explanation, see the cited literature in this section and the recommended readings in Appendix B.

Motion Tracking Requirements and Technologies

Eric Foxlin

InterSense Inc.

ericf@isense.com

1. INTRODUCTION

The science of motion tracking is fascinating because of its highly interdisciplinary nature and wide range of applications. This chapter will attempt to capture the interdisciplinary approach by organizing the subject differently from several excellent review articles already available (Bhatnagar, 1993; Ferrin, 1991; Meyer, Applewhite, & Biocca, 1992; National Research Council, 1995). These reviews tend to break trackers into several technology categories and evaluate the merits of each technology by inferring from commonalities amongst the existing trackers in that category. This survey will instead focus on what capabilities are required for various applications and what are all the technologies and combinations that could potentially be used to realize these capabilities.

Separate examinations of tracking methods are given from the point of view of the physicist, who seeks to design new and better sensors, and the mathematician, who seeks to take whatever measurements are available from the physicist's sensors and calculate the best possible estimate (or prediction) of the object's motion. This dual taxonomy is necessary in order to support a new emphasis on hybrid tracking techniques. To simply append hybrid tracking as a new technology in addition to the usual four or five technologies would be a disservice; there are a combinatorial number of different hybrids possible, and each may behave quite differently. By categorizing physical sensing principles according to the type of observation they yield and understanding how multiple observations can be mathematically blended together while accounting for the quality of each individual observation, a rationale is provided for the design and evaluation of these many potential hybrid systems. The founding philosophy for InterSense was that in most difficult tracking applications one can obtain better results at lower cost and weight by fusing measurements from a larger or more varied set of midquality sensors, rather than a smaller or more homogeneous set of high-precision sensors. This bias will come through clearly in the emphasis and organization of this chapter.

The structure of this chapter basically parallels the development cycle of a tracking system. The rest of section 1 and section 2 discuss several categories of motion tracking applications that will be considered, and the required tracking fidelity and ergonomics associated with each of these categories. This corresponds to the identification of a market need and development of a specification for a tracker that will meet this need. Sections 3 and 4 discuss the physics and math that are used to design a tracking system to meet this specification. In section 5, consideration is given to the engineering trade-offs that are involved in the implementation of the design during the product development phase. Section 6 discusses real-time systems integration issues that must be handled correctly when interfacing a motion tracker into a larger system. If this integration is not done well the application will perform poorly no matter how good the tracking system is, so a large effort must typically be devoted to this back-end “applications engineering” support to make sure the end user can fully benefit from the tracking system.

1.1 Applications for Motion Tracking

Motion tracking has a much wider range of applications than what will be discussed herein. For example, it includes onboard navigation systems or external tracking systems for aircraft, missiles, space vehicles, ships, submarines, UAVs, mobile robots, land vehicles, smart bullets, hockey pucks, baseballs, fish, birds, mobile phones, stolen cars, soldiers in the field, or doctors in a hospital. Attention is focused here on tracking human head, limbs, or hand-held objects for purposes of interacting with three-dimensional (3-D) computer-generated displays or tele-operators. Within these computer-generated environments, motion-tracking devices have four main functions:

1. view control
2. locomotion/navigation
3. object selection/manipulation
4. avatar animation

Even with this seemingly narrow definition, there is a vast array of motion tracking applications, and it is useful to categorize them into five broad groups to facilitate the discussion of requirements in section 2:

1. Visual VEs using opaque head-mounted displays (HMDs)
2. Visual VEs using fixed-screen displays (FSDs)
3. Augmented reality using see-through HMDs
4. 3-D audio environments using headphones
5. Avatar animation

There are many types of visual display devices used in virtual environment (VE) systems, with new ones being invented every year (see chap. 3, this volume). Category 1 and 3 applications use head-mounted display (HMD)-type displays. The term HMD-type display shall be used in a broad sense to include both true HMDs and handheld relatives (e.g., virtual binoculars, palmtop or camcorder-style displays, telescope sights, etc.) or boom-mounted displays. If the display movement is tracked and the view is rendered without separately tracking the head, then it is an HMD-type display. The standard opaque HMD or handheld display is occluding, while the nonoccluding HMD-like displays include either optical see-through (OST-HMDs) or video see-through designs (VST-HMDs), as well as head-mounted projectors.

Category 2 applications use fixed-surface displays (FSDs). The FSD shall denote any stationary display surface from a desktop monitor to a virtual model display (VMD) such as the ImmersaDesk, Virtual Workbench or PowerWall on up to a full spatially immersive display (SID) like the CAVE or VisionDome. The applications we are considering use head-tracked FSDs, in which the virtual camera viewing parameters are controlled in real time by the user's tracked head position to achieve a first-person perspective, usually rendered in stereoscopic 3-D using shutter glasses, polarized glasses, autostereoscopic display techniques, or any other method. For an FSD, the display does not move, but the user's eye points must be tracked relative to the display surface in order to calculate a skewed through-the-window perspective projection. The FSD examples listed in the definition above are all of a direct-view type. Because the user's hands are in front of the display surface and visible, these are considered nonoccluding displays, which can sometimes have registration requirements akin to see-through HMDs. There are also reflected-view FSDs, in which an angled mirror is placed between the user's head and hands to occlude the hands and prevent them from blocking the display, especially if force-feedback devices are required which would block even more of the display area.

In application categories 4 and 5, tracking is not used for view control of a visual display. Category 4 is a pure auditory VE using tracked headphones to produce spatialized sounds that augment the user's perception of the real world. Category 5 concerns avatar-animation applications (see chap. 15, this volume), in which tracking is used to animate a virtual surrogate body (or part of one), usually for others to view. Although slightly outside the above-defined scope of 3-D interactive motion tracking, this application will be at least briefly discussed since third-person avatars sometimes play a role in multiplayer interactive environments.

2. HUMAN FACTORS OF MOTION TRACKING

In the previous section, the realm of VE-related motion tracking applications was divided into five major categories according to display type. The display type dictates the performance required from the head tracker just to view objects without any manual interaction. If manual interactions are used, this adds requirements for handheld tracking devices, and perhaps additional requirements on the head-tracking device. In deciding the quality of head or hand tracking required for an application, there are several possible metrics for “good enough”:

1. User feels “presence” in the virtual world (see chap. 40, this volume).
2. Perceptual stability: Fixed virtual objects appear stationary, even during head motion.
3. No simulator sickness occurs (see chap. 30, this volume).
4. Task performance is unaffected by any tracking artifacts (see chap. 35, this volume).
5. Tracking artifacts below detection threshold of a user who is looking for them.

Clearly, all of these metrics are interrelated, and without additional clarification of experimental conditions, they are not even well-defined binary threshold tests. At the current level of understanding in the field, it is not even obvious how to rank these tests from least to most stringent. For example, keeping all tracking artifacts below detection threshold would mean that if the rest of the VE system were also perfect, the user would not be able to tell whether the scene was real or virtual. This would seem to be the most stringent metric possible for “good enough” tracking, but how can one be certain the system would not cause simulator sickness due to some subtle artifacts that the user cannot consciously discern? In addition, some of these metrics, especially presence, are highly dependent on factors other than tracking performance.

TABLE 8.1
Tracking Performance Specifications

I. Static

- Spatial distortion: Repeatable errors at different poses in the working volume, including effects of all sensor scale factors, misalignments, nonlinearity calibration residuals, and repeatable environmental distortions.
- Jitter: Noise in the tracker output that causes the perception of image shaking when the tracker is actually still.
- Stability or creep: Variations in the tracker output when still that are too slow to be seen as motion but which may be observed to cause a change in the mean output position of a stationary tracker over time. This may be caused by temperature drift or random processes affecting the sensors or by repeatability errors if the tracker is power-cycled or moved and returned to the same pose. There is not a clearly defined distinction between jitter and creep, as they represent the high and low frequency portions of a continuous noise spectrum. A reasonable cutoff might be to consider any motion slower than a minute hand (0.1 deg/sec) in orientation and slower than 1 mm/sec in translation to be creep, with everything else called jitter. Creep itself might be broken down into repeatability and short-term and long-term in-run stability.

II. Dynamic

- Latency: The mean time delay after a motion until the corresponding data is transmitted. It is possible to specify the latency of the tracker and other subsystems separately, but they do not simply add up (see section 6).
 - Latency jitter: Any cycle-to-cycle variations in the latency. When moving, this will cause stepping, twitching, multiple image formation, or spatial jitter along the direction the image is moving. Again, this is a system specification and is discussed more fully in section 6.
 - Dynamic error (other than latency): Any inaccuracies that occur during tracker motion that cannot be accounted for by latency or static inaccuracy (creep and spatial distortion). This might include overshoots generated by prediction algorithms or any additional sensor-error sources that are excited by motion.
-

There are several types of tracking errors that may contribute in varying degrees to destroying sense of presence or perceptual stability, causing sickness, or degrading task performance. Different authors or manufacturers have focused on different specifications or defined them differently, and every type of tracker has its own complicated idiosyncrasies that would require a thick document to characterize in complete detail. However, Table 8.1 presents six specifications that can capture the essential aspects of tracking performance that affect human perception of a VE system while a tracked object is still (static) or moving (dynamic).

These differ slightly from the traditional specifications of resolution, static accuracy and dynamic accuracy, but they provide a description of motion trackers that maps more readily to the psychophysics of viewing virtual environments. In tracking systems whose resolution is limited by noise rather than quantization, the classical resolution would be equivalent to jitter plus perhaps some of the short-term creep, depending on the time period of averaging that was used to make resolution discriminations. Static accuracy would include fixed spatial distortion as well as long-term creep, and dynamic accuracy would include everything on the list. Qualitative specifications, such as environmental robustness, range, line-of-sight requirements, and multiple-object tracking capability are important as well and must be considered in addition to the six error performance specifications listed above for determining the suitability of a tracker for an application.

Unfortunately, very little research has been completed so far about the effects of tracker errors on the five VE quality metrics listed above. More has been written about the effects of display parameters, image realism, and update rates on presence, and indeed it is impossible to quantify the effects of tracker parameters independent of these. Until a perfect display driven by a very fast image generator is developed, experiments to evaluate required tracking performance

will not be simple. The sections below summarize the few results that have been published and offer some additional speculation, which remains to be evaluated by experiments.

2.1 Tracking Requirements for VE Applications Using Opaque Head-Mounted Displays (HMDs; Category 1)

2.1.1 *Head-Tracking Requirements*

Opaque HMD-like displays range from highly immersive wide-FOV HMDs to less immersive hand-held devices such as binoculars or arms-length flat-panel displays. The highly immersive ones by definition strive for a magnification or zoom ratio of 1. Narrow-FOV binocular-style devices, on the other hand, generally have magnification much greater than 1, and “magic lens”-type flat-panel displays vary. The bulk of this discussion will focus on immersive HMDs, assumed to have a FOV and resolution matching the human visual system, with some commentary at the end about the implications of narrower FOV or higher magnification.

Tracker parameters that have been studied the most are latency and frame rate. So and Griffin (1995) studied how lag in tracked HMDs affected performance on a target tracking task. The task was to keep an HMD-fixed cross-hair reticle on a moving target that moves around randomly with a target root mean square (r.m.s.) velocity of 2, 3.5, or 5 deg/sec. The mean radial error in tracking performance increased linearly with increasing latency when additional 40-, 80-, 120- and 160-ms delays were added on top of the 40-ms base latency. The mean radial error increased more (about 50% increase) for faster moving targets than for slower targets (about 30%). The results demonstrated that delays as small as 80 ms can degrade task performance, although the effect of smaller delays could not be measured because of the inescapable base latency of 40 ms. Recently, a system with base latency of 27 ms has been built and used to test participants’ ability to notice additional latency in increments of 16.7 ms (Ellis, Young, Adelstein, & Ehrlrich, 1999). The psychometric functions for discrimination in a two-alternative forced-choice experiment were found to be independent of base latency; sensitivity to latency does not appear to follow a logarithmic Weber law, as do most other stimuli. Participants were just as able to discriminate a 16.7-ms increase in latency on top of a base latency of 27, 97, or 196 ms, from which one might extrapolate that they would also be able to discriminate a 16.7-ms latency from no latency. This is possibly bad news for those wishing to develop a VE that users cannot tell apart from reality, but it does not necessarily imply that there is also decreased task performance at such low levels of latency. Ellis, Adelstein, et al. (1999) studied the relative importance of latency, update rate, and spatial distortion to a variety of metrics related to tracking task performance, perceptual stability, realism, and simulator sickness. The task involved manually tracking a target in a virtual world presented via an immersive HMD, so it is not certain that the results are entirely due to head-tracking performance. It was found that frame rate and latency had a significant impact on task performance and perceptual stability, with latency having a much more dramatic effect. However, this study only went down to a minimum latency of 80 ms, which was already known to degrade tracking performance, so it does not answer the question of whether extremely small latency differences found to be subjectively noticeable are also detrimental to task performance.

Ellis, Adelstein, et al. (1999) also evaluated the impact of spatial distortion on task performance and other metrics. The spatial distortion studied in these experiments consisted of an upward curling of about 15 to 30 cm in the corners of a 1.2×1.8 m working volume. Since the distortion affected both head and hand trackers, participants would only perceive the difference between two relatively nearby points, and this difference was changing relatively

slowly. Not surprisingly, this gradual change in head-to-hand transformation did not have a significant correlation with simulator sickness symptoms or major impact on performance, but it did create a small increase in the Cooper-Harper workload scale, which is highly correlated with perceptual stability and normalized r.m.s. tracking error. It can be conjectured that distortions with higher spatial frequencies would produce greater impacts on all metrics, because they would require more adaptation for a user moving around in space.

No research has been reported yet on the effects of jitter on VE users, although it seems obvious that jitter which is visible will reduce the illusion of presence and may even contribute to simulator sickness. The threshold of detectable jitter is not known. From experience, it seems that jitter of 0.05 degrees r.m.s. in orientation and 1-mm r.m.s. in position is generally unnoticeable in an HMD with magnification of 1, but becomes fairly visible in a virtual binoculars simulator with 7 \times zoom. Note that when viewing distant virtual objects, tracker position jitter becomes irrelevant, and orientation jitter multiplied by zoom factor is all that matters. For viewing close objects, translational jitter becomes dominant. It is an interesting question whether humans are sensitive to perceived jitter in world space or screen space (pixels) or some combination. If the former, than humans might be psychologically more forgiving of an object jittering 2 pixels at 1 meter apparent depth (4 mm in world space) than an object jittering 1 pixel at 10 meters apparent depth (2 cm in world space). Other factors that affect perception of jitter are display resolution and whether or not graphics are antialiased.

Latency jitter has also been largely neglected in works examining the effect of latency on presence, simulator sickness, and task performance. One study examined the effect of artificially imposed sinusoidally oscillating frame rate variations on task performance, using a task of grabbing a moving-target object and placing it on a pedestal in a head and hand-tracked HMD virtual environment (Watson, Spaulding, Walker, & Ribarsky, 1997). This study found that at “higher” frame rates of 20 fps, superimposing oscillating frame time variations of 10 to 20 ms amplitude on a 50-ms average frame time did not interfere significantly with task performance. However, at lower frame rates of 10 fps, varying the mean 100 ms frame time by $+/-$ 60 ms did cause performance degradation if the oscillation was slow enough. This is probably because at slow oscillation frequencies, there would be quite a few frames in a row where the frame rate was only 6 to 8 fps. It should be noted that although the experiment introduced a high percentage of frame rate variation relative to the mean, the percentage of latency variation was much less because the system latency without artificially introduced delays was already 213 ms.

Although latency variations for a fast frame rate system were not found to degrade task performance much, our subjective experience is that they cause a variety of very distressing artifacts such as image and object stepping, multiple image formation, twitching, and jittering during head rotations. For a fixed latency system, the world appears to shift at the start and finish of a head rotation, but during the constant speed portion of the rotation the world appears stable, although displaced from its normal orientation by an angle proportional to the head speed times the latency. If there is latency jitter, then during the constant speed rotation the world will jitter by an amount proportional to the latency jitter times the speed of rotation. Interaction with the refresh rate of the display device will cause additional effects such as multiple imaging that are explained in more detail in section 6. More quantitative data is needed, but our experience with systems indicates that for very smooth apparent motion it is important to keep latency jitter below 1 ms.

2.1.2 Hand-Tracking Requirements

The most typical interactive VE uses a head-tracker on the HMD for view control and a tracking device held in the hand for object selection and manipulation. The hand or device

it holds (called manipulandum from here on) cannot be seen directly, but a graphical representation is provided that is used to select and manipulate virtual objects. If the graphical manipulandum is displaced from the real one, the absolute accuracy of tracking is relatively unimportant. It will suffice that translating or rotating the real manipulandum will cause the virtual one to follow in a smooth and predictable manner. With practice the user's eye-hand sensorimotor loop adapts to the displacement (see chap. 31, this volume). Good control and task performance can occur after adaptation is substantially complete, but the presence of significant latency interferes with this adaptation (Held, Efstatheou, & Green, 1966). Also, the user will be relatively inefficient or even disoriented during the period of adaptation and may spend a lot of time trying to locate the visual icon of the manipulandum. After adaptation, there may be negative aftereffects when returning to normal reality (see chap. 38 and 39, this volume). To avoid these problems, one may attempt to match the position of the visual representation to the actual position of the manipulandum so that the user can exploit natural proprioception without adaptation. This will produce a very natural and easy-to-learn interface if the absolute accuracy of the tracking system is better than the accuracy with which proprioception can sense hand position with the eyes closed. Due to visual capture (see chap. 22, this volume), the seen virtual manipulandum may be perceived as consistent with the felt real one even if tracking errors are somewhat large, but experiments need to be done to determine at what level of unpredictable tracking error this leads to noticeable sensory conflict and side effects. Whether the virtual manipulandum is colocated with or displaced from the real one, latency in tracking the manipulandum probably has equal consequences. Held et al. (1966), Ellis, Young, Adelstein and Ehrlich (1999), and Ware and Balakrishnan (1994) discuss the effects of this latency.

2.2 Tracking Requirements for VE Applications Using Fixed-Screen Displays (FSDs; Category 2)

2.2.1 Head-Tracking Requirements

There is no experimental data yet, but theoretically, head-tracking requirements for FSDs are far less demanding than for HMDs (Cruz-Neira, Sandin, & DeFanti, 1993). The primary reason is that changing head orientation to first order does not change the displayed scene. With HMDs, the most noticeable tracking artifact is orientation latency, because every time the head turns by any amount the displays must be immediately updated with images corresponding to the new look direction. Even a very small orientation tracking latency causes the whole virtual world to first rotate with the head, then settle back to its expected position, resulting in a disturbing loss of perceptual stability. With an FSD, the appropriate images for all allowable look directions are already on the walls and can be seen immediately as soon as the head is turned toward them, without having to redraw anything. Head translation does require redrawing the screens to update the off-axis perspective projections, but these changes are slight for small head translations, so moderate translational tracking latency is not too noticeable unless one makes unusually quick translations. Sensitivity to translational tracking errors is less problematic in an FSD than an HMD when viewing close objects, but worse for distant objects (Cruz-Neira et al., 1993).

Virtual environment FSD displays are almost always rendered in stereo, so the real tracking requirement is to track the 3-DOF position of each eyeball in order to render the left and right eye perspective views. Since it is easier to attach a sensor to the head than to each eyeball, this is usually accomplished by tracking the position and orientation of the head and using this orientation to calculate the positions of the two eye points as displacements from the head position sensor. There is therefore some sensitivity of the displayed images to head orientation tracking errors, but these errors only cause changes in the separation between the virtual eye

points used to create stereo. How much these temporary contractions in the virtual interocular distance affect stereoscopic fusion or depth perception for a given quality of orientation tracking still needs to be determined.

2.2.2 Hand-Tracking Requirements

While head-tracking requirements in FSDs are comparatively lenient if one only wishes to use the display for visualization, most FSDs are used for interactive design activities in which tracking one or more manipulanda is essential, and here the requirements are essentially the same as in category 1 applications. With reflected-view FSDs the real manipulandum is hidden behind the mirror and only a virtual representation can be seen, so tracking requirements should be equivalent to opaque HMD applications where the same conditions hold. In the direct-view arrangements such as a CAVE or Virtual Workbench, the virtual representation of the manipulandum is sometimes displaced from the real one so that it does not need to be accurately registered. In this case, the user is looking directly at the virtual manipulandum and the same requirements for latency, accuracy, and jitter should apply as in the previous cases. However, the real manipulandum may be visible in peripheral vision, and this may make the user more able to discern latency of the virtual relative to the real. Much more critical however are applications where an attempt is made to keep the virtual manipulandum precisely overlaid on the real manipulandum. Any errors in tracking are easily detected as visual misregistration, so the high tracking-accuracy requirements of augmented reality (AR) apply. It should be noted that such attempts are also frustrated by the impossibility of focusing the eyes simultaneously on both the real manipulandum held at arm's length and virtual one displayed on the screen way behind it. Therefore most practitioners display the virtual manipulandum at least slightly displaced from the real one, which also eases tracking requirements somewhat.

2.3 Tracking Requirements for AR Applications Using See-Through HMDs (Category 3)

2.3.1 Head-Tracking Requirements

Augmented reality systems, which overlay virtual annotations precisely on top of real objects in order to guide the user who is performing manual operations on these objects, are only useful to the extent that annotations are accurately registered with objects, and thus absolute accuracy of the tracking system takes primary importance. This is in sharp contrast with the situation for opaque HMDs, where jitter, latency, and latency jitter are crucial, but spatial distortion and creep are rarely noticed. For typical AR applications, the most important tracker specifications are latency, spatial distortion, and creep, because these cause visible misregistration. Jitter and latency jitter are also undesirable because they cause the annotations to shake or vibrate, but at least the entire world does not jitter as it does in immersive HMD applications, so the risk of simulator sickness is lower. The causes of registration error have been discussed and analyzed in the AR literature (e.g., Drascic & Milgram, 1996; Holloway, 1997). The consensus is that latency is usually the worst offender, but once that is addressed, optical distortion caused by the HMD optics must be tackled before millimeter-accurate tracking can be appreciated.

Not all AR systems require every virtual object to be precisely registered on a real object. Displaying virtual objects that appear to be floating in midair is useful for AR gaming, in which virtual beasts might jump through windows and attack the player, or for shared AR visualization, in which a 3-D model or data set might hover above a table while multiple participants view it from different angles. Nothing has been written about tracking performance requirements for this mode, but one would guess they will be slightly less demanding than for

direct overlay applications because precise registration to the millimeter or even centimeter level may not be required. Thus a slight spatial distortion such as a systematic offset or nonlinearity may be less noticeable, but sensitivity to latency is probably nearly the same. The threshold for noticing latency in both types of see-through HMD applications is thought to be lower than for immersive HMDs because there are real objects having zero latency visible for comparison. On the other hand, unconscious effects of latency such as decreased presence or simulator sickness are probably worse in opaque HMDs because the whole world loses its perceived stability.

2.3.2 Hand-Tracking Requirements

Tracked manipulanda are generally less discussed in the AR area, because the most common AR applications involve guiding a user to perform operations using a real tool on a real object. Since object–tool interaction provides its own visual and haptic feedback, virtual graphics are usually used just to annotate the object that needs to be acted upon. In this case the primary purpose of tracking the tool would be to provide feedback to the AR application software about whether an action has been completed. For example, if the AR program prompts the user to turn a certain bolt 90 degrees, it could determine, by tracking the wrench, when the bolt has been turned the correct amount, then automatically prompt the next action. To do this, the tool would need to be tracked with the same translational accuracy as the HMD in order to determine unambiguously when the actual tool has engaged the actual object. The orientation tracking requirement for the tool may be less stringent than for the HMD (which requires an orientation accuracy of about 0.1 degrees to register an annotation to within 1 mm at arm's length).

2.4 Tracking Requirements for Auditory VE Applications Using Headphones (Category 4)

The best 3-D-spatialized sound is generated using headphones to deliver to each ear specifically processed audio streams that vary as a function of the spatial relationship of the head to the sound source (see chap. 4, this volume). When headphones are used together with an HMD, the tracking requirements imposed by the visual display mode generally take precedence because visual acuity is higher than auditory localization acuity. However, in an FSD-presented VE or a real environment with no visual display, the need to track head orientation is driven by the need to make the sounds appear to come from a certain stable direction or object in space even as the head rotates. It is thus reasonable to ask what quality of head-tracking is required to fool the user into believing the sounds are coming from a fixed source location while the user moves through the space.

The directional resolution of binaural localization is best, about 1 degree in azimuth and 15 degrees in elevation, directly in front of the head (see chap. 4, this volume). This implies that orientation tracking jitter and short-term stability of better than 1 degree is all that is required to make sure a sound source does not appear to wobble around while the user's head is still. Accuracy of 1 degree is certainly sufficient to make a sound appear to come from the direction of a certain object, and may be needed if the user is blindfolded or cannot look at the source. However, if the listener can see the alleged sound source, then a phenomenon called visual capture or "the ventriloquism effect" makes the sound seem to emanate from the visual object, even if the auditory cues indicate a somewhat different direction (see chap. 22, this volume). Auditory depth perception is even weaker, so it follows that modest resolution and accuracy for both orientation and position are sufficient for pure auditory displays. Less is known about the temporal response of the binaural localization system. Logically, if there is a system latency

of Δt and the head pans at a constant angular rate ω the apparent location of all sound sources would shift by angle $\omega\Delta t$ in the direction of the head rotation, just as visual objects do in an HMD. Therefore, the orientation tracking latency requirement for perfect realism in an audio-only display may be just as critical as for an HMD. However, the ventriloquism effect may be able to compensate for this apparent auditory shift if it is only several degrees, so the detection threshold for latency in a spatialized audio system may actually be significantly higher than for an HMD. It is also unknown whether this auditory sensory conflict can contribute to simulator sickness.

2.5 Tracking Requirements for Avatar Generation Applications (Category 5)

Commercial full-body motion tracking systems are sold primarily for three application areas: biomechanics and gait analysis, motion capture, and performance animation. Avatar generation in VE applications (see chap. 15, this volume) is most similar to performance animation, which differs from the motion capture done for film special effects or medical diagnostics primarily in that it must be done in real time, and that motion that looks lifelike is usually sufficient even if not completely accurate. In VE applications, body avatars may be presented to the person being tracked, or to third-person viewers who may be other participants in a multiuser VE or nonparticipating trainers.

First-person avatars are unnecessary in category 2 and 3 applications because users can see their own real bodies. In category 1 displays, users who look down and see no legs may feel disembodied and lose some of their sense of presence in the virtual world. If a VE involves manual interaction, then at least avatars for the manipulanda (hands or handheld tools) must be presented. Motion tracking requirements for these manipulanda have already been discussed with respect to the manual interaction modes of category 1, 2, and 3 displays. In most systems, avatars of these manipulanda are presented as isolated floating objects, leaving the user the feeling of having invisible or nonexistent arms or even hands. This may not be important in a lot of applications, since visual feedback from the manipulanda is enough to accomplish interaction tasks. If it is psychologically desirable to have the hands and forearms that hold the tool visible, they can be drawn approximately most of the time without additional sensors by using inverse kinematics (IK, section 3.1.3). Nothing is really known about the required accuracy of representing these, but since the user's gaze and attention will usually be focused on the tip of the manipulandum, the forearm will only appear in the peripheral view and may not need to be drawn very accurately. On the other hand, if the user looks at an arm that is only tracked by IK and moves his elbow, he will see that the motion of the avatar does not follow correctly, which might defeat the purpose of rendering it. With the limited field of view available in current HMDs, the user will have great difficulty looking at his own torso, so it is rarely important to provide full-body tracking in these applications. The legs may be rendered if desired by a crude algorithm such as placing the feet directly under the head when standing, or in front of the chair when seated. Occasionally an application will warrant actually tracking the legs.

Avatar display to third-person viewers is more likely to provide a sufficient reason for full-body tracking. In a multiparicipant simulation, a given player knows basically what he is doing himself—standing, squatting, or crawling, for example—with visual feedback of his own body. Other players, however, have no such information, and it may be important. Is the other player aiming a gun at me or holding up both hands in surrender? Unlike the precise head and hand tracking that is required for VE navigation and interaction, this information requirement is often qualitative in nature. Duplicating the precision tracking sensors that are used for the head and hands on all other body segments may be more costly and cumbersome

than necessary. Furthermore, line-of-sight problems, which are endemic to all high-accuracy tracking technologies, are multiplied when trying to put sensors all over the body. Sections 3.1.2, 3.1.3, and 3.2.4 present approaches, which could potentially provide lifelike motion with greater freedom and simplicity than today's prevalent optical and magnetic body-trackers.

3. PHYSICS OF MOTION TRACKING

The previous sections have focused on the first two stages of a motion-tracking-system life cycle: Identification of the type of application for which a tracking system is required, and analysis of the performance requirements for that application. This section focuses on the next phase: choosing appropriate basic physical sensing technologies to measure motion in the intended environment. Designing a sensor to make a specific measurement, for example, a distance between two points, is a matter of selecting an appropriate physical principle to exploit, so this section will summarize various physical laws and forces that are available and how they may be used.

Classical physics views the world as a collection of particles that interact with each other through four fundamental forces: strong, weak, electromagnetic, and gravitational. The primordial branch of physics, mechanics, studies the motion of material bodies (particles or systems of particles such as rigid bodies) in response to these forces. The study of mechanics includes kinematics, which aims to describe geometrically possible motions of objects without regard to the forces that cause those motions, and dynamics, which reveals the motions that will actually occur, given both kinematic constraints and existing forces and mass distributions.

For classical mechanics, which is adequate for describing the motion of human heads, limbs, and handheld objects, all motion follows from Isaac Newton's laws of motion. This discussion therefore starts by looking at the kinematics (section 3.1) and dynamics (section 3.2) of human motion from a simple Newtonian perspective to see what tracking methods they may reveal. The analysis of the mechanics of large numbers of colliding molecules in air leads to acoustics, which is examined in section 3.3, as another rich source of tracking technologies.

Of the four fundamental forces, strong and weak forces only operate over extremely short distances inside the nuclei of atoms, and therefore have no obvious application in motion tracking sensors. A third fundamental force, gravitation, is indeed usable for motion tracking systems. Unlike the other three forces, gravity affects every particle with mass and therefore plays a role in the dynamics of every system on the earth. Therefore it is impossible to discuss the dynamics of motion in section 3.2 without introducing the role of gravity, so the possible use of gravity in tracking systems is discussed there instead of creating a separate subsection. The final fundamental force, electromagnetism, has the richest variety of manifestations that are useful for remote sensing of object position and orientation. Section 3.4 discusses the proposed use of electric fields for tracking, and section 3.5 surveys the use of magnetic fields, which have been the most common means of tracking until recently. Sections 3.6 and 3.7 present techniques for exploiting electromagnetic waves in the lower and upper halves of the electromagnetic spectrum respectively.

3.1 Kinematics: Mechanical Tracking

In classical mechanics, a particle is represented as a point in space, with a constant mass, m , and a time-varying position, $r(t)$, specified by three Cartesian coordinates $x(t)$, $y(t)$, and $z(t)$. Tracking this particle would consist of reporting, whenever asked, the then-current 3 DOF of $r(t)$, and is therefore called a 3-DOF (position-only) tracking problem. In addition to its position $r(t)$, the particle has a velocity $v(t)$, which is the derivative of the position vector,

$v(t) = r'(t) = (x'(t), y'(t), z'(t))$. According to Newton's second law, this velocity evolves according to $v'(t) = a(t) = F(t)/m$, where $F(t)$ represents the sum of all the forces acting on the particle. In the absence of external forces, the velocity remains constant (Newton's first law), and one could track the particle with no further measurements once one had obtained the position and velocity at any point in time. This is a complete statement of the kinematics of an unconstrained point particle and captures the essence of the world's first motion tracking technique, *dead reckoning*. Sailor's slang for "deduced reckoning," dead reckoning was used by early mariners to calculate vessel position by knowing the starting point, velocity, and elapsed time.

Your head is hopefully not a point particle. It is better approximated as a *rigid body*, which is modeled as a system of many particles constrained to maintain constant distances between one another. A rigid body requires 6 DOF to specify its pose (position and orientation), from which one can calculate the 3-DOF positions of all point particles that make up the body. The kinematics of a rigid body are somewhat more complex than a point particle, including an additional set of three nonlinear equations to relate the time derivatives of the three Euler angles that describe the orientation to the angular velocity components. Kinematics really gets interesting in the study of multiple rigid bodies interacting through constraint equations, such as a robotic arm or a human body. Kinematics of such linkage systems can be applied to motion tracking in three ways, outlined in the following three sections.

3.1.1 Fixed-Reference Forward Kinematics: Mechanical Linkages and Pull Strings

Perhaps the most straightforward approach to head tracking is to make some kind of direct physical connection to the object being tracked, the displacement of which can be easily measured using potentiometers, optical encoders, rotary or linear variable differential transformers, or cable-extension transducers. The first HMD was tracked with such a mechanical contraption (Sutherland, 1968). Simplicity of mechanical design has dictated the two most common linkages for 6-DOF measurement: a single segment that extends telescopically, or two rigid segments jointed together at an "elbow." In either case, the arm is attached at one end with a 2-DOF "shoulder" joint to some fixed reference base, and at the other end is attached with a 3-DOF "wrist" to the object being tracked. The main causes of lag or inaccuracy are flexion of the linkages and transducer quality. The linkages can be made rigid if they are short, and mechanical encoders are available with extremely good precision and fast response.

The biggest problem with mechanical arm trackers is range. Making the arm segments longer lowers the mechanical resonance frequency, which may lead to unacceptable lag or oscillation. It also increases the inertia felt by the user. Even if one is willing to make such sacrifices to achieve larger range, the range of a two-segment arm is ultimately limited by ceiling clearance for the elbow as it folds upward. As Meyer et al. (1992) point out, they are not very "sociable," because multiple arms cannot be used easily in a shared space. Mechanical-arm tracking remains an attractive alternative where the infrastructure needs to be present anyway—boom supported displays (see chap. 3, this volume) and force feedback devices (see chaps. 5 and 6, this volume) are prime examples.

Another mechanical approach to head tracking uses pull-string encoders mounted on the wall or ceiling, with the free ends of the pull strings attached to the object being tracked. High-precision instrumented pull strings, called cable-extension transducers, are available at low cost for industrial distance measurement applications. There are two ways to measure head position using strings. The first method uses three pull strings with the free ends of all three strings attached to a common point. The Cartesian position of the point in space

is found by trilateration. A second method would be to use a single pull string to measure distance and also direction. The direction the string departs the reel box could be measured by running the string through a hole in a very light, low-friction joystick on its way out from the box. It should be noted that to get faster response requires a tighter string-retraction spring, which might result in an annoying tugging if the forces from the various pull strings do not cancel each other out well. Like mechanical arms, pull-string arrangements have been used to provide force feedback (Ishii & Sato, 1994) and perhaps could also serve to help levitate a display.

3.1.2 Moving-Reference Forward Kinematics: Biokinematic Dead Reckoning

The mechanical trackers in the last section are grounded to a fixed reference base, thus limiting the range and introducing a cumbersome mechanical linkage system. When tracking creatures with rigid skeletons, there is a mechanical linkage system already present that could be used for tracking purposes. Most casual users will not allow you to instrument their skeleton directly with joint angle encoders, but you can approximate the joint angle measurement using strapped-on goniometers. Goniometers (joint angle measurement devices) may consist of two rigid plastic parts that strap on, for example to the thigh and shin, with an instrumented hinge between them that measures the knee angle. Alternatively, they may dispense with the rigid attachments and use a flexible bend sensing material based on fiber optics or conductive foam that changes resistance when it bends. In fact, virtual goniometers with no physical connection can be implemented by attaching sourceless orientation sensors to each side of the joint, or a magnetic source to one side and sensor to the other, and calculating the difference angle between them. Molet, Boulle, and Thalmann (1999) attached magnetic sensors to each body segment, then drove an animation of a human using only the angular differences between the sensors. They cite several advantages over the usual technique of using magnetically determined 6-DOF poses directly. In all cases, the tendency of strapped on devices to slip and the inevitable movement of flesh relative to the bones limit accuracy. To achieve higher accuracy, some vendors have connected from one goniometer to the next using rigid rods, producing in effect an exoskeleton for tracking. This is more cumbersome than isolated goniometers at each joint, but allows freer movement than a grounded mechanical tracker.

Whether measured by goniometers, an exoskeleton, electromyography (Suryanarayanan & Reddy, 1997), or a body-suit, the measured joint angles can be used to calculate the pose of each segment of the body, relative to a root node at the pelvis, using simple forward kinematics calculations. Joint angle data completely determines the *shape* of the whole body, but the position and orientation of the body as a whole must be determined by other means, for instance by tracking the 6-DOF pose of the root node. Unfortunately, this root-node tracking system turns an otherwise self-contained tracker into a system that must make reference to the external environment, introducing usual limitations such as range or line of sight.

It may be possible to track the position and orientation of the whole body just using self-contained goniometry if certain assumptions are made. For example, if it could be assumed that at least one foot is flat on the floor at all times, then that foot could be treated as the root node while it is in contact with the floor (perhaps determined by sensors on the soles). As long as the contact is maintained, the position and orientation of that foot are known to remain constant. During this time, the pelvis can be tracked relative to the grounded foot and the moving foot relative to the pelvis, all using just forward kinematics. When the moving foot lands it becomes the root node, and its current pose is maintained constant as the reference

for the whole body until it loses that status. Errors will gradually accumulate as a percentage of the distance traveled, but it should work much better than an ordinary pedometer, in that:

- It can keep track of height changes as the user climbs stairs.
- It keeps track of direction changes and therefore position, not just total distance traveled.
- Each stride is individually measured, not just assumed to be the average stride for the user.

If long-term position accuracy must be maintained, then some method of correcting the accumulated position errors must be devised, perhaps based on map-correlation techniques or some simple light beams that are intercepted by photoelectric sensors on the ankles as the user walks through doorways or near landmarks.

This concept remains to be tried in practice. It may need to be augmented with some accurate foot-roll sensors to compensate for the heel-to-toe roll during normal walking, and the accuracy would depend critically on the quality of the ankle goniometers, because any error there would cause the whole body to be tilted incorrectly. It would fail if the user runs or jumps or lifts both feet while sitting. An enhanced version called biodynamic navigation is introduced in section 3.2, which in theory may be able to handle these cases better.

3.1.3 Inverse Kinematics

A final application of kinematic calculations, again to the problem of whole-body tracking, is the use of inverse kinematics (IK) to deduce the pose of the whole body when only the poses of a few extremities, usually the head and hands, have been measured. Inverse kinematics problems are intrinsically more complex than forward kinematics, but a great deal of effort has been invested in developing algorithms to solve them, especially in the robotics community. In robotics, the desired pose for an end effector (i.e., robotic hand) to accomplish a task is specified, and the robot must figure how to control all the individual joint angles to get to the end effector into this pose. In a manipulator with redundant degrees of freedom, there may be a large number of different combinations of joint angles that result in the same end-effector pose, and the IK algorithm must solve for the combination that is optimal in terms of maximum speed, minimal work, or some other criterion. In the human-motion capture problem, the human brain has already solved this problem and controlled the joint angles to get the hand to a desired position. A sensor measures the pose of the hand and uses an IK algorithm to try to guess what is the most likely combination of poses for the rest of the body segments resulting in the measured end-effector pose. Discomfort factors may become part of this calculation. The amount of “guesswork” can be reduced by using more sensors (for example, by adding another sensor on the shoulder or the back), but the whole purpose of IK is to capture full-body motion using a minimal number of sensors. Badler, Hollick, and Granieri (1993) used a fairly minimal set of four sensors, which happens to be the number provided by many commercial 6-DOF tracking systems, to control an animated figure called Jack by inverse kinematics (see chap. 15, this volume). The sensors were placed on the head, hands, and waist. First, the spine was modeled as a single flexible rod with two axes of flexion and one of torsion, controlled by the waist and head sensors. Next, the arm positions were estimated by IK using the measured hand positions and shoulder positions consistent with the spine torsion. Finally, Jack’s center of gravity was calculated from the updated upper body configuration, and the legs were moved along animated stepping sequences to positions that could support the body mass.

3.2 Dynamics: Gravimetric and Inertial Tracking

3.2.1 Accelerometers and Gravimetric Tilt Sensing

An accelerometer is basically equivalent to a proof mass suspended in a housing by a spring and constrained to slide only along the sensitive axis. The displacement of the proof mass from the rest position provides a reading of the nongravitational acceleration acting on the accelerometer, traditionally called specific force, \mathbf{f} . Because gravity affects both the proof mass and housing equally, the accelerometer does not directly sense the acceleration due to gravity (an accelerometer in free fall reads zero), but when it is not accelerating, such as when resting on a table, it reports an acceleration of 1 g upward, which is due to the upward push of the table to keep it from falling. Thus, a stationary accelerometer in Earth's gravity field produces an output proportional to the sine of its tilt angle with respect to the horizontal, and can be used as an inclinometer. A high-quality servo-accelerometer can have an accuracy of $10 \mu\text{g}$, which is sufficient to measure a tilt angle of 0.0006 degrees, an order of magnitude smaller than the vertical deflections due to gravity anomalies. Even extremely low-cost silicon accelerometers based on micro-electro-mechanical-systems (MEMS) technology can measure pitch and roll of a static headset to within a degree or so. The so-called sourceless head-trackers that were included with consumer HMDs of the early 1990s were based on this principle, using an inclinometer to measure pitch and roll, and a compass for yaw. The problem is that any inclinometer, whether it is made from two horizontal accelerometers, a mechanical pendulum, or a fluid-filled bubble level, must be acceleration-sensitive in order to sense gravity. Any real horizontal accelerations will add to the apparent vertical component that cancels gravity, producing a resultant that is no longer vertical. Even moderate head motions produce "slosh" errors of 20 to 30 degrees. This is a physical limitation that cannot be overcome through improved sensor design. Judicious adjustment of damping, pendulosity, and rotational inertia can decrease the frequency response to horizontal accelerations, but the low-frequency motions characteristic of head translation will always come through if the device has fast enough dynamics to be useful. A sourceless orientation-tracking alternative without slosh is presented in the next section.

3.2.2 Gyroscopic Orientation Tracking

Despite their tremendous potential performance advantages, the use of gyroscopes came relatively late to human-motion tracking (Foxlin, 1993). Before this, gyros were built with spinning wheels, or lasers and were too large and expensive for human motion tracking, and mechanical ones also produced distracting inertial reaction torques and noise. Motivated by the automotive market, the 1990s saw the commercial introduction of a new class of much smaller and cheaper gyros, now called coriolis vibratory gyroscopes (CVGs). A CVG is a kind of mechanical gyro (as opposed to optical gyros such as the ring laser gyroscope and the fiber-optic gyroscope), but it requires no spinning mass. Instead, a proof mass is made to oscillate at a fairly high frequency, usually in the tens of kHz, and a pickoff is provided to measure the secondary vibration mode caused by the Coriolis force $\mathbf{F} = \boldsymbol{\omega} \times \boldsymbol{\nu}$, which pushes the mass to vibrate in a direction perpendicular to the primary driven vibration. CVGs have been implemented with a wide variety of different geometries—vibrating rings, hemispherical shells, tuning forks, vibrating wheels, cylinders, and triangular or rectangular prisms. They have been made from quartz, ceramic, metal, and silicon elements, and the vibrations are caused and detected using piezoelectric, magnetic, electrostatic, or optical effects. An overview of the physics of CVGs is provided in Lynch (1998). In particular, the micromachined silicon CVGs have the potential in the long term to become extremely small and inexpensive, and possibly

even combine three-axis sensing with electronics on a single chip. Such developments will make MEMS gyroscopes even more attractive for widespread deployment in human-motion tracking applications.

Some gyros measure orientation directly, as with vertical and directional spin-position gyros, which maintain spatial direction of the spin axis despite case motion by using isolation gimbals. Most modern gyros do not have gimbals, and they measure the angular rate of rotation around a sensitive axis. If three such rate gyros are mounted with orthogonal sensitive axes, the three angular rate signals can be integrated together to keep track of the current orientation of the sensor assembly relative to where it started.

Regardless of the sensor technology or orientation tracking mechanization, gyroscopic tracking provides a number of performance advantages that are crucially important to interactive graphics applications. Because they are self-contained, inertial sensors can track with undiminished performance over an unlimited range without any line-of-sight or interference concerns. This is a significant advantage over all externally referenced tracking technologies, which cannot increase the working volume without degrading the signal-to-noise ratio and interference susceptibility. A second crucial advantage is extremely low jitter. Gyroscopes measure angular rate with very low noise, approximately 0.001 deg/sec for midquality gyroscopes. This produces no visible angular jitter, even at very high zoom ratios. Even with very low-cost gyros, which currently have noise levels closer to 0.5 deg/sec, the angular rate signal needs to be integrated, and in the process the noise is attenuated by the low-pass filtering effect of an integrator, so that the resulting angular jitter of about 0.02 degrees is invisible in VE applications. A third important advantage of gyroscopic rotation tracking is speed. The outputs can be sampled and the orientation updated as often as desired. This can even be done right before a display refresh for final image shifting (see section 6.2). Because of the low jitter of gyroscopically measured orientation, there is never a need to perform low-pass filtering for noise reduction, and the latency can be a fraction of a millisecond. What's more, the inertial angular rates measured by gyros can be used to perform prediction with several times greater accuracy than without them (see section 4.4). Jitter and latency in orientation are the critical performance parameters for HMD tracking. Therefore, orientation tracking based on gyroscopic angular rate sensors should be used for any high-quality VE using an HMD, unless the tracking range is so small that an external tracking source can provide low enough jitter and latency in the intended environment.

The problem with tracking orientation using only gyros is drift. There are several causes of drift in a system that obtains orientation by integrating the outputs of angular rate gyros:

- Gyro bias, $\delta\omega$, when integrated causes a steadily growing angular error $\phi(t) = \delta\omega \bullet t$
- Gyro white noise, $\eta(t)$, when integrated leads to an angle random walk (Brownian Motion) process $\phi(t) = \int_0^t \eta(\tau)d\tau$, which has expected value zero, but a mean-squared error growing linearly in time
- Misalignment, nonlinearity, and scale factor calibration errors of the gyros lead to accumulation of additional drift proportional to the rate and duration of the motions
- Gyro bias instability, which means that even if initial gyro bias is known or can be measured and removed, the bias will gradually change, producing a residual bias that gets integrated to create a second-order random walk in angle. Bias stability is often the critical parameter for orientation drift performance, since constant gyro bias and deterministic scale factor errors can usually be calibrated and compensated effectively.

Gyro drift may be solved by using higher accuracy sensors and algorithms to keep the drift rate low, and requiring the user to return to a known position and restart after a certain period of

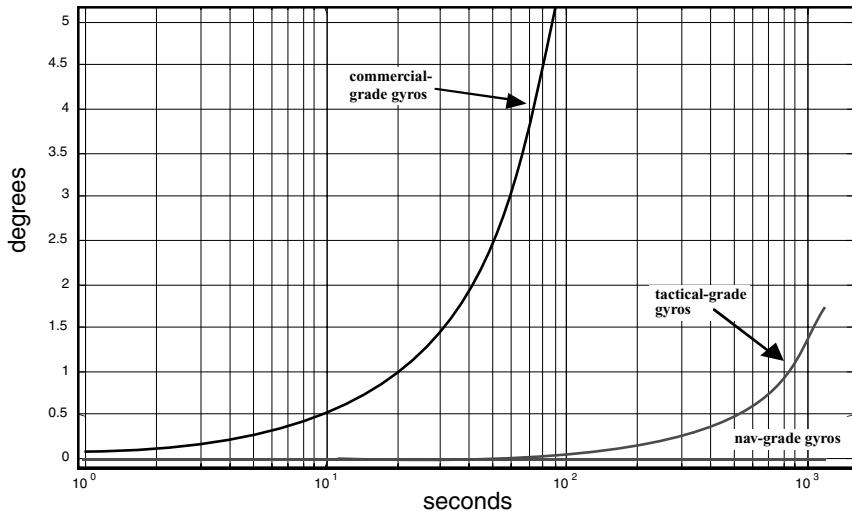

FIG. 8.1. Comparison of $1-\sigma$ random orientation drift performance of various gyros over a 20-minute simulation.

time. Figure 8.1 illustrates the achievable drift performance for typical gyros of different grades. This simulation examines the effects of various gyro error sources over 20 minutes for an object that is not moving—scale-factor calibration errors are thus not included and would lead to additional error accumulation as a function of the particular motion trajectory of the object. The simulation assumes gyro bias stabilities of $1500^\circ/\text{hr}/\sqrt{\text{hr}}$, $15^\circ/\text{hr}/\sqrt{\text{hr}}$, and $0.015^\circ/\text{hr}/\sqrt{\text{hr}}$ for commercial, tactical, and navigation grade gyros respectively, with initial gyro biases known to 150 deg/hr, 15 deg/hr, and 0.0015 deg/hr, respectively. Angle random walk caused by the gyro noise component has negligible effects over the simulation period, but it prevents the initial biases from being measured perfectly prior to the run. Initial bias uncertainties are the dominant cause of drift for the first 36 seconds, after which bias instability takes over.

An examination of Fig. 8.1 leads to the conclusion that today's commercial grade gyros (devices used in automobiles, camcorders, model helicopters, and low-cost head-trackers) can only be used for a minute or so before drift becomes distracting and the user needs to reset the orientation tracker. Head-orientation trackers may significantly extend this by deadbanding the gyro outputs to zero when they are below a certain threshold. This eliminates the random drift when the head is still, but introduces "slippage" error accumulation whenever the head rotates below the angular-rate threshold. On the other hand, tactical-grade gyros used in short-range missile guidance are good enough for uninterrupted head-tracking for more than 20 minutes, which may be quite acceptable for many uses, and navigation-grade gyros are complete overkill if only orientation is needed. Unfortunately, the price ratio between tactical and commercial gyros roughly follows the 100-fold performance ratio, and they are also too large and heavy for head-mounted use. However, there is optimism that MEMS gyroscopes over the coming decade will be gradually closing in on the performance of tactical grade gyros, and it may eventually become feasible to make a light and affordable head-orientation tracker out of gyros alone, requiring only occasional resets by the user.

Another solution is to correct the drift of gyros using occasional measurements from another source. If only orientation needs to be tracked, it is possible to do this while still maintaining the advantages of a sourceless tracker (Foxlin, 1993, 1997). Gravimetric tilt sensing, discussed in the previous section, corrects drift in pitch and roll, and a magnetic compass can be used to

correct drift in yaw if necessary. The problems with slosh in the gravimetric tilt sensors can be overcome because the gyros do not need to be corrected very often. Clever algorithms determine moments when the horizontal acceleration is likely to be negligible, and measurements at these times are introduced with higher weighting factors, for example, using an adaptive Kalman filtering approach (Foxlin, 1996). Because there may be sustained periods of motion when no tilt measurements can be used, some orientation error may build up, and once calmness is restored the Kalman filter may try to correct this rapidly enough to create some perceptible motion. To mask this, a perceptual enhancement algorithm holds back the correction until the user again begins to move and applies it gradually proportional to the speed of head rotation.

Geomagnetic compassing provides a cheap and effectively sourceless way to correct drift in yaw; at least this source is provided by the earth and is present over most of its habitable surface. However, the accuracy of magnetic compasses in many environments is poor (see section 3.5.1). Temporary magnetic disturbances can be detected and prevented from entering using something similar to the antislosh techniques used to screen gravimetric tilt measurements. A degree of accuracy can be achieved that is suitable for many applications that just require the forward direction of a virtual world to remain consistent for a seated user. If the user is free to reorient toward the forward direction, or if the duration of use is limited, than the use of a compass may not even be necessary. However, in applications requiring registration accuracy, such as an outdoor AR application, magnetic compassing is not a suitable choice, and physics provides yet another option, still sourceless, called *gyrocompassing*. A mechanical gyrocompass makes use of the spin of the earth to cause the spin axis of a gyroscope to align itself toward true north through a damped gyroscopic precession. The same concept can be used with a stationary cluster of angular-rate sensors to detect the direction of the earth's angular velocity vector, then project it onto a horizontal plane to find north. This requires gyros with sensitivity that is a small fraction of Earth's 15 deg/hr rotation rate. To detect yaw with an accuracy of 0.2 degrees would require gyros good to 0.05 deg/hr. Unfortunately, gyros of this caliber won't be small enough for use on an HMD for a great many years, if ever.

3.2.3 Inertial Position Tracking

The previous section discussed the use of inertial angular-rate sensors (gyros) for orientation tracking, which offers great advantages due to the self-contained, fast, and noiseless measurement. In many applications it is also desirable to track position, and the aforementioned advantages would theoretically apply as well to a 6-DOF tracking system built with gyros to determine orientation and accelerometers to measure changes in position. In fact, this combination of sensors has been used successfully for inertial navigation systems (INS) in ships, airplanes and spacecraft since the 1950s. In this section we review the basic operating principles of inertial navigation, discuss the differences between human-scale inertial tracking and geographic-scale inertial navigation, and analyze the present and future options for use of pure or aided inertial tracking in human-machine interaction.

Originally navigation systems were built with a gimbaled platform (Fig. 8.2a) that was stabilized to a particular navigation reference frame by using gyros on the platform to drive the gimbal motors in a feedback loop. The platform-mounted accelerometers could then be individually double integrated to obtain position updating in each direction. Most recent systems are of a different type, called *strapdown INS* (Fig. 8.2b), which eliminates mechanical gimbals and measures the orientation of a craft by integrating three orthogonal angular-rate gyros strapped down to the frame of the craft. To get position, three linear accelerometers, also affixed to orthogonal axes of the moving body, measure the nongravitational specific force of the body relative to inertial space. This specific force vector, \mathbf{f}^b , measured in body

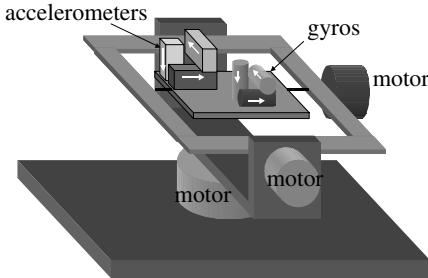

FIG. 8.2a Stable-platform INS.

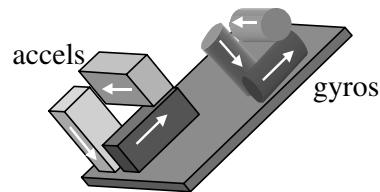

FIG. 8.2b Strapdown INS.

coordinates, is resolved into geodetic navigation coordinates using the current orientation of the body determined by the gyros. Position is then obtained by adding the local gravity to \mathbf{f}^n to get the total kinematic acceleration of the body $\mathbf{a}^n = \mathbf{f}^n + \mathbf{g}_l^n$, and then performing double integration starting from a known initial position. Figure 8.3 illustrates this flow of information.

Drift in linear position determined by an INS arises from several sources. First, there are accelerometer instrument errors corresponding to each of the four gyro-error types listed above. Since position is obtained by double integrating acceleration, a fixed accelerometer bias error results in a position drift error that grows quadratically in time. It is therefore critical to accurately estimate and eliminate any bias errors. An even more critical cause of error in position measurement is error in the orientation determined by the gyros. An error of $\delta\theta$ in tilt angle will result in an error of $1g \cdot \sin(\delta\theta)$ in the horizontal components of the acceleration calculated by the navigation computer. Thus, to take proper advantage of μg -accurate accelerometers, pitch-and-roll accuracy must be better than $1\mu \text{ rad} = 0.000057^\circ$ for the duration of the flight, which puts a far more difficult task on gyros than on accelerometers. In practice, it is gyroscopes, not accelerometers, which limit the positional navigation accuracy of most INS systems, because the effects of gyroscopic tilt error will soon overtake any small accelerometer biases.

The scale of the human-motion-tracking problem is vastly different from that of global navigation. Tracking is only required over a small area, but it requires precision on the order of a centimeter or less, whereas with navigation a kilometer is often sufficient. The size and cost of sensors must also be scaled down tremendously for human body-mounted use. Thus, inertial human-motion tracking would need to achieve far higher accuracy using tiny sensors than navigation systems are able to achieve using instruments far larger and more costly. A reasonable question is whether or not purely inertial 6-DOF motion tracking will ever be viable.

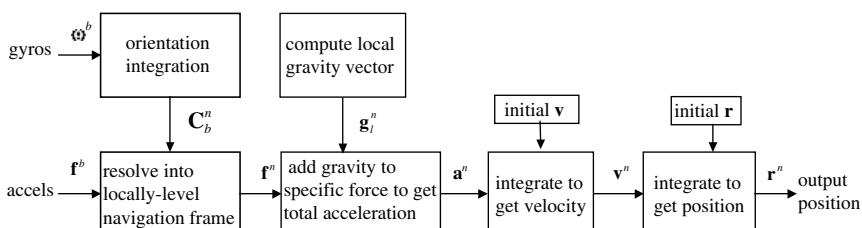

FIG. 8.3. Basic strapdown inertial navigation algorithm.

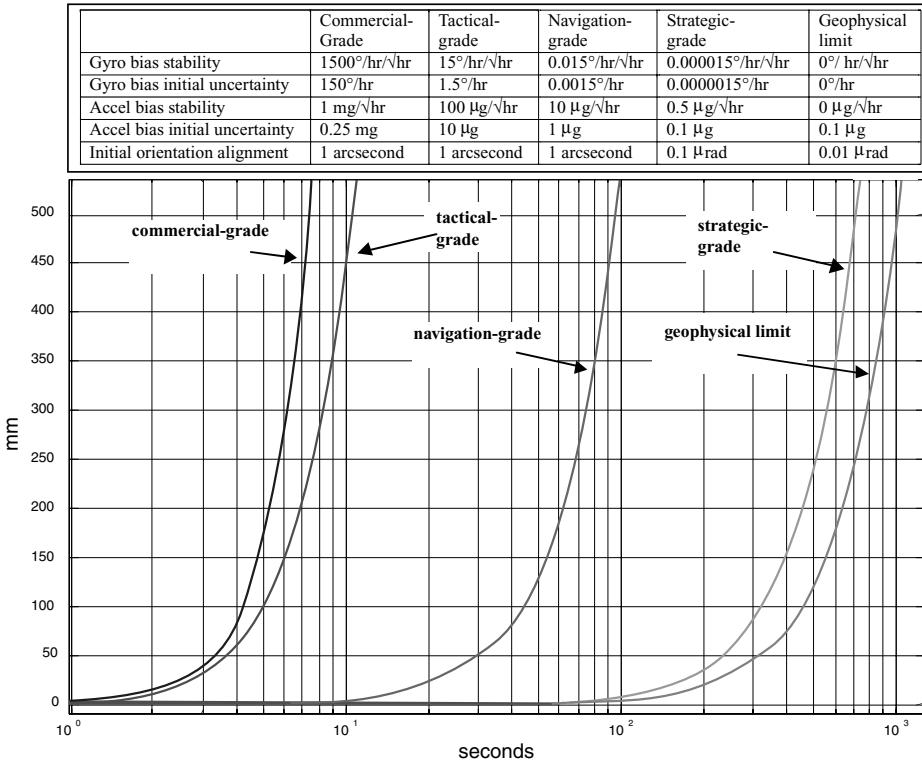

FIG. 8.4. Comparison of $1-\sigma$ random-position drift performance of commercial, tactical, navigation, strategic-grade, and “perfect” inertial navigation systems over a 20-minute covariance simulation.

Figure 8.4 shows the results of a simulation designed to answer this question. It depicts positional drift rates of navigation systems using sensors of various grades. As with the orientation drift plotted in Fig. 8.1, the simulation only considers the effects of random error sources, predominantly those of the gyros, on drift accumulation for a stationary object over a 20-minute interval. If the object is moving, there will be additional drift due to scale factor calibration errors. The gyro and accel bias stability numbers listed in the figure represent typical values for the four grades of inertial measurement unit generally recognized in the industry. In addition, a drift curve is plotted for a theoretically perfect inertial measurement unit to show the physical limits of inertial sensing for small-scale position measurement. There are gravity anomalies, which create deflections of the local gravity field from the vertical by up to 30 arcseconds, corresponding to horizontal acceleration errors on the order of $150 \mu\text{g}$. These have been mapped out in great detail by gravity surveys, and sophisticated inertial navigation systems are able to compute a local gravity vector with residual errors below $1 \mu\text{g}$. It is impossible to drive these residual errors all the way to zero, though, because local gravity conditions are constantly changing due to earth tides, seismic activity, and cultural features such as buildings and trucks. All these effects produce gravitational variations on the order of $0.1 \mu\text{g}$ —approximately equivalent to the pull of a 1-meter-radius stone ball close to its surface. Because it would not be practical to map out all these extremely local spatiotemporal variations in gravity, the simulation assumes the geophysical limit on accuracy of inertial navigation to be $0.1 \mu\text{g}$. Remarkably, strategic-grade systems come very close to reaching this limit for short-term navigation. However, MEMS gyros are currently below the tactical performance benchmark and may make it

to navigation-grade performance levels over the next several decades, but they are unlikely to go beyond. Therefore, human-motion tracking systems that can maintain position to a few centimeters for more than a minute without external correction are not on the horizon. Nonetheless, 6-DOF inertial sensors are of prime importance in human-motion tracking as part of hybrid tracking systems in which they impart robustness, smoothness, and low latency, and reduce the requirements, and therefore cost, of other technologies with which they are combined (e.g., Foxlin et al., 1998). Techniques have been developed which allow inertial trackers to operate on motion-base simulators or moving vehicles without being disrupted by platform motions (Foxlin, 2000).

3.2.4 Body-dynamics-model-based Tracking

The preceding discussion indicates that pure, unaided inertial navigation in its general form will never be an option for prolonged motion tracking on the human scale. The general form described above can track the motion of an arbitrary object moving along an arbitrary trajectory. All 6 DOFs may evolve independently according to any continuous functions of time, within the limits on angular velocities and linear accelerations imposed by the maximum ranges of the sensors. In other words, the only kinematic constraint assumed in the development of the strapdown INS algorithms is that the body being tracked is rigid. Nothing needs to be known about its mass distribution, the forces acting on it, or kinematic constraints of connection or contact with other rigid bodies. If significant kinematic constraints or a priori dynamics models can be exploited, there is a possibility of tracking for longer time periods without the need for external position information. To illustrate this idea, two hypothetical inertial tracking concepts are outlined below: zero-velocity-updating based on foot contact constraints, and body-dynamics-model-based tracking.

Researchers on the BodyLAN project at BBN have proposed a boot-mounted personal inertial navigation system (PINS) to help a soldier keep track of and report his own position during global positioning system (GPS) outages (R. LaRowe, personal communications, June, 1997). It would operate just like an ordinary INS, except every time it determined that the foot was in contact with the ground it would reset velocity to zero. Each minitrip would be just as accurate as the ones before it, and total positional error would only accumulate linearly with the number of steps taken. This may provide reasonable short-term accuracy using only one sensor on the shoe.

If full-body motion capture is the goal, a dynamical model for the body may go a long way toward reducing the amount of sensing hardware needed. Suppose the body is modeled (crudely) using 17 rigid segments and two 3-DOF “goosenecks” to represent the lower and upper spine. If each segment were independently tracked with a 6-DOF sensor there would be 102 degrees of freedom. However, kinematic constraints reduce this to about 39 independently controllable joint angles. Although there are a large number of muscles in the body, they work together in groupings to produce a net effect that can be approximately described by 39 torque values as a function of time. The complete state of the body can be described by 6-DOF for the root node plus 39 joint angles. These 45 generalized coordinates evolve according to a dynamical equation driven by the 39 muscle torques and constraint forces on any parts of the body that come in contact with the floor or other fixed objects. If the masses and moments of inertia of all the segments were approximately known (say by body scanning or just guesswork), it would be possible to produce lifelike animation by controlling the joint torques in a coordinated time sequence and enforcing constraints with techniques from physically based modeling. Conversely, estimating the motion of an actual human participant could potentially be reduced to estimating these 39 torques. By stacking generalized coordinates,

their derivatives, and all causative forces and torques in the state vector of a dynamic system, it might be possible to develop a large centralized Kalman filter that can estimate the evolution of the joint angles from a set of indirect measurements such as angular velocities and/or linear accelerations. By modeling unknown muscle torques with an appropriate stochastic process, a fairly small number of sensors may suffice to achieve observability of the motion over time. Using exclusively inertial and gravimetric sensors would make this solution sourceless, so the range of motion would be unlimited. Unlike the biokinematic reckoning approach, ballistic motions of the body are captured in the dynamics model, so the participant can run and jump without losing tracking. The potential for optimal and self-consistent motion estimation using any desired, even seemingly incomplete, combination of sensors warrants further investigation.

3.3 Acoustic Waves

One of the earliest position tracker technologies, used by Ivan Sutherland in his pioneering HMD work (Sutherland, 1968) and widely available today in many commercial products, is ultrasonic time-of-flight (TOF) ranging in air. Acoustic trackers can be very inexpensive (witness the Mattel “PowerGlove” that was sold in toy stores in the early 1990s and included a 6-DOF ultrasonic tracker as a subsystem). Alternatively, they can have fairly large tracking range or high accuracy. Typical drawbacks are latency, update rate, and sensitivity to ultrasonic noises in the environment, but these can be overcome in hybrid configurations with inertial sensors.

All known commercial acoustic ranging systems operate by timing the flight duration of a brief ultrasonic pulse. In contrast, the system used by Sutherland employed a continuous-wave source, and determined range by measuring the phase shift between the transmitted signal and the signal detected at a microphone. Meyer et al. (1992) point out that this enables continuous measurement without latency, but can only measure relative distance changes within a cycle. To measure absolute distance, one needs to know the starting distance and then keep track of number of accumulated cycles. Another problem, which may be the reason no successful implementation of the “phase coherent” approach has been developed, is the effect of multipath reflections. *Multipath*, a term also associated with radio transmission, refers to the fact that the signal received is often the sum of the direct path signal and one or more reflected signals of longer path lengths. Since walls and objects in a room are extremely reflective of acoustic signals, the amplitude and phase of the signal received from a continuous wave acoustic emitter in a room will vary drastically and unpredictably with changes in position of the receiver.

An outstanding feature of pulsed TOF acoustic systems is that it is possible to overcome most of the multipath reflection problems by simply timing until detecting the first pulse that arrives, which is guaranteed to have arrived via the direct path unless it is blocked. The reason this simple method works for acoustic systems but not for RF and optical systems is the relatively slow speed of sound, allowing a significant time difference between the arrival of the direct path pulse and first reflection.

Point-to-point ranging for unconstrained 3-D tracking applications requires the use of transducers with radiation and sensitivity patterns that are as omnidirectional as possible, so that the signal can be detected no matter how the emitter is positioned or oriented in the tracking volume. The beamwidth of the sound emitted from a circular piston transducer is inversely proportional to D/λ , where λ is the wavelength and D is the diameter of the piston. To achieve an approximately hemispherical omnidirectional pattern ($+/- 60^\circ$ 3 dB points) requires $D/\lambda = 0.6$ (Baranek, 1954). For a typical ultrasonic tracker frequency of 40 kHz, $\lambda = 9$ mm, and one is required to use very tiny speakers and microphones with active surfaces of about 5.4-mm diameter. This is convenient for integration into human-motion tracking devices and helps

reduce off-axis ranging errors, but the efficiency of an acoustic transducer is proportional to the active surface area, so these small devices cannot offer as much range as larger ones. To improve the range, most systems use highly resonant transducers and drive them with a train of about six or more electrical cycles right at the resonant frequency to achieve high amplitude. This results in a received waveform that “rings up” gradually for about 10 cycles to a peak amplitude then gradually rings down. For a typical pulse-detection circuit that stops the timer at the peak of the envelope, this means the point of detection is delayed about 10 cycles, or about 90 mm, from the beginning of the waveform.

It should now be clear that as long as the reflected path is longer than the direct path by more than 90 mm, the detection circuit will have already registered the peak of the first pulse and stopped the timer before the reflected signal begins to arrive. Formalizing this analysis, let us call the time delay from the beginning of the pulse waveform to the peak or whatever feature is detected by the receiver circuitry t_d . Thus the displacement of this detection point from the beginning of the waveform is $R_d = c_s t_d$, where c_s is the speed of sound in air. Let R_1 be the distance from the emitter to a reflecting object, and R_2 the distance from the reflecting object to the receiver. Any reflection path length $R_1 + R_2$ that is longer than the direct path length R_0 by more than R_d will not corrupt detection. Thus objects outside the ellipsoid defined by $R_1 + R_2 = (R_0 + R_d)$ with the emitter and receiver transducers as its foci cannot possibly cause multipath ranging error because signals reflected off of them will arrive after detection is complete. Conversely, objects inside this “ellipsoid of interference” risk causing reflections that interfere with the direct path signal to slightly distort range measurement. The major axis of this ellipse is of length $2a = (R_0 + R_d)$, and the distance between the foci is $2c = R_0$, so the minor axis is of length:

$$2b = 2\sqrt{a^2 - c^2} = \sqrt{(R_0 + R_d)^2 - R_0^2} = \sqrt{2R_0 R_d + R_d^2}$$

For a transmitter-receiver separation R_0 of 2 m, and the typical R_d of 90 mm, the width of the ellipsoid in the middle would be 0.6 m. This allows significant opportunity for extraneous objects such as hands to come near enough to the line of sight between transmitter and receiver to produce reflections that corrupt the range measurement. Much of our own development work has therefore focused on the design of circuitry to reliably detect a sound burst much earlier than its peak. By detecting on the second or third cycle instead of the tenth, the volume of the “ellipsoid of interference” can be reduced by a factor of four or more, resulting in far fewer multipath errors in typical real-world situations. This phenomenon is little discussed in the literature, but in our experience it is one of the most important issues for accurate ultrasonic tracking outside of controlled laboratory settings.

There are of course many other design trade-offs and considerations dictated by the physics of ultrasonic waves in air and transducer design. Ultrasonic noise sources such as banging metal fall off rapidly with increasing frequency, so operating at a higher frequency is very beneficial for avoiding interference and also offers higher resolution due to shorter wavelengths. However, selecting a higher frequency also means less range due to problems with transducer size and frequency-dependent attenuation of sound in air. Attenuation of sound in air due to molecular absorption is basically negligible at 1 kHz, starts to play a significant role (compared to spherical spreading losses) by 40 kHz, and becomes the dominant factor in limiting range by 80 kHz. It also depends very significantly on relative humidity, with the humidity level that causes greatest attenuation shifting as a function of frequency (Baranek, 1954).

Since increasing the frequency much beyond 50 kHz is usually not an option due to range problems, other techniques may be considered to improve resolution and immunity to ambient noise sources. For resolution enhancement, a common trick is phase locking. Using some envelope-based technique to determine the rough TOF, the final TOF is determined by finding

the zero-cross of the carrier wave nearest to the rough TOF detection point. Since the slope of the carrier wave is very steep as it crosses zero, the location of the zero-cross point is not much affected by additive noise, and resolutions of a small fraction of a millimeter are easily obtained. However, no phase-locking technique has been devised yet which can consistently pick out the same individual wave of the carrier every time no matter how the transducers move, so the technique occasionally produces 9-mm jumps in the output. To improve rejection of ambient noise, any communications engineer would probably suggest driving the emitter with a complex unique waveform and detecting it with a matched filter at the receiver. However, this is not easy to accomplish because: (1) the entire signature waveform has to be very short in order to avoid multipath by getting an early detection; and (2) the piezoelectric transducers have narrow bandwidth and cannot be made to transmit very nonsinusoidal waveforms.

The main factors limiting accuracy of ultrasonic ranging systems are wind (in outdoor environments) and uncertainty in the speed of sound. The update rate of acoustic systems is limited by reverberation. Depending on room acoustics, it may be necessary for the system to wait anywhere from 5 to 100 ms to allow echoes from the previous measurement to die out before initiating a new one, resulting in update rates as slow as 10 Hz. The latency to complete a given acoustic position measurement is the time for the sound to travel from the emitter to the receivers, or about 1 ms per foot of range. This is unaffected by room reverberation and is usually well under 15 ms worst case. However, in a pure acoustic system with a slow update rate, system latency is also affected by the need to wait for the next measurement. Hybrid tracking can improve both update rate and latency dramatically.

3.4 Electric Field Sensing

Before the remarkable successes of 19th-century physics, electricity, magnetism, radio, and light were all considered separate phenomena. In the wake of Einstein's special theory of relativity, one can see that there is a single fundamental force required to explain all these effects, i.e., electromagnetic force. Nonetheless, these four distinct manifestations of electromagnetic force behave quite differently, and different motion tracking possibilities are treated separately in this and the next three sections.

The electric field is the only one of the four that has not been routinely used for motion tracking, however, electric fields are theoretically detectable, and certain fish use them to sense object shape and distance. The use of static fields from charged objects is unlikely to produce practical tracking systems due to the difficulty of keeping the charge from leaking off, or other objects from getting charged, but oscillating electric fields bypass these problems. Zimmerman, Smith, Paradiso, Allport, & Gershenfeld (1995) have implemented a system for tracking hand motion or body location using capacitive sensing of electric fields. A radiating electrode and a ground electrode are set up in a workspace, and any conductive object that comes between or near them affects the capacitance between them. A human hand inserted between the plates acts as a conductive object connected to a large conductive mass that acts as a charge reservoir ground if it is outside of the capacitor gap. As the hand is inserted further into the capacitor gap, it shunts away more of the electric field lines that otherwise would have reached the ground electrode and therefore reduces capacitance. In another arrangement, an emitter electrode is placed close to or in contact with a person's body so that the excitation field is coupled into the person and their entire body becomes an electric field radiator. Then, the closer the hand approaches the ground electrode, the greater the capacitance.

Such a system is capable of low latency, high resolution, and can be built with lightweight low-power electronics that could be integrated into a palmtop or even wristwatch computer. Sensing is unaffected by nonconductive objects and requires no contact with the user's body. However, the electric field geometry in the dipole near-field regime is too complex for accurate

analytical modeling, and some form of training or calibration procedure is necessary to convert the capacitance measurements from multiple electrodes into a position estimate. The potential for precision tracking with electric fields is not good. The system will track the whole human body as a “blob,” or that part of the body that is inserted in the electric field region. It can therefore be used with large-scale electrodes to tell where people are in a room or with smaller scale electrode arrangements to track where a hand is when it is inserted into the region between electrodes. In this latter example, it may be useful for qualitative gesture tracking but not for quantitative precision pointing, because the indicated position will be affected by the shape of the hand, arm, and stance of the body if it is too close to the field region.

3.5 Magnetic Field Sensing

Unlike electric fields, magnetic fields are unaffected by the presence or absence of human bodies and other nonmetallic objects in the environment. This offers a tremendous opportunity, because it enables magnetic trackers to overcome the line-of-sight requirement that plagues acoustic, optical, and externally connected mechanical trackers. Magnetic tracking technologies have a long history and to date have been more widely deployed in human-machine interface tracking applications than any other technology.

3.5.1 Geomagnetic Sensing

Loadstone (magnetite) was known to the ancients, who eventually discovered that if suspended properly it tends to align itself toward the north, and the magnetic compass was invented. Thus, the world’s first motion tracking system was a yaw direction indicator based on the earth’s magnetic field. Modern navigators learned how to build electronic compasses with digital readout, and these became the head tracker of choice for consumer HMDs of the early 1990s, because their ultralow cost offset poor performance and lack of position tracking capability.

Earth’s magnetic field from the surface outward approximates a magnetic dipole field (i.e., the magnetic field pattern produced by a small circulating current loop). The radial and tangential components of a dipole magnetic field are given by the equations:

$$B_r = \frac{2m \cos \theta}{r^3}$$

$$B_t = \frac{m \sin \theta}{r^3}$$

where m is the magnetic dipole moment, θ is the angle away from the north pole, and r is the radius from the center of the dipole source (derived from Purcell, 1965, p. 365).

Magnetic north deviates from true geographic north by an amount called the magnetic declination, D , which varies about $+/- 20^\circ$ across the United States because of the slant of the magnetic dipole axis, with anomalies as large as 60 degrees in certain regions due to ore deposits. To use a compass effectively for navigation, it is essential to correct the compass reading with the local value of D . Even with access to a good map of local declinations, the accuracy of a compass can be limited by changing magnetic disturbances caused by solar winds, which can cause hourly deviations of $+/- 0.3^\circ$ on magnetically turbulent days.

An electronic compass must find the direction of the horizontal field while disregarding the effect of the vertical field. Modern compasses, such as the ones used in HMDs, sense the full magnetic-field vector, then use pitch-and-roll information obtained by gravimetric and/or gyroscopic means to calculate the components of this vector in the horizontal and vertical directions. They then calculate heading using only the horizontal components.

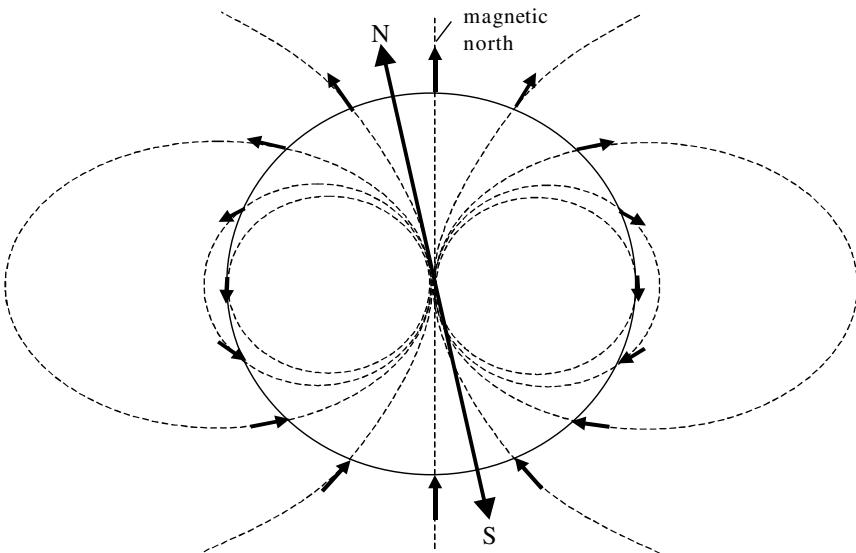

FIG. 8.5. Earth's magnetic field at the surface. The field is 0.3 gauss horizontal at the magnetic equator and 0.6 gauss vertical at the magnetic poles, which are inclined 11 degrees with respect to the spin axis.

Referring to Fig. 8.5, it can be seen that the dip-angle or magnetic inclination, I , varies from 0 degrees at the equator to 90 degrees at the poles. The error in compassing calculation due to a tilt measurement error ε is:

$$\text{compass error} = \tan^{-1}[\sin(\varepsilon) \tan(I)]$$

so in Burlington, Massachusetts, where $I = 69.27^\circ$, every 1 degree of tilt error will cause a compass yaw error of 2.64 degrees. In northern Europe or Canada, the magnetic inclination I approaches 80 degrees, with tilt error amplification factors of 4 to 5. This means that even a state-of-the-art magnetometer that has been calibrated to 0.1 degrees may experience yaw errors of several degrees when used with a good gyro-stabilized inclinometer of 0.5 degrees peak tilt error. When used with a plain inclinometer that experiences many degrees of slosh error whenever a person moves, the yaw reading will twist several times as much as the pitch and the roll slosh. This is the effect that made the simple inclinometer/compass orientation trackers in early consumer HMDs virtually unusable. As a final warning, even if one could build a perfect gyro-stabilized inclinometer/compass, it would still be subject to yaw errors of typically 10 to 20 degrees in buildings due to furniture and building materials, and 3 to 5 degrees in urban outdoor areas due to nearby buildings, cars, and signposts. Clearly, geomagnetic sensing cannot be relied on as a primary yaw determination means in applications such as AR, which demand absolute accuracy better than a couple of degrees.

3.5.2 AC and DC Active-Source Systems

A few years after Sutherland's early HMD-tracking experiments, Jack Kuipers of Polhemus Navigation Sciences invented a technique for tracking the position and orientation of a fighter pilot's helmet, using AC magnetic field coupling from a 3-axis source to a 3-axis sensor (Kuipers, 1975; Raab, Blood, Steiner, & Jones, 1979). More recently, similar systems using quasi-DC fields have been developed (Blood, 1989), and both technologies are now widely used in a broad range of human-machine interface applications.

In both systems, magnetic fields are generated by a source consisting of three orthogonal coils of wire activated in sequence by the electronics control unit to generate three orthogonal magnetic dipole fields similar in shape to Earth's dipole field, illustrated in Fig. 8.5 but on a much smaller scale. For AC systems, the source is activated with oscillating currents of 7 to 14 kHz, and the sensor consists of a similar triaxial coil assembly that is able to measure components of these oscillating magnetic fields by inductive pickup.

For the DC systems, the triaxial sensor assembly uses devices sensitive to small DC magnetic fields, namely any of the sensor types that are used in electronic compasses. Traditionally, the most popular such sensor was the fluxgate magnetometer, but recently magneto-resistive, magneto-inductive, and hall-effect sensors have been replacing fluxgates. After each source coil is activated with a DC current, the system waits for eddy currents induced in any nearby metal objects to die out before measuring the resulting field. This way, the DC tracker is unaffected by any nonmagnetic conductors, which cause trouble for AC trackers due to eddy currents.

The magnetic field magnitude, $b \equiv \sqrt{B_r^2 + B_t^2}$, falls off with the inverse cube of distance r from a dipole source. Naively, one might assume that this means that magnetic tracker resolution and accuracy will degrade according to the cube of the transmitter-receiver separation d_{tr} . Unfortunately, Nixon et al. (1998) have shown analytically that at least position resolution must degrade as the fourth power of separation distance, and have confirmed experimentally that both position and orientation follow this trend for AC and DC magnetic trackers. The reason for the fourth power is that position resolution is not dependent on the magnitude of the magnetic field, but rather on the gradient of this magnitude with distance:

$$\Delta r = \frac{dr}{db} \Delta b \propto r^4 \Delta b.$$

This means a small disturbing field, Δb , will produce a position error component along the radial axis proportional to d_{tr}^4 . It is not obvious from this analysis why the orientation errors should also grow proportional to d_{tr}^4 , but the experimental data show that they do.

In addition to the dramatic effect of range on performance, which affects both AC and DC trackers the same way, there is a significant difference between the two in terms of sensitivity to external interference sources. The most common sources of interference are mains power wiring, appliances generating interference at 50 or 60 Hz, and computer monitors. Because the sensors in AC trackers only detect signals in a frequency band centered around typically 8, 10, 12, or 14 kHz, they are virtually immune to low-frequency-mains interference. AC trackers are able to operate at 0.2- to 0.25-mm resolution at a range of 600 mm in an ordinary room environment without special synchronization and filtering. DC sensors are sensitive at low frequencies and produce over 30 mm of position noise at the same range. To attenuate this down to a much more tolerable level, a DC tracker's sampling frequency should always be synchronized to twice the mains frequency, and then a filter employed to average two adjacent samples, thus canceling the interference.

Nixon, McCallum, Fright, & Price (1998) also analyzed the effects of metals on AC and DC trackers. Different types of metals were tried, and it was found that the DC tracker was completely unaffected by brass, aluminum, and stainless steel, but committed larger errors than the AC tracker in the presence of copper, ferrite, and mild steel. Presumably, the AC tracker performed better with ferromagnetic steel because the magnetic permeability decreases with frequency. They concluded that the best countermeasure is to keep the transmitter close to the receiver and metals far away from both of them.

The latency of magnetic tracking is limited only by the rate a system can cycle through three excitation states (plus a zero-excitation state in DC trackers to remove the effect of earth's magnetic field) and the need for noise reduction filtering. Adelstein et al. (1996) measured the

latencies of modern DC and AC magnetic trackers using a carefully designed mechanical testbed and data analysis procedure to isolate the internal latencies of the trackers. With all filtering disabled and tracking a single receiver, they report latencies of 7.5 and 8.5 ms, respectively, for position, and less for orientation. In an environment with 60-Hz power-line noise, the DC tracker will normally need to be used with a two-tap averaging filter at 120 Hz, adding about 4 ms of additional latency. The main trade-off to consider is range versus resolution versus latency. If resolution is just acceptable at a range r , then at $2r$ with no filtering there will be 16 times as much noise. To filter that noise back to the original level using a simple rectangular moving average filter would require 256 taps, thus adding a latency of 128 times the sampling period. More sophisticated filters can, of course, be designed to accomplish the same noise reduction with fewer taps, but the example illustrates the general idea of the trade-offs involved.

3.6 Radio Waves, Microwaves, and Ultrawideband (UWB) Technology

Radio waves and microwaves have not been exploited much in tracking human motion, but they are widely used in navigation systems and various airport landing aids and radar systems. They have begun to find application in local positioning systems that find RF asset tags in warehouses or hospitals (Lanzl & Werb, 1998) and are likely to be used for human-motion tracking systems in the future as the precision improves and the technology becomes smaller and cheaper. Electromagnetic wave-based tracking techniques are capable of providing vastly greater range than quasi-static electromagnetic fields because radiated energy dissipates as $1/r^2$, whereas the dipole field strength gradient drops off as $1/r^4$. Furthermore, radio waves suffer negligible absorption losses in air and are virtually unaffected by wind and air temperature, so they are uncompromised outdoors or in large open spaces, where acoustic systems have difficulty. Unfortunately, radio waves are rapidly attenuated in water, so the human body is opaque to all radio frequencies useful for precision ranging.

3.6.1 Radio, Microwave, and Millimeter-wave (mmw) Ranging

Most radionavigation systems operate on the principle of time-of-flight (TOF) range-finding, much as described for acoustic ranging in section 3.3. The waves travel about a million times faster (roughly 1 ft/ns as opposed to 1 ft/ms for sound), making the task of measuring TOF with sufficient precision much more difficult. For example, ranging with 1 mm resolution would require a timer that can count at 300 GHz, implying expensive and power-consuming electronics based on gallium arsenide or indium phosphide semiconductors.

One technique to eliminate the requirement for such high-speed timers is interferometry using a continuous wave source. The transmitted and received waves are combined, and the phase difference between them can be measured to a small fraction of a wavelength. As with phase-based acoustic ranging, this approach suffers from an integer ambiguity problem: The distance between the transmitter and receiver can change by any integer multiple of the wavelength and the phase difference will be the same. It is therefore necessary to know initial position and keep track of the number of phase rollovers during tracking, then add the integer number of wavelengths to the fractional wavelength determined by phase interferometry to compute total distance. If the object moves too fast, gets temporarily blocked, or receives interference, there is a possibility of cycle slips leading to gross ranging errors.

Another approach to avoid the need for extremely high-speed digital counters is to use a combination analog/digital timer. A digital counter is run at a reasonable rate, say 1 GHz, and on each cycle it initiates an analog ramp signal. Reception of the pulse stops the ramp

generator and digital timer, and the stored voltage on the ramping capacitor is sampled and used to interpolate between the counter stop value and the next count.

Another approach is to take advantage of the high speed of light to make ranging measurements at a very high repetition rate, and then average thousands of separate ranging measurements taken over a brief interval to produce a range measurement of higher resolution. Using conventional narrowband signals, only a limited number of separate bursts can be transmitted per second because each necessarily requires many cycles of the carrier to ring up and down again, but the next section describes technology for producing temporally shorter duration pulses.

A more sophisticated approach is the delay-locked loop (DLL) employed in global positioning system (GPS) receivers. A digital pseudo-random noise (PRN) code is modulated on the microwave carrier before transmission from the satellite. A replica of the code is played back in the receiver with a time delay τ , which can be adjusted using a numerically controlled oscillator and multiplied by the incoming PRN code from the received signal. The resulting product is averaged over a period of time, yielding a signal representative of the correlation between the incoming PRN code and the local copy. The DLL uses a feedback loop to keep adjusting the delay τ to maximize this correlation signal. If the clock in the receiver were exactly synchronized with the clock in the satellite, the resulting time delay τ obtained by the DLL would provide a direct measure of the TOF from the satellite to the receiver. Since the receiver does not have an atomic clock, it is likely to have some clock bias Δt_c , and this must be estimated and added to τ to get the true range. In GPS, this is accomplished by measuring the “pseudoranges” from four satellites to solve for the four variables x , y , z , and clock bias Δt_c .

The autocorrelation of the PRN code is essentially a unit impulse so that multipath reflected copies of the code delayed by more than one chip have nearly zero correlation with the direct path signal and therefore don't disrupt the DLL's tracking loop. The chip length of the P-code signal, which is used for precise tracking after initial acquisition and lock are achieved, is 154 cycles (one period of the 10.23-MHz master oscillator), or about 29 meters long. Therefore, any multipath signals that travel paths longer than the direct path by more than 29 meters can usually be rejected. This provides a reasonable measure of multipath rejection for an airplane, because signals that bounce off the ground will be delayed by well over 29 meters before they get to the plane. However, for ranging between a “pseudolite” and receiver that are both in a building or near the ground, this provides almost no protection. Designing a custom spread-spectrum solution for VEs using higher frequency microwaves and fewer carrier cycles per chip might ultimately reduce the chip length to a few meters, but the analysis in section 3.3 for acoustic systems suggests that in human-scale tracking applications we need to reject all signals that are delayed more than a couple centimeters.

At the high-frequency extreme of the microwave spectrum, with wavelengths from 1 cm down to 1 mm, lie the millimeter waves, which exhibit behavior halfway between radio waves and light. They have recently become an active area of research, and practical applications in law enforcement are beginning to emerge (Williams, 1999). Most of the recent interest stems from the lightlike capabilities of the waves. Because of the very short wavelengths it is actually possible to build an imaging sensor in a man-portable size by packing an array of tiny antennas into the focal plane behind a plastic lens. Passive MMW imagers can visualize warm people through walls or detect cooler concealed weapons, even nonmetallic ones, beneath a person's clothing from a distance. Active MMW radar is under development to detect the distance of objects in a scene as well as their horizontal and vertical locations. Neither the passive nor active MMW imaging sensors offer enough cross-range resolution for precision HMD or tool tracking in virtual environments, but millimeter waves could also potentially be used for simple point-to-point TOF ranging between omni-directional transmit and receive

antennas. Compared to lower microwave frequencies used in GPS and other RF tracking systems, millimeter wave electronics can operate with much wider bandwidth, which could potentially be used to achieve higher resolution and tighter rejection of multipath interference. In fact, since the wavelengths are of the same size as those used in acoustic ranging, the simple early-detection-of-first-arriving-wavefront strategy could possibly be implemented with minor modifications in a MMW system. The electronics are currently much more expensive and complex than audio frequency electronics, and the Federal Communications Commission (FCC) has not yet allocated any spectrum above 60 GHz, so the commercial deployment of such a solution is a long-term prospect.

3.6.2 Ultrawideband (UWB) Ranging

UWB ranging makes use of nonsinusoidal electromagnetic signals such as impulses. Because there is no carrier frequency these are sometimes called time-domain, carrierless, or baseband signals. These signals have been studied since the 1970s and applied to radar (Taylor, 1995) as well as communications (Win & Scholtz, 1998). Interest has increased lately due to the development of simple low-power electronic circuits for generating and timing short impulses, including the famous micro-impulse radar (MIR) from Lawrence Livermore Laboratory (McEwan, 1993), used in commercial applications such as studfinders and automobile warning radars.

Most UWB schemes use short pulses approximating impulse functions or doublets, such as a half-sine pulse or a Gaussian monocycle signal (derivative of a Gaussian function having a doubletlike shape with a positive excursion immediately followed by a negative one). By transmitting a sequence of such impulses with a random nonperiodic distribution in time, the frequency spectrum of the signal is kept flat like white noise, and no appreciable interference is caused in narrowband radio receivers. Likewise, the UWB receiver tunes in a specific UWB transmission by knowing in advance the PRN code for the expected distribution of pulses in time, and is therefore relatively immune to interference from narrowband transmitters because it is only receptive during occasional, narrow time windows. UWB cannot be allocated specific regions of the spectrum, as with conventional RF systems, because it necessarily emits energy across the whole spectrum, from DC to several GHz. However, its emissions look like very-low-level background noise and are therefore potentially interoperable with conventional systems. The FCC is currently considering whether to allow commercial UWB deployment and how to regulate it. Narrowband systems accommodate multiple users in a given area by assigning each transmitter a different frequency band (frequency-division multiple access, or FDMA), and spread-spectrum systems further allow multiple transmissions on the same frequency band by using different spreading codes (code-division multiple access, or CDMA). UWB instead accommodates different transmitters because each is transmitting pulses following different pseudo-random time-hopping patterns, with a low probability of two pulses colliding because they are so short. By spreading each bit of information or ranging operation over many pulses, even occasional collisions are tolerable.

The outstanding advantage of the UWB paradigm is the improved ability to reject multipath signals. With pulses as short as 200 ps, all reflection paths delayed by 6 cm or more can be easily disregarded. For this simple reason, it is this author's opinion that if precise and robust electromagnetic ranging in indoor environments ever happens, it will be based on UWB impulses. Logically, this ought to be achievable with much simpler electronics than those required to demodulate a complicated spread-spectrum signal. If this turns out to be true in practice, and if the FCC develops a policy that allows UWB transmissions without too many restrictions, then this may eventually become a preferable method of ranging in VE motion tracking systems.

3.7 Optical Tracking

There are a particularly large number of different designs that use visible or near-infrared light in some way to track motion. There is no apparent reason to try more exotic techniques using ultraviolet or far-infrared, and X rays with high enough energy to penetrate flesh and solve the line-of-sight problem are not safe, so the rest of this section will assume the use of visible or near-IR light. Most optical trackers use some form of bearing sensors (e.g., cameras, lateral-effect photodiodes, or quad cells) to track pointlike targets or beacons, as discussed in section 3.7.1. Other optical techniques are discussed in sections 3.7.2 and 3.7.3. Since most computer vision approaches involve identifying certain fiducials or landmark points, they are included in the beacon-tracking discussion.

3.7.1 Beacon Tracking

Beacon trackers can be classified into *outside-in* and *inside-out* systems. Outside-in beacon-tracking is the simplest and most common arrangement. Two or more cameras are mounted on the walls or ceiling looking in on a workspace. The sensors detect the direction to the targets or beacons attached to the object being tracked, and a computer then triangulates the 3-D positions of the beacons using the bearing angles from the two nearest cameras. The biggest problem with outside-in systems is a trade-off between resolution and working volume. If sensors employ narrow FOV lenses the resolution is good, but the volume of intersection of the FOV is small. With wide-angle lenses, working volume can be increased at the expense of resolution. For example, to cover a $16 \times 16 \times 8$ ft working volume inside a $20 \times 20 \times 10$ ft room using four cameras mounted in the corners of the ceiling would require cameras with 78 degree horizontal and 76 degree vertical FOV. Assuming $1,000 \times 1,000$ pixel cameras and 0.1-pixel resolution for locating beacons, this would yield a resolution of about 0.7 mm. This is quite adequate positional resolution for most applications, but the orientation must be computed from the positions of three beacons mounted on a rigid triangle. A triangle of 15 cm per side would provide orientation resolution of about 0.4 degrees, which is too much jitter for some applications.

An alternative arrangement called inside-out optical tracking places bearing sensors on the object being tracked and the beacons at fixed locations on the ceiling or walls (Wang et al., 1990). This approach yields orientation resolution equivalent to the angular resolution of the bearing sensors, which is easily better than required even using modest-resolution sensors. However, to achieve position resolution comparable to an outside-in system requires multiple sensors looking out in different directions, which can be too heavy for some applications. Conceivably, one could use outside-in tracking to achieve good position resolution combined with a single outward looking camera to provide good orientation resolution.

Beacon trackers may be further classified according to whether they use imaging or non-imaging sensors for detecting the bearing angles to targets. Imaging sensors such as CCD or CMOS cameras require some digital computation to find locations of targets in the image. They have the advantages that they can find the locations of multiple targets in a single image and that the locations can be accurate even if there is background clutter as long as the image processing is smart enough to distinguish the actual targets from clutter. Nonimaging sensors such as quad cells (e.g., Kim et al., 1997) and lateral effect photo-diodes (LEPDs, e.g., Wang et al., 1990) are pure analog sensors that determine the centroid of all light in the FOV. They require no digital image processing, but care must be taken to ensure that the only light seen by the sensor at any given time is a single bright target. These sensors are therefore always used with active light-source targets that can be switched on one-at-a-time. In most cases, the targets are infrared LEDs and the sensor is equipped with an IR filter to block all visible light clutter. A background subtraction between the result with the LED on and the result with

it off can be used to further reduce error caused by any IR sources other than the intended target. There is one type of error that even background subtraction cannot help: reflected light from the LED when it is turned on. For example, if the FOV of the sensor includes both an LED target on the ceiling and a portion of the wall, then some of the light from the LED will diffusely illuminate the wall and shift the centroid toward the reflection patch on the wall. To minimize this, the University of North Carolina inside-out optical tracker uses a cluster of outward looking LEPDs with only 6 degrees FOV each (Welch et al., 1999), so that when a particular sensor sights a target on the ceiling it is unlikely to also pick up a reflection on a wall. However, the system must use a very dense array of LEDs so that there will always be beacons available within the FOV of several of the sensors. Because outside-in systems require wide-FOV sensors to achieve good overlap volume, nonimaging sensors are not suitable for these systems.

Another type of nonimaging sensor is the one-dimensional (1-D) CCD array. These are often used with a cylindrical lens to measure a 1-D bearing angle with extremely high resolution. Arrays with 5,000 pixels or more are readily available, and extraction of the center of the target distribution in one dimension requires only minimal digital signal processing. Because there are discrete pixels and no analog centroid processing, they are not subject to the same problems with clutter and reflections, just described for quad cells and LEPDs. There are many commercial systems of quite similar form that have three 1-D bearing sensors mounted in a preassembled rigid bar of about a meter or more in length. In a typical case, the bar is mounted horizontally on the wall, and the LED targets are flashed one at a time. The two sensors at the ends of the bar are arranged horizontally and used for a simple 2-D triangulation to determine horizontal coordinates of the LED in the plane of the bar. The sensor in the center of the bar is arranged vertically and measures the elevation angle from the plane of the bar to the target, which is translated into the height of the target using the known horizontal location. Such systems provide high resolution and accuracy within a certain wedge-shaped volume in front of the tracking bar.

In contradistinction, imaging sensors can be used with active, retroreflective, or even passive targets. Many commercial videometric motion capture systems use cameras with a ring of LEDs around the lens to track balls coated with retroreflective film containing thousands of tiny corner-cube reflectors, which return light back along the direction it came. Because the light source is so close to the camera lens, the balls reflect all the light toward the camera and appear very bright in the video image relative to normal objects, which return only a small percentage of the illumination back toward the camera. The illumination scheme makes the targets so much brighter than the background that the only image processing required is to threshold the image and then find the centers of all the white circles. This technique can be used in both outside-in and inside-out tracking systems, but only works well indoors where ambient illumination is not too high. Passive targets such as printed fiducial marks or natural scene features require considerably more image processing computation to track. Since they are no brighter or darker than other white or black objects in the scene, they must be identified on the basis of size, shape, and/or location using computer vision algorithms. The relentless pace of microprocessor development is making this method increasingly viable for cost-effective real-time tracking. Soon there will be CMOS cameras with enough onboard image-processing functionality to perform certain target extraction algorithms. The potential advantages of a vision-based tracking method using passive landmarks are compelling, especially for inside-out systems. Advantages over an electro-optical system using active targets include:

- No need to wire up the ceiling with an array of active LEDs.
- Range can therefore be expanded at much lower cost.
- Large numbers of users can share the same set of landmarks with no scheduling conflicts.

- Wearable system is untethered, without requiring radio telemetry.
- They can use wide-FOV cameras without errors due to reflection, and therefore far fewer landmarks.

Advantages over a videometric system using retroreflective targets are:

- No need to carry an illumination source (and power for it) on the person being tracked.
- Targets are flat instead of spherical.
- Targets can be uniquely coded, and image processing can identify the location and identity of each.
- They can work indoors or outdoors.
- With increasing computer vision sophistication, there is the potential to track natural scene features as targets, and thus enable tracking in an arbitrary unprepared environment of unlimited range.

In light of these advantages, most recent research on tracking for AR has focused on vision-based tracking (e.g., Hoff, Nguyen, & Lyon, 1996; Koller et al., 1997; Mellor, 1995; Neumann & Cho, 1996). Since AR requires a self-contained wearable tracker that can operate over large areas with minimal preparation, inside-out vision-based tracking is a natural fit. So far, outward-looking vision alone has not yielded sufficient robustness, but hybrid techniques that combine inertial or magnetic tracking with vision are likely to succeed. For many VE applications the region of tracking is fairly defined, and data is needed off-body to drive a graphics workstation. In these conditions, an outside-in approach may be more natural, if optical tracking is needed at all.

3.7.2 Optical TOF Ranging

There are a variety of optical tracking techniques that do not entail finding the bearing angles from a sensor to certain target points. One such class of techniques involves optical ranging, in which the time of propagation of a light beam is used to measure the distance from a source to a detector much like the previously described acoustic and RF ranging methods. Both phase interferometry (of the carrier or of a slower modulation signal) and straightforward TOF counting for pulses exist. The most widely used optical ranging technique is lidar, in which distance along a laser beam to a reflecting target is measured based on round-trip TOF. The laser beam must be specifically pointed at the target. This is quite convenient for manual surveying applications with stationary targets. Automatic tracking systems for moving targets have been built by mounting the lidar on a servo-controlled pan-tilt mechanism programmed to continuously follow a given target once it has been locked on. The 3-DOF position of the target can then be directly read out in spherical polar coordinates using the current azimuth and elevation angles of the pan-tilt servo and the radius measured by the lidar. Such a system is accurate but very expensive and can only track one target at a time. If the line of sight gets temporarily blocked the system will lose lock, and reacquiring the target may require a time-consuming scan.

Ducharme, Baum, Wyntjes, Shepard, and Markos (1998) have prototyped an omnidirectional point-to-point optical ranging system analogous to the acoustic and RF approaches discussed above. The light from a laser diode is fanned out by a special lens to approximate a hemispherical point-source radiator. The laser diode is amplitude modulated by a 1-GHz sine wave, and a photodiode receiver within the illumination cone of the emitter produces a copy of this sine wave phase shifted by an amount proportional to the distance from the source. A digital phase processor circuit measures the phase difference between the transmitted and

received signals and keeps track of phase wraparounds, which occur if the distance changes by more than 30 cm. Because of the omnidirectional emitter and receiver, the system will probably suffer from the same multipath issues discussed for similar acoustic and RF techniques, and the continuous-wave narrowband modulation scheme prevents the use of the multipath mitigation strategies described for those systems. However, under controlled laboratory conditions, the prototype exhibited peak ranging errors of $+/- 0.2$ mm over a range from 1- to 1.5-m separation. There are other point-to-point ranging techniques based on focus or intensity, but these are obscure and not very appropriate for VE motion tracking.

3.7.3 Structured Light

The techniques discussed so far used either no light sources or approximations of point sources, possibly time modulated. There are many technologies that generate spatially-modulated light fields such as lines, grids, or even more complex patterns, often scanned or otherwise time varying. Most of these aim to recover the 3-D geometry of a scene, so this section will focus only on a few simple examples, which are concerned primarily with tracking.

The most common such technology is the laser scanner (Sorensen, Donath, Yang, and Starr, 1989), which is now commercially available in a variety of different configurations. In all of them, a laser beam is fanned out into a plane and then swept through the workspace by a spinning mirror. The time difference between the moment when the light plane crosses a reference detector mounted in the scanning mechanism and the moment it crosses a tracking detector in the workspace provides a measure of the bearing angle from the scanner head to the tracking detector. In a simplified configuration for illustrative purposes, there would be two scanners placed, say, in the front left and front right corners of a room. The two scanners would be synchronized so that a sequence of three nonoverlapping scans would occur for each revolution of the motors: a horizontal sweep from the left scanner followed by a horizontal sweep from the right scanner followed by a vertical sweep from the right scanner. (Two sweeps in different directions from a single scanning motor can be accomplished with a multifaceted mirror and/or multiple lasers.) The two horizontal bearing angles and the known baseline separation between the scanners would be used to triangulate the horizontal coordinates of the detector, then the vertical bearing angle would be used to calculate the height, just as with linear CCD-based trackers. In fact, the system can be construed as a form of beacon tracker in that it measures the bearing angle from one device, the scanner, to a point target, the detector.

State-of-the-art laser scanners can achieve bearing angle measurement resolution on the order of 0.1 milliradians—quite comparable to state-of-the-art camera/beacon systems. The major difference is that the sensor is located at the target rather than at the origin of the bearing angle. Mathematically, the configuration illustrated above is an outside-in system, but physically it is inside-out, with the data being measured and made available at a detector on the person. If the position data is needed onboard the moving object, as in robotic navigation, it can be computed autonomously on the robot using just the timing of the detection pulses without the need for any RF telemetry. Unlimited numbers of users can share the structured light fields without mutual interference. On the other hand, if the goal is to remotely track a moving user in a workspace, it may be more natural to use a camera-based outside-in tracker to avoid the need for data telemetry and computer circuitry on the person being tracked.

A variation on the scanner theme has been recently proposed that does not use any lasers, but rather an ordinary lightbulb inside a rotating cylindrical shadow mask to produce a structured light field (Palovuori, Vanhala & Kivikoski, 2000). The clear cylindrical drum is printed with a series of vertical black stripes whose varying widths and spacing form a pseudo-random bar code. A receiver contains matched-filter correlators for each of the shadow masks that are

simultaneously rotating in the workspace, and thereby measures the code delay (proportional to bearing angle) from all the sources simultaneously and continuously through code-division multiple access. The potential advantage is continuous measurement, but it remains to be seen if the resolution will be sufficient.

Another class of structured-light devices uses projectors to paint patterns on the scene, and a camera viewing the patterns solves for its own pose if it knows the geometry of the surfaces on which the light is projected or is smart enough to recover the geometry from the distortions of the pattern. Livingston (1998) has proposed a very clever twist on this idea, in which the scene geometry does not need to be known or recovered in order to track the camera. The concept is based on algorithms from computer vision (Longuet-Higgins, 1981), which can solve for the pose of a second camera relative to a first camera given a number of corresponding points in the two images, even though these points are at arbitrary and unknown locations in 3-D. He replaces the first camera with a projector that flashes points one at a time into the scene so that correspondence with the points observed by the camera is easy. Since the projector uses the same projective geometry as a camera, the computer vision algorithms may be directly applied to compute the pose of the camera relative to the projector. The primary application for this technique is video-see-through AR, because the tracking can be done using the forward-looking cameras that are already part of a video-see-through HMD without having to mount 3-D fiducials inside of the object being looked at. If that object is a human body, mounting fixed fiducials inside is impossible.

We know of no example in the literature, but a conceivable structured light technique is the use of polarized light. For a simple example, consider a person wearing a lightbulb atop his helmet with a sheet of polarizing material over it. Above him on the ceiling is a photo detector with a sheet of polarizer spinning in front of it. The received intensity will oscillate with two peaks and two troughs per revolution of the motor, and the phase shift of this signal is a measure of the yaw direction of the person's head. A more elaborate scheme could be developed to measure multiple degrees of freedom.

4. MATHEMATICS OF MOTION TRACKING

4.1 Observables and Pose Recovery Algorithms

None of the sensing technologies described in the previous section directly measures position and orientation. Instead, each sensor measures certain *observables* which are functions of the desired position and/or orientation. Acoustic, RF, and certain optical methods measure *range* from one transducer to another. Most optical technologies, and some radar and sonar methods, measure *bearing angles* from a sensor to a target, while goniometers measure *joint angles* between connected rigid bodies. Other examples include homogeneous or dipole *field components*, angular or linear *velocities* or *accelerations*, and GPS *pseudo-ranges*.

Since a single measurement of any of these types does not in itself reveal the position and orientation (collectively called *pose*) of the object, calculations called *pose recovery algorithms* are used to solve for the pose from several measurements. Some classic pose recovery algorithms are *trilateration* to solve for position using three range measurements, and *triangulation* using bearing angles from two cameras. Although trilateration is just a matter of finding the intersection of spheres of known radius, it is surprisingly difficult to come up with an efficient, exact, and general algebraic solution in three dimensions, and this remains an active area of research (e.g., Manolakis, 1996).

Classical triangulation, where the bearing angles are measured from multiple known observation points to an unknown target, is a simple matter of intersecting rays or planes. However,

there are some pose estimation problems in computer vision, which are closely related yet far more difficult. The most important of these is perhaps the perspective-n-point-problem (PnP), in which a camera observes n 3-D points and finds their corresponding 2-D projections on the image plane (basically bearing angles from the camera to the points). If the 3-D points are known and the goal is to determine camera pose, the problem is historically called the *exterior orientation problem* or *space resection problem*, but more simply should be called n -point camera pose estimation. The problem was first solved with three points in 1851 and has been solved many different ways since, which are reviewed and compared in Harelick et al. (1994). While direct three point algorithms exist, they produce four solutions, and a unique solution requires a minimum of four points. Until recently such multipoint overdetermined solutions were iterative or nonlinear (e.g., Longuet-Higgins, 1981). However, Quan and Lan (1999) just introduced a direct linear solution using only five points, and a two-step linear solution for four points, which also have fewer restrictions on the geometry of the points (e.g., the points may all be coplanar). Clearly, closed-form algebraic pose recovery algorithms are very complex, and the state of the art is still advancing.

4.2 Kalman Filtering and Multisensor Fusion

All of the pose recovery algorithms discussed in the previous section are designed to solve for the pose of an object at time t given a set of measurements that are functions of that pose at time t . In other words, they assume either that the object is not moving or that a complete set of measurements sufficient to determine the pose can be made simultaneously at time t . Even in the latter case, the traditional pose recovery algorithms are not optimal, because they reestimate the entire pose from scratch at every frame, throwing away any information in its past history.

In a seminal paper, Kalman (1960) combined a recursive formulation of least squares estimation with a state-space system dynamics model to develop a practical algorithm for computers to estimate the state of a dynamical system (e.g., pose of a moving object) by optimally combining past history, new measurements, and a priori models and information. The Kalman filter (KF) has become the foundation of modern multisensor data fusion and estimation because it provides the unique best estimate of the state of a linear dynamic system and can also be applied to nonlinear problems using the extended Kalman filter (EKF), often with near-optimal, robust, and computationally efficient performance. We will not derive the Kalman filter here; the reader is referred to the many excellent textbooks on the subject (e.g., Bar-Shalom & Li, 1993; Brown & Huang, 1992; Gelb, 1974). In a nutshell, the Kalman filtering procedure consists of two steps: a prediction step that extrapolates where the object will be at time t_{k+1} based on its position at time t_k , and a correction step that is performed whenever there is a measurement available from a sensor that provides even partial or indirect information about the position.

An outstanding benefit of the Kalman filter is that it is very flexible about timing and the order in which it receives and processes measurements. There is no requirement for periodic measurements. This enables flexible integration of data from disparate sensors that are not even synchronized, making the design of hybrid trackers using multiple types of sensor technologies much easier. For example, an aided inertial navigation system may have signals from various navigation aids such as GPS, radio landing beacons, altimeter, radar, and so forth, arriving at different times. Each fix may have a different measurement model (1-D range measurement, 2-D bearing angle, 3-D GPS position fix, etc.) and is processed when and if it is available. A partial correction to the state is made immediately. This approach fits particularly well with inertial navigation systems, which by their very nature consist of a high-rate inertial integration process, which drifts and gets updated whenever a star fix or landmark sighting is

made. However, the asynchronous updating capability is valuable in other applications too. For example, in ground-based aircraft tracking, bearings from multiple geographically distributed radars with unsynchronized scan rates are combined (Bar-Shalom & Li, 1995). Relying even more heavily on the incremental partial updating ability of the Kalman filter is a problem called bearings-only tracking, in which infrared or sonar bearing-angle measurements taken at different points along the trajectory of a moving vehicle are fused over time to yield the location of the target (e.g., Nardone, 1980). In active vision systems, a robot-mounted camera looks around the room and whenever it sees a feature it recognizes, it updates its estimate of its own location and that of the feature (e.g., Chenavier, 1992; Harris, 1992). Welch and Bishop (1997) coined the term SCAAT (single-constraint-at-a-time tracking) to refer to this type of updating and used it to improve the update rate and accuracy of the University of North Carolina optical ceiling tracker, which had previously used a batch pose-recovery algorithm. They point out quite rightly that this feature is particularly valuable in virtual environment systems, where high update rates and low latency are essential and could beneficially be applied to magnetic and acoustic trackers as well. In fact, the InterSense IS-900 takes advantage of sequential Kalman processing of individual range measurements to reverse the usual direction of flight and therefore eliminate the propagation latency of acoustic tracking (Foxlin, Harrington, & Pfeiffer, 1998).

Another major benefit of Kalman filtering theory is to provide a rigorous basis for the design of hybrid motion-tracking systems. The Kalman filter produces not only an estimate of the trajectory of a moving object, but also a covariance matrix that represents the statistical uncertainty of that estimate over time. In a simulation technique called *covariance analysis* (Gelb, 1974), one can evaluate the RMS accuracy that will be achieved by fusing together measurements from any particular combination of different sensors. Many of the different sensing principles discussed in section 3 have complementary properties. Covariance analysis can help determine which technologies have the greatest synergy in an application and can help optimize the trade-offs involved in the specification of hardware subsystems' performance and number and layout of sensors or targets. Covariance analysis results comparing many different combinations of inertial, ultrasonic, inside-out and outside-in optical sensors are used by Intersense to design customized hybrid configurations to meet customer requirements at lowest hardware complexity and cost.

4.3 Auto-mapping

In trackers built for short-range tracking, all the necessary sensors are usually built into one preassembled, precalibrated reference unit, which serves as the coordinate frame reference for the tracking data. For larger area tracking, a single sensor reference unit cannot provide enough coverage area, and multiple sensor units or landmarks must be spread throughout the work area. In this case a method is needed to auto-map the positions of the entire array of landmarks or sensors in a global reference frame by moving a calibration unit through the environment in advance. If the intended tracking environment is essentially unbounded, as in an outdoor wearable AR application, even this is impossible and it is necessary to discover and auto-map the landmarks on-the-fly during tracking. This is what we shall mean by auto-mapping from here on.

This problem has received a great deal of attention in the computer vision and mobile robotics navigation communities. In computer vision, the problem is referred to as *structure from motion* (SfM), and the primary goal is to reconstruct the geometry of a scene from moving-camera imagery. The camera motion trajectory must be determined in the process, but that is not the main goal. There are several approaches to the problem, some involving deducing the shapes of surfaces from optical flow and others involving auto-mapping the 3-D positions of a set of feature points and then connecting the dots. The modern EKF approach was introduced

to the latter school by Broida et al (1990), who used 2-D bearing measurements over a sequence of frames to recursively estimate the camera pose and the 3-D locations of the observed feature points. Azarbayejani and Pentland (1995) refined the approach by simultaneously estimating focal length and changing the representation of the point positions into a 1-D format, which allows stable performance even if the initial feature positions are unknown.

The mobile robotic navigation community calls the problem *simultaneous localization and mapping* (SLAM) and considers a wider variety of sensors including sonar, radar, and lidar as well as vision. Unlike SfM, the primary goal of SLAM is often to know the location of the robot. Developing a map of the environment is a necessary means to that end. The robotics community has been working on the problem even longer, and an EKF approach was introduced by Smith, Self, and Cheeseman (1987) with similar structure. Like the early SfM papers, the early SLAM implementations employed a standard full-covariance Kalman filter. The position states of all N landmarks were appended to the vehicle position states to produce a giant augmented state vector. The covariance matrix of this augmented state vector maintains information about the cross-correlations between all the landmark and vehicle position states. Unfortunately, this rapidly becomes impractical for large numbers of landmarks, since the computational complexity increases with N^2 . A naïve solution is to drop the cross-correlations between the landmark position estimates, decoupling the problem into separate small KFs for each landmark. This reduces the problem to order N, but in practice the estimates will eventually diverge because each new measurement, say to beacon n, is treated as independent information even though the position error of beacon n is actually highly correlated with that of a previously measured beacon n-1. Soon the vehicle will think it has been given a lot of independent information and knows precisely where it is, but in reality the positions of both beacons and the vehicle are all correlated and likely off in the same direction. Much current research focuses on trying to find a work-around to this problem. Some approaches use local submaps, each of which maintains cross-correlations, and then attempt to stitch them together to form a global map (Leonard, 2000) or build a relative map storing only interlandmark distances so that repeated measurements are uncorrelated (Csorba, Uhlmann, & Durrant-Whyte, 1997). Unfortunately, the latter approach does not even estimate the pose of the vehicle. Another very interesting approach is a new method of data fusion called *covariance intersection* (CI) which replaces the Kalman measurement update process with something that is suboptimal but does not assume each measurement to be uncorrelated with previous ones (Julier & Uhlmann, 1997). This is one of the few techniques available so far for handling very-large-scale auto-mapping problems in a very general mathematical framework.

4.4 Prediction

A good motion tracker should have the ability not just to accurately follow the current pose of the user, but also to predict motion enough to compensate for the end-to-end delay of a VE system caused by tracker latency, communications, rendering, and image scan-out on the display. Depending on the number of pipelined rendering stages and frame rate, system delay typically ranges from 25 ms to 150 ms or more. Obviously, longer predictions are less accurate, so prediction is not a panacea for slow virtual environment generators. However, when the total latency is less than about 60 to 80 ms, it can help dramatically.

All prediction is based on the Taylor Series expansion:

$$x(t + T_p) = x(t) + \dot{x}(t) \cdot T_p + \frac{1}{2}\ddot{x}(t) \cdot T_p^2 + \frac{1}{6}\dddot{x}(t) \cdot T_p^3 + \dots$$

The more derivatives at time t are accurately known, the further into the future this prediction holds. In model-free prediction (most of the work to date) this formula is applied separately

to each of the 6 degrees of freedom, as if they each could evolve independently. This is the most general approach but doesn't take advantage of any kinematic constraints that might be known to exist, such as attachment of a head to a neck.

Normally one only has samples of the position and orientation variables at discrete points in time and must obtain the derivatives by numerical differentiation, which is noisy. Early efforts to use prediction with magnetic trackers used a Kalman filter to estimate the derivatives (Friedmann, Starner, & Pentland, 1992; Liang, Shaw, & Green, 1991) with much less noise because it performs optimal smoothing based on an a priori model of head motion. Nonetheless, it is much better to actually measure the velocities or accelerations using inertial sensors. Azuma and Bishop (1994) showed two to five times higher accuracy with inertial sensors measuring the derivatives compared to a prediction method where these quantities had to be estimated from the optical position tracker data using a Kalman filter.

Whether using estimation or inertial sensing to obtain the derivatives, a model-based approach would allow longer prediction with the same accuracy from the same data. To see this, consider a hand which is constrained to remain attached to the end of a forearm, which is rotating about the elbow joint. Essentially, a model-free prediction would predict the future location along a straight-line projection of the current velocity of the hand, whereas a model-based method would predict the future location along the circular arc originating from the elbow. If predicting far enough into the future that the elbow would significantly rotate, the latter would be far more accurate. Akatsuka and Bekey (1998) proposed an extremely simplified model of head motion (a lollipop on a stick of length L, rotating about a fixed point at the base of the neck), and showed improved prediction compared to a model-free approach, although the paper doesn't explain how the model is used in the predictor. For human-motion prediction using a fairly simple model of 17 rigid objects, a model-free prediction would have $17 \times 6 = 102$ separate variables, whereas a model based approach would reduce this to predicting approximately 46 joint angles. By respecting these kinematic constraints much accuracy would be gained, but even more might be attainable by considering a dynamics model of the body including mass distributions and muscle forces. Hans Weber at the University of North Carolina, has been working primarily on the former, and Dov Adelstein at NASA Ames has an interest in the latter, but neither has yet published results (personal communications, June 5, 2000).

In addition to improving the kinematics models underlying prediction, there may be some benefits achievable with adaptive multiple-model filtering. In a Kalman filter, the state of the system is always modeled as a linear dynamic process driven by white noise. The white noise is used to model the unknown inputs, namely muscle forces (when no inertial sensors are present) and derivatives of these forces when inertial sensors have directly measured the effects of the forces. This isn't a very good model of human behavior, as it assumes random motion going on all the time with the same intensity. Real human-motion is much more episodic, having periods of stillness interspersed with bursts of motion activity. The onset of the motion is unpredictable, but once the motion starts it is likely to follow a certain course. Filters for tracking aircraft from radar observations make use of multiple-model techniques in which they use a second order kinematics model driven by white noise acceleration during straight and level flight and switch to a third-order model driven by white noise jerk during maneuvers that involve acceleration.

There are a variety of statistical techniques for detecting the onset of maneuvers and switching models or adjusting the blend of multiple concurrently running models (Bar-Shalom & Li, 1993). In addition, it would seem that model selection could be viewed as a classification problem and traditional classification algorithms such as neural nets or fuzzy logic could be usefully combined with the KF estimation paradigm, although this has not been discussed in the literature. Like aircraft motion, human-motion may also be classifiable into

several distinct modes, but it will require model-switching on much shorter time frames, and the maneuvers are more complex and may require many more than two different modes. This is a fertile ground for research on prediction that has not yet been adequately explored. Short of this variable-state-dimension multiple-model approach, there are adaptive techniques for tuning the process noise to increase it during maneuvers. The best prediction methods of the future will probably combine all three techniques: inertial sensing, specific kinematic modeling, and adaptive stochastic models that adjust to the presence or absence of "maneuvers" such as gestures or visual pursuit patterns. Better yet, virtual environment designers will select rendering platforms that can render 60 frames per second without pipelining, and even simple prediction algorithms will be sufficient for the 20 to 30 ms of prediction that are required in such a system.

5. ENGINEERING OF MOTION TRACKING

To develop motion tracking systems into successful commercial products requires disciplines that are often quite foreign to the types of researchers who work with the physics and mathematics concepts outlined in the previous two sections. For such researchers, the end goal is often a proof of concept demonstration running on a UNIX or Windows computer, with sensor data read in through serial ports or data acquisition boards using vendor-supplied driver software over which the researcher does not have adequate control. Synchronization and timing may be dependent on a system clock with inadequate resolution, and the operating system may randomly interrupt tracking software to perform other tasks. Most obvious of all, the demonstration tracking system may require a lab cart to haul around and have so many boxes and cables that it is irreproducible and treacherously unreliable.

To go from this type of demo to a reliable, producible, and cost-effective device requires methodical software and hardware engineering practices and great attention to detail. Code must be written by professional real-time embedded programmers using a real-time operating system, or perhaps no operating system but a lot of careful benchmarking, timing diagram design, and conformance testing. Bug and feature tracking, and release-level testing, which were at best informal in the research laboratory take on highest priority and consume many times over the number of months that were required to build the original working prototype.

Besides robustness and performance, the obvious engineering goals are miniaturization, power reduction, cost reduction, and increased ease of use. A particular need that has not yet been addressed satisfactorily for most trackers is wireless multiuser tracking. For HMD-based systems, the limiting factor has been the difficulty of making the HMDs themselves wireless, because video imagery requires much higher bandwidth than does tracking data. However, FSD-based VEs are increasing in popularity, and stereoscopic viewing glasses are wireless. There is therefore a real need for wireless tracking in these environments. Certain tracking technologies have no electronics on the object being tracked and are therefore intrinsically wireless. These include computer vision techniques to directly track the image of the hands or their silhouettes (Leibe et al., 2000) or passive markers on handheld tools (Dorfmueller, 1999). For other tracking technologies, which require electronic sensors on the moving object, power consumption must be reduced to allow battery operation and infrared or RF telemetry provided to bring the data back to the host. Designing such telemetry links has previously required a great deal of RF engineering, but there is rapid progress recently in the development of embeddable RF modules or even single-chip radio solutions, driven by developments in the mobile computing and telecommunications sectors. Of particular interest is an emerging standard called Bluetooth, which is designed to facilitate hassle-free data exchange between cell phones, PDAs, notebooks, and other portable and office-based electronics (www.bluetooth.com). The

Bluetooth consortium members will soon begin to introduce a variety of low-cost single-chip radios that support data rates over 700 Kbit/sec, quite enough for several trackers in a VE.

6. SYSTEMS INTEGRATION OF MOTION TRACKING

After all of the best engineering practices have been followed, a wonderful motion tracker with low latency and state-of-the-art prediction algorithms gets shipped to a user who integrates it with a VE system and frequently gets miserable results. This happens because end-to-end system latency and image stepping are properties of the whole system and cannot be cured by the tracker without modifications to the rest of the system. The comments in the previous section about real-time programming apply equally to the development of VE system software, and this must be done in accordance with a synchronization policy that the motion tracking system supports.

Before discussing the solutions, consider some of the problems of poorly synchronized systems:

- Latency jitter, multiple images, image stepping
- Longer average latency
- Image shearing

In a typical asynchronous VE system, the tracker loop, graphics rendering, and display scan out all operate independently. The display refreshes at a constant rate, say 60 Hz, following a raster pattern from top to bottom. There are exceptions, such as calligraphic CRT displays and frameless rendering (Bishop, Fuchs, McMillan, & Scher-Zagier, 1994), but these are not in common use. The rendering process will have a nonconstant update rate that may vary from over 70 Hz down to less than 30 Hz, depending on the complexity of the part of the scene in view. The tracker runs internally at its own constant rate, say 130 Hz, and either spits data at the host computer continuously or provides the latest data record whenever it is polled. Figure 8.6 below illustrates a section of this asynchronous operation, with continuous mode tracker reporting, as the renderer frame rate drops from about 70 Hz to just below 30 Hz.

The light-colored bars in the top row indicate frames of the video that contain freshly rendered images; the dark bars on frames 5, 8, and 9 indicate “dropped frames” where there was no new rendering cycle computed in time so the frame buffer scanned out the same image as the last frame. Dropped frames cause the perception of multiple images (Moore, 1996). To see this, consider a 60-Hz display device driven by a graphics engine that renders at 30 Hz so that every other frame is dropped. As the eye tracks a moving object in the series of new frames and blends the sequence of discrete frames into an apparent continuous motion, the repeated

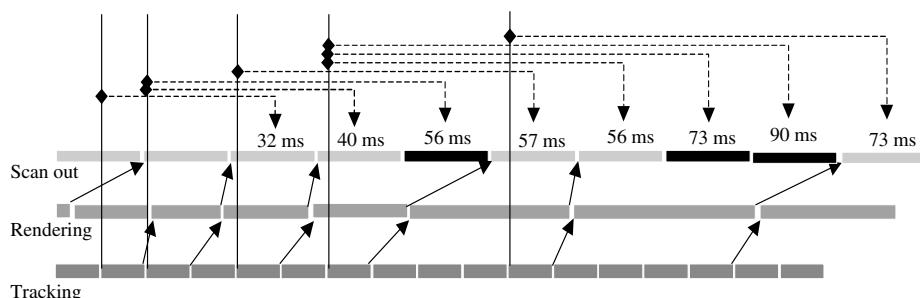

FIG. 8.6. Illustration of typical nonsynchronized VE system.

frames do not fit into this interpolated motion trajectory, but rather create a ghost image of the object lagging behind it by a distance proportional to the speed of motion. Likewise, a 20-Hz graphics update rate would produce a triple image. A similar triple image can be seen in field sequential color displays in which the same image is redrawn three times, and the image therefore separates into nonaligned red, green, and blue images even at field rates of 180 Hz. It is apparent from the figure that at rendering rates of 60 Hz or more there will be no dropped frames, from 30 to 60 Hz there will be single dropped frames, and as soon as the renderer dips below 30 Hz there is the possibility of occasionally dropping two frames in a row, as shown. If frames are dropped only sporadically they may appear as image twitching rather than a steady multiple image, but this can be equally annoying.

Even when no frames are being dropped and the image generator is rendering at a steady 60 Hz, there is a variable latency between the sampling of the head motion sensors and the display of the image. This latency ranges from 33.3 ms for best-case synchronization to 58.5 ms for worst case, for objects halfway down the raster display. When there is no synchronization policy, the latency will be varying across this range due to the beat frequencies between the display refresh, rendering cycle, and tracking loop. At a head rotation rate of 200 deg/sec, this latency variation of ± 12.5 ms will cause ± 2.5 degrees peak spatial oscillation. Thus, in an unsynchronized system, the effects of latency jitter are probably even more detrimental than the effects of the average latency itself, and average latency is also worse in this system than it needs to be. Finally, the effect of image shearing is caused by the 16-ms difference in latency between the top of the image and the bottom. This causes objects at the bottom of the image to lag behind those at the top and vertical lines to take on a slant proportional to the speed of panning. The remainder of this section discusses approaches to solving these problems.

6.1 Hard Genlock

Figure 8.7 illustrates a traditional and dependable synchronization policy that can be used to integrate a VE system with tracking. Used universally in professional video production and in many high-performance VE simulators, this system is based on a master “genlock” synchronization pulse at the video field rate, to which all other processes in the system are slaved. This imposes a requirement for the image generator to strictly maintain a 60-Hz frame rate. To accomplish this, the scene must be simplified until no portion of the scene causes “overloading,” or else the rendering software must be provided with automatic level-of-detail control that checks every frame and merges polygons if necessary to keep the total load below the point of overloading.

The case illustrated shows the lowest latency configuration with no pipelining in the renderer. This is called *guaranteed single-frame latency*, and is becoming the norm on modern personal computer graphics cards. Genlocking still works with pipelined graphics architectures:

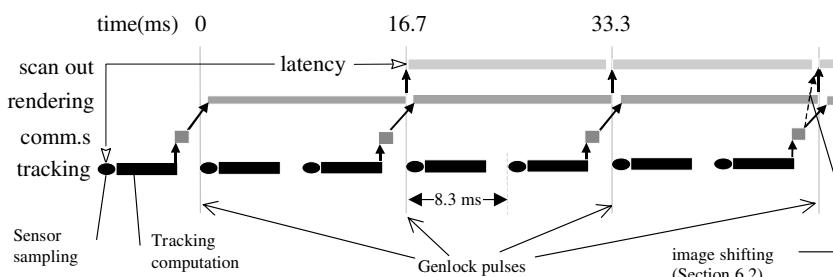

FIG. 8.7. Baseline synchronization policy using master “genlock” signal.

The latency will be larger but still constant. The tracker loop is shown running at twice the genlock rate. The first sensor sampling is initiated directly by the genlock pulse, and another one is internally initiated exactly half a frame period later. With many trackers it would be sufficient to sample at 60 Hz, but for inertial trackers a quicker update rate helps integration accuracy, and for DC magnetic trackers the 120-Hz rate allows the use of a two-tap filter for canceling 60-Hz interference, as discussed in section 3.5. With the inertial tracker, the latency from sensor sampling to the beginning of display screen scan out is 25 ms, as shown in the figure. This latency is so small that it can be compensated very effectively with prediction. In a pipelined rendering system, overall latency may be increased by one or more frames so that prediction algorithms may begin to demonstrate some noticeable overshoot. To overcome this, it is recommended that the motion tracker be sampled again right before the final stage of the rendering pipeline, with a newer and more accurate prediction used to drive final rendering operations. Because this view vector may be off by a degree or two from earlier predictions, it would be necessary to perform the earlier culling with a slightly enlarged viewing frustum, then narrow it down to final size on the last stage. Note from the drawing that the tight loop-timing shown is only possible if the communications of tracker data to the host can be completed before the beginning of the next frame. With an rs-232 serial port running at 115,200 bits/sec, a tracker datum containing six 4-byte floats can be transmitted in 2.3 ms. For longer data packets (e.g., containing multiple sensor data), less efficient encoding, or slower baud rates, either a faster communications link must be found or a longer latency endured.

6.2 Image Shifting

The effect of small rotation angles of a virtual camera in azimuth and elevation is nearly equivalent to a simple linear translation of a 2-D image. This fact makes it possible to perform a final adjustment of the scene using the very latest tracking data after the final stage of rendering, just before or during scan out. The last cycle in Fig. 8.7 has a dotted arrow showing how data from the tracker is used not only to start the next rendering cycle, but also to compute an image shift amount for the frame just rendered, right before scan out. The new tracker datum is based on sensor data sampled only 8.3 ms before scan out, and thus can be predicted forward with almost no error. Yaw and pitch values are compared to predictions that had been used for the rendering process, and the differences are used to determine the necessary horizontal and vertical shift values.

Image deflection was conceived by Rediffusion in the 1970s and implemented in the early 1980s by the Naval Air Warfare Center Training Systems Division (NAWCTSD) for a laser projector display (Breglia, 1981) and by the Institute of Sound and Vibration Research for a CRT in an HMD (So & Griffin, 1992; Wells & Griffin, 1984). In a CRT, it can be achieved with simple analog electronics, which add an additional offset current to the horizontal and vertical deflection yokes of the CRT. For LCD displays, they cannot be deflected this way, but the shifting can still be accomplished without bothering the main CPU by playing with the frame-buffer-addressing hardware. In both cases, the image has to be slightly overcomputed to allow shifting. The amount of overcomputed area can be greatly reduced by using the best possible prediction technique before rendering.

Even with a system that is tightly genlocked and designed to maintain a steady 60-Hz image rendering rate, there is always a concern that it may at some point become overloaded and drop some frames. Image shifting can also be used to help compensate for lost frames by predicting and shifting the previous frame until a newly rendered frame is available (Moore, Pope, & Foxlin, 1998). In a system where 60-Hz rendering is not possible due to cost limitations but the display must be run at 60 Hz to prevent flicker, image shifting can help reduce the multiple images effect, although it does have some side effects for moving objects in the scene (Moore, 1996).

A more sophisticated technique, which is basically an extrapolation of the image shifting concept, is the “address recalculation pipeline” architecture proposed by Regan and Pose (1994). Instead of just overcomputing the frame a little on each side, they compute a complete surrounding world, rendered on six faces of a cube around the user’s current head position. Once this is rendered, the user with an HMD can look all around, and the orientation tracker is used to read out an appropriate portion of the six-sided frame buffer, automatically undistorted by hardware in real time at 60 Hz. Latency with respect to head-orientation changes is therefore eliminated. However, whenever the user translates in position, all six faces of the cube have to be rerendered. Since translational movement has relatively small effects on distant objects, closer objects get rerendered first, thus minimizing the translational latency penalty. By keeping sets of objects at different distances in different frame buffers, which are composited together during scan out, they can be rerendered at different rates.

All the prediction, synchronization, and shifting techniques discussed so far are designed to achieve consistent and minimal latency from the head motion to the beginning of image scan out. However, the scan out itself takes 16 ms, and so objects toward the bottom of the display screen will suffer more latency than objects at the top. The most obvious manifestation of this is during horizontal scanning, when everything in the frame appears to slant. A solution called just-in-time pixels (Olano et al., 1995) has been proposed, in which ideally each pixel is rendered separately with tracker data concurrent to its display time. Olano et al. (1995) suggest an approximation by using a separate viewing transformation for each line, or even just two transformations for the first and last pixel, with all others calculated by linear interpolation. In practice, the effect will be very nearly linear over the 16-ms scan period, so all that is needed is to measure the head rotation rate about the vertical axis with a gyro, or estimate it with a Kalman filter and then shift each scan line by an increasing amount proportional to this rate. Reichlen (1993) implemented a frame buffer with this shifting feature built in. It is of course also possible to predistort each polygon in software if it is known how fast it will be moving across the screen.

7. SUMMARY OF RECENT PROGRESS AND FUTURE POTENTIALS

Since Meyer et al.’s 1992 Survey of Position Trackers, the field has evolved and produced some new tracking options as well as some new demands. Drift-corrected gyroscopic orientation trackers have appeared, and where only orientation is needed they now provide an affordable use-anywhere solution with sufficient resolution, robustness, responsiveness, and sociability for HMD fly-through applications. Outside-in optical tracking has increasingly made inroads in motion capture and is beginning to reach a level of real-time performance and price suitable for performance animation. Laser scanners have come out of the laboratory and are now commercially available from several sources. The realization of the need for hybrid tracking has sprung up everywhere, with an acoustic-inertial hybrid on the market and research papers on magnetic-inertial, optical-inertial, and optical-magnetic combinations signaling a diverse future. GPS has proliferated throughout the world, and, driven by huge volumes, vendors have succeeded in shrinking complex receivers down into incredibly tiny packages. The field of machine vision, bolstered by industrial parts inspection applications and the ascent of PC computing power, has made great strides in bringing formerly expensive algorithms down to the level of routine use, including a new breed of compact vision systems and smart cameras suitable for embedding. Ultrawideband radio technology has appeared in the form of microimpulse radar products, and at least theoretically holds out the promise for an improved method of omnidirectional point-to-point ranging.

Two paradigm shifts in the VE field are happening which are creating new types of requirements for motion tracking systems. The first is a trend away from HMDs and towards FSDs, such as the CAVE, the virtual workbench, and personal minidome projectors. In simulation and training where a sense of presence is an important aspect of the application HMDs are still the norm, but for systems design (see chap. 52, this volume) and information visualization (see chap. 53, this volume), easier group dynamics tend to favor the headgear-free FSD paradigm. This reduces the need for high-resolution low-latency head-orientation tracking, but increases the emphasis on high-quality 6-DOF hand tracking. Furthermore, the user is no longer forced to don a heavy headset with a cable, so the requirement for a lightweight wireless tracking device is increasing. A second trend is the increasing interest in AR (see chap. 48, this volume). This creates requirements for tracking that is far more accurate and, at the same time, small enough to wear and able to operate over a large range in a cluttered environment. The consensus is that a hybrid of inside-out computer vision and inertial technology is likely to be the best fit for this problem, and that is unlikely to change since that is the solution that biological evolution has developed for the same problem. Initial offerings will require the use of artificial fiducial marks to simplify the computer vision requirements, but the long-term goal is to make use of natural features found in both indoor and outdoor scenery to allow unrestricted tracking in arbitrary unprepared environments.

This survey has attempted to overview physical principles that can be exploited for VE-style motion tracking applications. It is a testament to the diligence of the engineers in the field that almost all of them are already being used. However, a few ideas have been discussed that have not yet been developed as far as they could, or in some cases have not even been discussed in the literature. These represent the “low-hanging fruit” that may be able to yield new and useful tracking technologies for certain applications in the next few years. For example, the biokinematic reckoning approach of section 3.1.2 or the biodynamic model-based tracking of section 3.2.4 may yield new approaches to full-body avatar animation with significant mobility and cost advantages over the magnetic and optical systems that are prevalent today. The potentially reduced multipath incidence with ultrashort electromagnetic impulses mentioned in section 3.6.2 suggests that this could eventually become a better alternative than acoustic ranging in aided inertial trackers, especially outdoors. The polarized light technique in section 3.7.3 might make an alternative to the compass for correcting inertial yaw drift in confined metallic environments such as inside a vehicle. The vision-aided inertial approach, with GPS priming in outdoor applications, will eventually find a wide audience as portable and wearable systems become common. The research groundwork in these areas is being laid today, and it is possible to imagine in the foreseeable future ubiquitous computing devices offering new human-machine interface capabilities based on position and orientation tracking.

1. INTRODUCTION

Development of instruments for tracking eye movements has been under way for over 25 years (Cornsweet & Crane, 1973; Young & Sheena, 1975). Early eye trackers were cumbersome devices in which the user wore uncomfortable gear, such as bulky helmets or other equipment affixed to the head. Except under the most controlled conditions, these devices were not capable of maintaining their calibration because it was difficult to maintain strict positioning of the devices on the head. More recently, eye trackers have been developed that attempt to overcome these shortcomings. Ultralight headband-mounted trackers have been developed that reduce slippage. Also, newer devices, based on a tracking system mounted on the display screen rather than the head, permit the user to roam relatively freely over a comfortable region of space.

The primary goal of early eye trackers was to support research in human visual data acquisition. But as instrumentation technology continued to evolve, it eventually led to applications in a variety of settings where understanding of human perception, attention, search, tracking, and decision making are of great importance. This includes industrial inspection (Megaw & Richardson, 1979), medical image analysis (Reuter & Shenck, 1985), visual response to advertising (Lohse & Johnson, 1996; Russo & LeClerc, 1994), and analysis of the performance of airplane pilots (Sanders, Simmons, & Hoffman, 1979). More recently, eye-tracking measures have been used to understand the causes of cybersickness in flight simulators and virtual environment (VE) devices (Kaiser, 1999) and to pinpoint theories of language processing (Eberhard, Spivey-Knowlton, Sedivy, & Tanenhaus, 1995). At the same time, there have been efforts to develop eye trackers as visual communication and control devices (Freedman, 1984; Jacob, 1991; Velichkovsky & Hansen, 1996), e.g., to aid disabled people (Yamada & Fukada, 1987). In particular, eye movement-based human-computer interaction (HCI) techniques have been studied to assess the ability of gaze, along with speech and tactile

interactions, to provide more natural interactions with computers than the traditional mouse and keyboard.

This chapter discusses the use of gaze-based communication and control systems to support multimodal interactions, in real and virtual environments. Specifically, it first describes how these new trackers work (section 2), then, how they are used as input devices (section 3), how they are being integrated into VE systems (section 4), the human factors analyses that are underway to assess the effectiveness of eye tracking in comparison and in combination with other modalities (section 5), and concludes with an assessment of future directions in eye tracking for virtual environments (section 6).

2. HOW EYE TRACKERS FOR VE WORK

Eye trackers have been developed for measuring many properties of visual behavior, for example, saccade and smooth pursuit, as well as accommodation, vergence, and pupillary response. The key measurements for visual communication and control that have been used are saccades and pursuit, and the fixations between these movements.

Normal eye movements (e.g., in reading) consist of saccades, or jumps, from one fixation (stationary position) to another. Typically saccades range in amplitude from 1 to 20 degrees, corresponding to a duration of 30 to 70 msec, and peak velocities of 70 to 600 deg/sec, respectively (Bahill & Stark, 1979). When following slowly moving targets in the range of 1 to 30 deg/sec, the eye can track these movements with a smooth-pursuit behavior that appears to partially stabilize the image of the target on the retina (Young & Sheena, 1975).

Several basic techniques have been used for tracking eye position. They can be divided into contact and noncontact methods. The contact method uses magnetic induction of two sets of orthogonal induction coils, driven in quadrature, on a scleral ring worn on the eye of the participant. Rotation of the eye results in changes in the amounts of phase-locked horizontal and vertical induced currents picked up by the scleral ring, thereby providing a signal proportional to eye position. The search coil technique provides accurate measurement of two-dimensional (2-D) eye position, but requires local anesthesia that limits the experimental session to about 20 minutes (Remmel, 1984). Among the noncontact methods, the limbus eye tracker is the simplest and least expensive. Two infrared (IR) photo-emitters pulsed at 1 kHz are aimed at the iris (dark)-scleral (white) boundary on either side of the eye. More, or less, light will be reflected depending on the position of the eye relative to the emitter. A pair of infrared detectors picks up the reflected light from the emitters. The differential signal from the emitters is demodulated and filtered to provide a signal proportional to horizontal eye position. This technique provides a relatively easy-to-use recording method, but it is limited to horizontal eye movements. Another technique is the Purkinje eye tracker, which measures the relative displacement of the images formed by the reflection of a light source at the anterior corneal surface and the posterior lens surface, which are known as the first and fourth Purkinje images, respectively. Rotation of the eye results in a greater displacement of the first relative to the fourth Purkinje image, thereby providing a signal proportional to eye position. However, this device requires precise alignment and is not suitable for experiments that permit relatively free movement by the participant (Young & Sheena, 1975).

The video-based eye tracker is the most suitable for 2-D recording of eye movements of a participant who is relatively free to move about in a region of space. It is currently used for communication and control in virtual environments. The tracker captures a video image of the

eye illuminated by a distant, low-power, infrared light source and creates an image that is seen as a highlight spot on the surface of the cornea. The image is analyzed by a computer, which calculates the centroid of the corneal reflection as well as the centroid of the pupil. The corneal reflection from the front spherical surface of the eye is insensitive to eye rotations, but it is sensitive to translational movements of the eye or head. On the other hand, the pupil center is sensitive to both rotation and translation. Thus, the difference between the pupil center and the corneal reflex provides a signal proportional to eye rotation, and thereby the direction of gaze, which is relatively free of translational artifacts.

In head-mounted eye trackers, the IR source, the camera that views the eye, and a second camera that views the observed scene are all mounted on the head. Additionally, as the user roams about in a prescribed space, a magnetic sensor is affixed to the head to record the position of the user in the space. The system computes the point of gaze in the image obtained by the scene camera. On the other hand, in more recently developed computer interface-type trackers, the IR source and one camera are gimbal-mounted on a stationary platform containing the computer display. The user is not required to wear any devices. After a simple calibration procedure, the tracker can be used to record eye gaze position in the monitor display. Moreover, the user would be able to use the eye as a pointer in the same fashion one would use a mouse. Both systems allow the user to operate in a hands-free mode.

Two methods of illuminating the eye are in common use, dark-pupil and bright pupil. In the dark-pupil technique, the IR source is off-axis, causing light to be trapped in the interior of the eye. The pupil appears very dark in the eye image. On the other hand, if the IR illumination is provided coaxial to the eye, the eye appears to glow brightly. The dark pupil provides somewhat less contrast than the bright pupil for detecting iris boundaries. However, the bright pupil may interfere with the corneal reflex for relatively larger eye movements. Moreover, the bright pupil technique requires precise alignment of the incident and reflected light (which is consistent with our experience at the Vision Laboratory of the Rutgers University Center for Advanced Information Processing [CAIP]). Therefore, for measurements that allow for relatively free movement of the participant, the dark pupil technique is preferred.

Video-based eye trackers capture images of the eye using a standard RS170, 30 frames/sec video camera. Each frame is composed of two 512×240 interlaced fields that result in a 512×480 pixel image. However, since the tracker analyzes each field independently, images can be captured at a field rate of 60 times/sec. This relatively rapid recording of data allows for separation of fixations from saccades. The eye movement results can be plotted as a scan path, that is, locations of the sequence of fixations in the scene and paths of the saccades connecting them. Scan path plots are useful as indicators of the human observer's regions of interest during a visual task. The fixation locations derived from the data are also useful for eye-mouse-type pointing and menu selection operations described in section 4.

To make these systems work reliably, a number of technical issues need to be addressed. For example, gimbal-mounted eye trackers attached to computer displays must:

1. Lock on to and track the eye as the user's head moves about in the space in front of the display (usually a rather confined volume of space).
2. Maintain the image of the eye in sharp focus for reliable computation of the centroids using some form of autofocus.
3. Measure and keep track of the distance of the eye from the screen in order to compute the visual angle subtended by the screen (required to maintain pointing accuracy).
4. Be easily calibrated.

FIG. 9.1a. Head-mounted eye tracker.

Head-mounted trackers must:

1. Strictly maintain their position on the head or be able to recalibrate themselves with small shifts in position.
2. Provide for untethered operation (in most applications), either by RF links for the tracker and the magnetic head position sensor or by integration into wearable computers.

The value of this technology as an input mechanism will be closely linked with the degree to which problems associated with these issues are solved. Examples of head-mounted and computer-display-mounted eye trackers are shown in Fig. 9.1 (courtesy of ISCAN, Inc.).

FIG. 9.1b. Gimbal-mounted eye tracker to be affixed to a computer display.

3. THE USE OF EYE TRACKERS AS A COMPUTER INPUT DEVICE

It is a common and often valid assumption that what a user is looking at on a computer screen is also the object the user wishes to select. Thus, people have attempted to use the eye tracker as an input device primarily for menu selection. Because the eye tends to rapidly saccade from place to place, object selection is defined by a dwell time of the eye resting on an object, usually 250 milliseconds. However, holding the eye in one position for 250 milliseconds is difficult for users. Dropping the dwell time to something more comfortable, e.g., 100 milliseconds leads to what is known as the “Midas” touch, that is, an overselection of screen objects. Notable successes have occurred with this type of input device for severely handicapped individuals, but everyday computer users find this form of input difficult and tiring (Jacob, 1991).

A key problem with using the eye as an input device for a computer system is that it already is being used as a visual input device for the human. As such, there are likely to be conflicts between the desired computer input behavior and the automatic human-eye behavior. Rather than requiring conscious control of the eye for selection, researchers have more recently looked at modeling the human-eye behavior in order to build intelligent heuristics for determining the computer input the user wants to make. A simple heuristic is that used by Zhai, Morimoto, and Ihde (1999). In their studies they assume that where the eye is looking is where the mouse cursor is best placed. No selection is made. Selection is still done by depressing the mouse button, but the user no longer has to move the mouse cursor a long distance to reach the desired selection target.

In another study by Tanriverdi and Jacob (2000), a threshold count of “landings” is used to deduce the desired selection object. It is assumed that if the eye saccades to a specific area of the screen a specified number of times, then the selection object in that area is the user’s input. This heuristic is more complicated than simply counting the saccades over a selection object because a saccade may not even land on the desired object, only close enough to view it. Both of these mechanisms make inferences that may be undesired by the user so that, like the Midas touch of short eye dwell times, users may be faced with the extra effort of “undoing” the computer’s decision making.

An alternate modality study, with speech recognition systems correcting speech recognition errors with additional speech, proved to be incredibly frustrating and time consuming for users (Karat, Halverson, Horn, & Karat, 1999). This is why both input designs (Tanniverdi & Jacob, 2000; Zhai, Morimoto, & Ihde, 1999) required a manual confirmation of a selection either with a mouse or Polhemus “click.” A user could also gracefully exit from a computer inferred selection simply by looking elsewhere.

In addition to being a useful input mechanism when other methods are impractical or impossible (e.g., speech in a noisy environment), there is strong potential for combining input information from multiple modalities to further enhance the recognition of the information provided by any individual input device. For example, if gaze were combined with speech, it is possible that when a user says, “Put that there,” the eye saccades to the location implied by “there” when the word is said. The timing interrelationship of the speech and the eye movement would then tell exactly where the “there” implied by the speech is located despite having a very noisy set of eye movements. The location of the eyes can also help untangle speech recognition. If a speaker said, “the red triangle,” this could be understood as different from “the red quadrangle” simply by knowing that the speaker’s eyes were saccading about a region of the screen containing the triangle not the quadrangle. Similar advantages might also be gleaned from looking at where a user is pointing or gesturing.

At this time, no natural, simple solution exists for using gaze alone for input selection. However, the above designs suggest that the use of gaze as an input mechanism is becoming

more viable. Our own studies, and the two studies referenced above that make inferences from a user's natural eye behavior indicate that the design of a viable interaction mechanism is more complicated than simply using gross eye motor movements and dwell times. Such a mechanism may have to be trained to individual eye movement behaviors of the user as speech recognizers are now trained or be based on other basic eye movement behavior.

Head-mounted displays (HMDs) currently have limitations for gaze input because maintaining calibration is difficult due to slippage of the head-mounting device. Calibration is also a problem with a desk-mounted eye tracker, but the difficulties are not as severe. A gradual loss of calibration occurs over time, especially if the user is gazing at objects at the outer limits of the virtual scene. What is needed are mechanisms built into the VE that recalibrate the user periodically. Another calibration problem occurs if the user is moving to and fro during interaction. Face-tracking algorithms are being used (Yang, Stiefelhagen, Meier, & Waibel, 1998) to capture this motion and reset screen distance for the eye tracker. Overall, either head mounted or desk-mounted eye tracking devices are still difficult to use and take considerable fiddling, adjustment, and programming to interface with virtual environments. So, although promising as input devices, their English sports car tuning needs keep them from becoming over-the-counter input devices.

4. INTEGRATION OF EYE TRACKERS INTO MULTIMODAL VE SYSTEMS

Current human–machine communication systems rely, predominantly, on keyboard and mouse inputs that inadequately represent human capabilities for communication. More natural communication interfaces based on speech, sight, and touch can free computer users from the constraints of keyboard and mouse. Although these alternative modality interfaces are not currently sufficiently advanced to be used individually for robust human–machine interaction, they are sufficiently advanced to provide simultaneous multisensory exchange of information. Towards that end, the Rutgers University CAIP Center, under the National Science Foundation STIMULATE program (Flanagan et al., 1999), is conducting research to establish, quantify, and evaluate techniques for designing synergistic combinations of human–machine communication modalities. The modalities under study are sight, sound, and touch interacting in collaborative multiuser environments (see Fig. 9.2). The CAIP Center's goal is to design a multimodal HCI system with the following characteristics and components:

- Force-feedback tactile input and gesture recognition
- Automatic speech recognition, sound capture by microphone arrays and text to speech conversion
- Gaze and face tracking along with face verification for secure access
- language understanding and fusion of multimodal information (part of multimodal input management)
- Image understanding with region of interest detection and visual feature extraction
- Applications for collaborative work and design problems

As presently implemented, the current multimodal system incorporates the following components and characteristics:

- Force-feedback tactile input and gesture recognition
- Gaze tracking by a desk-mounted eye tracker, sound capture by a microphone array, automatic speech recognition, and a speech synthesizer
- Language understanding and fusion of multimodal information using a multimodal input manager

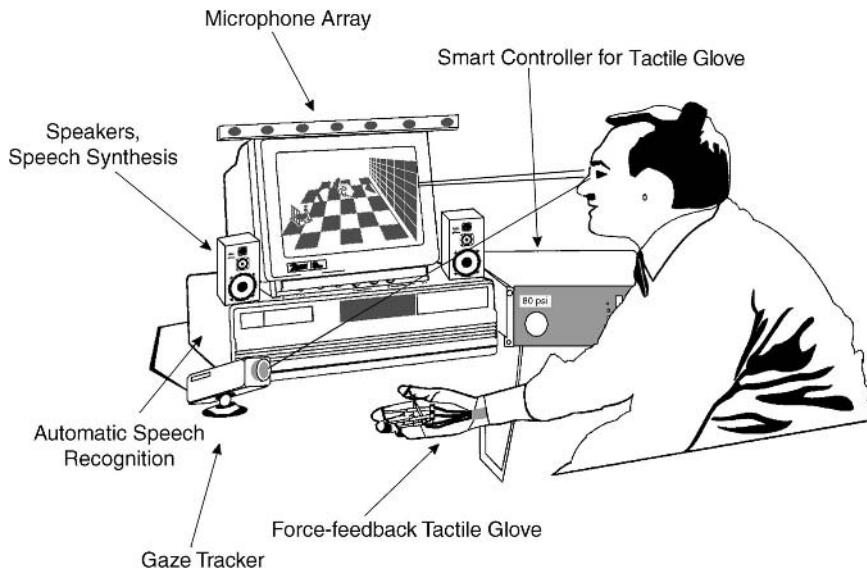

FIG. 9.2. CAIP Center multimodal system.

- Collaborative desktop used in an application requiring manipulation of 2-D and three-dimensional (3-D) graphical objects and icons on topographical maps (crisis management/disaster relief)
- Application for collaborative diagnosis of medical images

The integration of different input devices into one multimodal system also involves the integration of different platforms and languages. The contribution of gaze input to the multimodal system is to provide gaze directed hands-free visual communication. In the current implementation, gaze serves as a mouse-type pointer used in conjunction with the speech recognizer for issuing and carrying out commands like "Select it" and "Drop it." The gaze tracker used is a desk-mounted, nonintrusive ISCAN RK-726. It consists of a gimbal-mounted camera, an IR light source, and an ultrasonic depth sensor. The camera and IR source are used to compute the centroids of the pupil and the corneal reflection. The ultrasound sensor measures the distance of the eye from the screen to focus the camera lens automatically and to compute the visual angle subtended by the display screen.

The electronics for processing image data, carrying out tracking operations, and storing and transmitting data are mounted on a PCI bus circuit board installed in a Pentium personal computer (PC). This PC provides not only the coordinates of where the user is looking, but also the pupil diameter. It is possible to store gaze patterns and analyze them after the session. The gaze tracker PC is connected to a SUN Ultra workstation via a serial port connection. The main computer for the multimodal system is a Pentium Pro PC, which receives all multimodal inputs from the gaze tracker, tactile glove, and speech recognizer.

The main language used for the implementation of the multimodal system is Java because of its platform independence. An operating system (OS) level driver, Gaze Server, has been developed in the C programming language because of limited support for low-level programming in Java. The gaze server, which runs on the SUN Ultra workstation, reads the serial port from the eye tracker computer and writes gaze coordinates out to a socket. Since sockets are well supported in Java, a Java driver—Gaze Client—forms a TCP/IP (transmission control protocol/Internet protocol) connection with the gaze server to read the gaze coordinates. The coordinates of the eye position are then sent to the multimodal system after some preprocessing,

which includes smoothing and translation of the coordinates to the appropriate screen location. The Gaze Handler in the modality manager and fusion agent uses these coordinates. The gaze handler, to give the user feedback on the accuracy of eye tracking, generates a gaze cursor on the screen. Similar OS level drivers, Java drivers, and modality handlers exist for all the independent modalities in the system.

One of the challenges faced in the use of the eye tracker as a mouselike pointing device is that the human eye does not move in the same calm and controlled fashion as the hand-controlled mouse. The eyes jump around from spot to spot. Special filters and averaging techniques have been developed to make the movements appear smooth and natural (Andre, 1998). These smoothing functions have the potential of interacting with the human's eye control, causing users to adjust their movements based on what they see is happening with the cursor on the screen.

Tracking the eye, determining gaze location on the monitor, and drawing the cursor on the monitor is carried out in real time. Although sockets are used for the connection, no noticeable delay is seen in the gaze cursor implementation for the multimodal application, though sometimes, due to high network traffic, system response time increases causing loss of eye position data and jumpiness of the gaze cursor. For this reason, a slightly different system integration approach has been used for human factors studies of the eye tracker as an input device. The human-factors testing program runs on a SUN workstation and reads directly from a serial port connection from the eye-tracker computer, thus avoiding network delays.

Calibration accuracy is another critical aspect of gaze tracking. Being 1 or 2 degrees off track is very distracting to the user and can result in mistaken commands. With desk-mounted eye trackers, the user is allowed to move the head but the degree of freedom is limited to about 1 cubic foot. The requirements for freedom of head movement and accuracy of tracking are obviously interdependent. Gaze tracking accuracy has been observed to be very sensitive to head movement, and it is very easy to lose calibration. One simple solution to this problem is to recalibrate. During experiments, it has been seen that calibration only takes about 10 seconds for an experienced user. This is a reasonably short period, so it is not a burden on the user or the application. However, for recalibration to be used effectively as a solution to the accuracy drift, the application has to provide specific commands to automate the process of calibration. In addition, data capturing is subject to human-perception inaccuracies. Although electronic performance characteristics of the eye tracker show that it is accurate to a fraction of a pixel, in practice, when humans are used to calibrate the system the accuracy is off by nearly as much as 5 pixels or 0.45 degrees.

Another problem faced in the implementation of the gaze tracker as a pointing device is that the presence of the gaze cursor causes what can be termed *Cursor drift*. This happens when the user is distracted by the presence of the gaze cursor on the screen, and starts tracking this cursor, thereby drifting further away from the target. If the eye tracker is always accurate, this problem is solved because the need for a gaze cursor disappears, improving the naturalness of the system.

For current eye-tracking systems, stable performance requires that all eye-tracker parameters (e.g., maximum and minimum pupil size, maximum and minimum corneal reflection size) have to be accurately adjusted for each user.

5. AN EVALUATION OF THE EFFECTIVENESS OF EYE TRACKING AS AN INPUT MECHANISM

Implied in the efforts to use gaze as an input medium is a belief that using the eye's positioning gives a user faster performance than other input devices. Certainly, eye saccades occur much quicker than hand motions or speech utterances used by more traditional input devices, but

producing an effectively engineered gaze input device that actually takes advantage of the eye's speed may be difficult in practice. Early studies on the use of an eye tracker (Ware & Mikaelian, 1987) indicate that performance time is nearly one-half that of a mouse but with curious speed/accuracy trade-offs based on differences in the design of the target acceptance methods (pressing a button, dwelling on the target, etc.). Performance with any input device is dependent on differences in the design of the device not just the choice of input modality. For example, target acquisition times vary in a pointing task using a mouse depending on the shape and number of buttons on the mouse.

One can expect to uncover similar and often large differences when using eye-tracking hardware that varies in minor ways in the design of the user interface. In addition, the merging of gaze with a multimodal system with many types of input devices can also be expected to affect the overall performance of gaze input. We have therefore undertaken a series of experiments to capture the performance times of gaze in our multimodal setup for a simple target selection task. The next few paragraphs provide an overview of studies that were run and the results. The reader can find a more detailed presentation of these studies in Lin, Kaur, Tremaine, Hung, and Wilder (1999).

The experiment required users to position their eyes in a start circle until a target circle appeared at random positions on the screen. Users were then to saccade as rapidly as possible to the target circle and hold their eyes within the target until the software (200 ms) had recognized target acquisition. Users were first given a set of practice trials followed by 64 experiment trials. The direction of the target, target size, and distance to travel to the target were varied. A regression analysis was performed on the data to fit it to a log linear model based on target distance and target size. Such a model was developed for each of the four target directions used. Typical motor studies show that a user's performance is directly proportional to the distance traveled and inversely proportional to the target size, i.e.:

$$MT = a + b * \log_2 (2D/W) \text{ where}$$

MT = movement time

a and b are constants dependent on the properties of the input device

D = distance traveled

W = width of the target

This model is known as Fitts' law (Fitts, 1966) and is the standard mechanism used to examine and compare performance characteristics of a multitude of computer input devices (Mackenzie, 1992). Because this model is based on an iterative succession of motor control signals that the brain sends out to guide motor function, it is not surprising that eye movement has been shown to follow the same model as other motor types of target acquisition tasks (Bahill & Stark, 1979). Fitting a target acquisition task to Fitts' law tells the input device designer many details about the user's performance and how the device design is affecting the performance. For example, it may be that a log linear model does not fit the data well and that a linear model does. This implies that the motion that the user is making is not ballistic (i.e., does not have an acceleration and deceleration component) and that the user is required to exercise more guided motor control throughout the task. This type of performance is seen with pull-down menus, where users need to keep the cursor within the confines of the menu. It may also be that the constant a is very large. This implies that the device carries a cognitive load with it (e.g., the device may require the coordination of multiple muscle groups to start target acquisition, such as in using a glove to point to a target). Finally, the value b may be high, indicating that the performance of the input device deteriorates quickly as either the distance traveled increases or the target size decreases. Such performance occurs, for example, when a user is required to

do multiple motor tasks simultaneously (e.g., holding down a mouse button in order to drag an object to a target).

The data resulting from our experiment were examined to evaluate the ISCAN eye-tracker input device used. When the experimental data were fit to a log linear model, an extremely poor correlation of 30% was achieved. This correlation was so low compared to the 90% Fitts found in his motor tasks that the data were examined at a low level, looking at each point captured by the eye-tracking device instead of the start circle leaving and target circle arriving time. The data showed that fixations as well as saccades were being included in the measures, with the user making small fixations just outside the start circle and/or just before they reached the target circle. A velocity threshold of 13 cm/sec was used to distinguish saccades from fixations and the fixations were discarded as error data. Overall, eight types of errors that occurred in the experiment were categorized. These included:

- Overshoots: Participant leaves the target circle after entering it.
- Lost gaze position: Eye tracker lost the gaze position due to a hardware failure or because the participant looked out of the boundary of the screen.
- Tick larger than 100 milliseconds due to workstation slow response.
- No saccade at all (i.e., velocity never exceeds the threshold).
- Velocity stays above saccade threshold in the target circle.
- First fixation point outside start circle.
- Second fixation point outside end circle.
- Out of envelope.

“Out of envelope” referred to a “wandering eye” that moved to the target circle in a curved path, moving far outside an envelope of acceptable efficient movements. Removing these variations in the data improved the Fitts’ law correlation to 65%. There was, however, wide variation among participants. The Fitts’ law model does not fit gaze as well as other pointing devices because the data show that participants are not making single clean gaze movements as they do with other devices. The resulting model predicts that roughly, for distances of 10 cm, gaze is 1.7 times faster than recent mouse designs. For distances of 20 cm, gaze selection performance is 2.1 times faster. The performance advantage can be found in the speed of the saccades, not in the cognitive time it takes to begin the task. The values of a for different mouse designs and gaze were comparable, as were the slopes of each performance model.

In summary, using gaze as an input mechanism is potentially quite promising. It is definitely faster than other input mechanisms, but its downside is that the eye, because of its dual usage, exhibits somewhat erratic performance. More detailed focus on eye behavior, such as using velocity thresholds to distinguish between saccades and fixations, is likely to improve the design of gaze input devices.

6. FUTURE DIRECTIONS

Approximately every 5 years a researcher investigates the use of eye tracking as an input device. Their conclusions are mixed about its viability because of the problems that are encountered in accurately interpreting data. Eye-tracking devices also improve significantly every 5 years so that both their cost and invasiveness are dropping. Our studies of gaze as an input mechanism, like prior studies, show large performance advantages for gaze. They also suggest that more considered design of input algorithms for processing eye-tracker data may circumvent problems facing the use of this mechanism as an input device. The combination of an eye tracker with other input modalities also indicates useful advantages that can be exploited in the interpretation of input from any one of the modalities.

7. CURRENT EYE-TRACKING RESEARCH IN VIRTUAL ENVIRONMENTS

Research in VEs is a growing and fluid field, so we hesitate to generate a list of research institutes or individuals that are conducting eye-tracking research in virtual environments. Also, given that this is a chapter in a book, no claims are made for such a list's validity over time. Below a set of key individuals and their research institutes currently involved in this work is provided. No claim is made either for the exhaustiveness or continued validity of this list. Individuals who are interested in obtaining further information on this area may want to look at the proceedings of the eye-tracking symposium that is jointly sponsored by ACM SIGCHI and ACM SIGGRAPH. The symposium takes place in late fall and the proceedings can be found in the Association for Computing Machinery's (ACM) digital library: <http://www.acm.org/dl>.

Gesture Recognition

1. INTRODUCTION

A primary goal of virtual environments (VEs) is to provide natural, efficient, powerful, and flexible interaction. Gesture as an input modality can help meet these requirements. Human gestures are certainly natural and flexible, and may often be efficient and powerful, especially as compared with alternative interaction modes. This chapter will cover automatic gesture recognition, particularly computer vision based techniques that do not require the user to wear extra sensors, clothing, or equipment.

The traditional two-dimensional (2-D), keyboard- and mouse-oriented graphical user interface (GUI) is not well suited for virtual environments. Synthetic environments provide the opportunity to utilize several different sensing modalities and technologies and to integrate them into the user experience. Devices that sense body position and orientation, direction of gaze, speech and sound, facial expression, galvanic skin response, and other aspects of human behavior or state can be used to mediate communication between the human and the environment. Combinations of communication modalities and sensing devices can produce a wide range of unimodal and multimodal interface techniques. The potential for these techniques to support natural and powerful interfaces for communication in VEs appears promising.

If interaction technologies are overly obtrusive, awkward, or constraining, the user's experience with the synthetic environment is severely degraded. If the interaction itself draws attention to the technology rather than the task at hand, or imposes a high cognitive load on the user, it becomes a burden and an obstacle to a successful VE experience. Therefore, there is focused interest in technologies that are unobtrusive and passive.

To support gesture recognition, human position and movement must be tracked and interpreted in order to recognize semantically meaningful gestures. While tracking of a user's head position or hand configuration may be quite useful for directly controlling objects or inputting parameters, people naturally express communicative acts through higher level

FIG. 10.1. Observable communication acts (such as gestures) are the result of expressing intent via communication modalities.

constructs, as shown schematically in Fig. 10.1. The output of position (and other) sensing must be interpreted to allow users to communicate more naturally and effortlessly through gesture.

Gesture is used for control and navigation in CAVEs (Cave Automatic Virtual Environments; Pavlovic et al., 1996; see chap. 11, this volume) and in other VEs, such as smart rooms, virtual work environments, and performance spaces. In addition, gesture may be perceived by the environment in order to be transmitted elsewhere (e.g., as a compression technique to be reconstructed at the receiver). Gesture recognition may also influence—intentionally or unintentionally—a system’s model of the user’s state. For example, a look of frustration may cause a system to slow down its presentation of information, or the urgency of a gesture may cause the system to speed up. Gesture may also be used as a communication *backchannel* (i.e., visual or verbal behaviors such as nodding or saying, “uh-huh” to indicate “I’m with you, continue,” or raising a finger to indicate the desire to interrupt) to indicate agreement, participation, attention, conversation turn taking, and so forth.

Given that the human body can express a huge variety of gestures, what is appropriate to sense? Clearly the position and orientation of each body part—the parameters of an articulated body model—would be useful, as well as features that are derived from those measurements, such as velocity and acceleration. Facial expressions are very expressive. More subtle cues such as hand tension, overall muscle tension, locations of self-contact, and even pupil dilation may be of use.

Chapter 8 (this volume) covers technologies to track the head, hands, and body. These include instrumented gloves, body suits, and marker-based optical tracking. Most of the gesture recognition work applied to VEs has used these tracking technologies as input. Chapter 9 (this volume) covers eye-tracking devices and discusses their limitations in tracking gaze direction. This chapter covers interpretation of tracking data from such devices in order to recognize gestures. Additional attention is focused on passive sensing from cameras using computer vision techniques. The chapter concludes with suggestions for gesture-recognition system design.

2. THE NATURE OF GESTURE

Gestures are expressive, meaningful body motions—i.e., physical movements of the fingers, hands, arms, head, face, or body with the intent to convey information or interact with the environment. Cadoz (1994) described three functional roles of human gesture:

- Semiotic—to communicate meaningful information.
- Ergotic—to manipulate the environment.
- Epistemic—to discover the environment through tactile experience.

Gesture recognition is the process by which gestures made by the user are made known to the system. One could argue that in GUI-based systems, standard mouse and keyboard actions used for selecting items and issuing commands are gestures; here the interest is in less trivial cases. While static position (also referred to as posture, configuration, or pose) is not technically considered gesture, it is included for the purposes of this chapter.

In VEs, users need to communicate in a variety of ways, to the system itself and also to other users or remote environments. Communication tasks include specifying commands and/or parameters for:

- Navigating through a space
- Specifying items of interest
- Manipulating objects in the environment
- Changing object values
- Controlling virtual objects
- Issuing task-specific commands

In addition to user-initiated communication, a VE system may benefit from observing a user's behavior for purposes such as:

- Analysis of usability
- Analysis of user tasks
- Monitoring of changes in a user's state
- Better understanding a user's intent or emphasis
- Communicating user behavior to other users or environments

Messages can be expressed through gesture in many ways. For example, an emotion such as sadness can be communicated through facial expression, a lowered head position, relaxed muscles, and lethargic movement. Similarly, a gesture to indicate "Stop!" can be simply a raised hand with the palm facing forward or an exaggerated waving of both hands above the head. In general, there exists a many-to-one mapping from concept to gesture (i.e., gestures are ambiguous); there is also a many-to-one mapping from gesture to concept (i.e., gestures are not completely specified). And, like speech and handwriting, gestures vary among individuals, from instance to instance for a given individual, and are subject to the effects of coarticulation.

An interesting real-world example of the use of gestures in visual communications is a U.S. Army field manual (Anonymous, 1987) that serves as a reference and guide to commonly used visual signals, including hand and arm gestures for a variety of situations. The manual describes visual signals used to transmit standardized messages rapidly over short distances.

Despite the richness and complexity of gestural communication, researchers have made progress in beginning to understand and describe the nature of gesture. Kendon (1972) described a "gesture continuum," depicted in Fig. 10.2, defining five different kinds of gestures:

- *Gesticulation*—spontaneous movements of the hands and arms that accompany speech.
- *Language-like gestures*—gesticulation that is integrated into a spoken utterance, replacing a particular spoken word or phrase.
- *Pantomimes*—gestures that depict objects or actions, with or without accompanying speech.
- *Emblems*—familiar gestures such as "V for victory," "thumbs up," and assorted rude gestures (these are often culturally specific).
- *Sign languages*—linguistic systems, such as American Sign Language, which are well defined.

FIG. 10.2. Kendon's gesture continuum.

As the list progresses (moving from left to right in Fig. 10.2), the association with speech declines, language properties increase, spontaneity decreases, and social regulation increases.

Within the first category—spontaneous, speech-associated gesture—McNeill (1992) defined four gesture types:

- *Iconic*—representational gestures depicting some feature of the object, action, or event being described.
- *Metaphoric*—gestures that represent a common metaphor, rather than the object or event directly.
- *Beat*—small, formless gestures, often associated with word emphasis.
- *Deictic*—pointing gestures that refer to people, objects, or events in space or time.

These types of gesture modify the content of accompanying speech and may often help to disambiguate speech, similar to the role of spoken intonation. Cassell et al. (1994) describe a system that models the relationship between speech and gesture and generates interactive dialogs between three-dimensional (3-D) animated characters that gesture as they speak.

These spontaneous gestures (*gesticulation* in Kendon's continuum) make up some 90% of human gestures. People even gesture when they are on the telephone, and blind people regularly gesture when speaking to one another. Across cultures, speech-associated gesture is natural and common. For human–computer interaction (HCI) to be truly natural, technology to understand both speech and gesture together must be developed.

Despite the importance of this type of gesture in normal human-to-human interaction, most research to date in HCI, and most VE technology, focuses on the right side of Fig. 10.2, where gestures tend to be less ambiguous, less spontaneous and natural, more learned, and more culture-specific. Emblematic gestures and gestural languages, although perhaps less spontaneous and natural, carry more clear semantic meaning and may be more appropriate for the kinds of command-and-control interaction that VEs tend to support. The main exception to this is work in recognizing and integrating deictic (mainly pointing) gestures, beginning with the well-known “*Put That There*” system by Bolt (1980). The remainder of this chapter will focus on *symbolic gestures* (which includes emblematic gestures and predefined gesture languages) and *deictic gestures*.

3. REPRESENTATIONS OF GESTURE

The concept of gesture is loosely defined and depends on the context of the interaction. Recognition of natural, continuous gestures requires temporally segmenting gestures. Automatically segmenting gestures is difficult and is often finessed or ignored in current systems by requiring a starting position in time and/or space. Similar to this is the problem of distinguishing intentional gestures from other “random” movements. There is no standard way to do gesture recognition—a variety of representations and classification schemes are used. However, most gesture recognition systems share some common structure.

Gestures can be static, where the user assumes a certain pose or configuration, or dynamic, defined by movement. McNeill (1992) defines three phases of a dynamic gesture: prestroke, stroke, and poststroke. Some gestures have both static and dynamic elements, where the pose is important in one or more of the gesture phases; this is particularly relevant in sign languages. When gestures are produced continuously, each gesture is affected by the gesture that preceded it, and possibly by the gesture that follows it. These *coarticulations* may be taken into account as a system is trained.

There are several aspects of a gesture that may be relevant and therefore may need to be represented explicitly. Hummels and Stappers (1998) describe four aspects of a gesture which may be important to its meaning:

- Spatial information—where it occurs, locations a gesture refers to.
- Pathic information—the path that a gesture takes.
- Symbolic information—the sign that a gesture makes.
- Affective information—the emotional quality of a gesture.

In order to infer these aspects of gesture, human position, configuration, and movement must be sensed. This can be done directly with sensing devices such as magnetic field trackers, instrumented gloves, and datasuits, which are attached to the user, or indirectly using cameras and computer vision techniques. Each sensing technology differs along several dimensions, including accuracy, resolution, latency, range of motion, user comfort, and cost. The integration of multiple sensors in gesture recognition is a complex task, since each sensing technology varies along these dimensions. Although the output from these sensors can be used to directly control parameters such as navigation speed and direction or movement of a virtual object, here the interest is primarily in the interpretation of sensor data to recognize gestural information.

The output of initial sensor processing is a time-varying sequence of parameters describing positions, velocities, and angles of relevant body parts and features. These should (but often do not) include a representation of uncertainty that indicates limitations of the sensor and processing algorithms. Recognizing gestures from these parameters is a pattern recognition task that typically involves transforming input into the appropriate representation (feature space) and then classifying it from a database of predefined gesture representations, as shown in Fig. 10.3. The parameters produced by the sensors may be transformed into a global coordinate space, processed to produce sensor-independent features, or used directly in the classification step.

Because gestures are highly variable, from one person to another and from one example to another within a single person, it is essential to capture the essence of a gesture—its invariant properties—and use this to represent the gesture. Besides the choice of representation itself, a significant issue in building gesture recognition systems is how to create and update the database of known gestures. Hand-coding gestures to be recognized only works for trivial systems; in general, a system needs to be trained through some kind of learning. As with speech recognition systems, there is often a trade-off between accuracy and generality—the more accuracy desired, the more user-specific training is required. In addition, systems may be fully trained when in use, or they may adapt over time to the current user.

Static gesture, or pose, recognition can be accomplished by a straightforward implementation of Fig. 10.3, using template matching, geometric feature classification, neural networks,

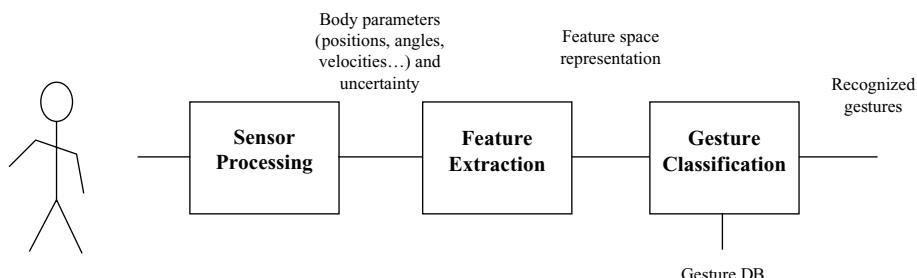

FIG. 10.3. Pattern recognition systems.

or other standard pattern recognition techniques to classify pose. Dynamic gesture recognition, however, requires consideration of temporal events. This is typically accomplished through the use of techniques such as time-compressing templates, dynamic time warping, hidden Markov models (HMMs), and Bayesian networks. Some examples will be presented in the following sections.

3.1 Pen-based Gesture Recognition

Recognizing gestures from 2-D input devices such as a pen or mouse has been considered for some time. The early Sketchpad system in 1963 (Johnson, 1963) used light-pen gestures, for example. Some commercial systems have used pen gestures since the 1970s. There are examples of gesture recognition for document editing, for air traffic control, and for design tasks such as editing splines. More recently, systems such as the OGI QuickSet system (Cohen et al. 1997) have demonstrated the utility of pen-based gesture recognition in concert with speech recognition to control a virtual environment. QuickSet recognizes 68 pen gestures, including map symbols, editing gestures, route indicators, area indicators, and taps. Oviatt (1996) has demonstrated significant benefits of using speech and pen gestures together in certain tasks. Zeleznik, Herndon, and Hughes (1996) and Landay and Myers (1995) developed interfaces that recognize gestures from pen-based sketching.

A significant benefit of pen-based gestural systems is that sensing and interpretation is relatively straightforward as compared with vision-based techniques. There have been commercially available personal digital assistants (PDAs) for several years, starting with the Apple Newton, and more recently the 3Com PalmPilot and various Windows CE devices. These PDAs perform handwriting recognition and allow users to invoke operations by various, albeit quite limited, pen gestures. Long, Landay, and Rowe (1998) survey problems and benefits of these gestural interfaces and provide insight for interface designers.

Although pen-based gesture recognition is promising for many HCI environments, it presumes the availability of, and proximity to, a flat surface or screen. In VEs this is often too constraining; techniques that allow the user to move around and interact in more natural ways are more compelling. The next two sections cover two primary technologies for gesture recognition in virtual environments: instrumented gloves and vision-based interfaces.

3.2 Tracker-based Gesture Recognition

There are a number of commercially available tracking systems (covered in chaps. 8 and 9), which can be used as input to gesture recognition, primarily for tracking eye gaze, hand configuration, and overall body position. Each sensor type has its strengths and weaknesses in the context of VE interaction. While eye gaze can be useful in a gestural interface, the focus here is on gestures based on input from tracking the hands and body.

3.2.1 *Instrumented Gloves*

People naturally use their hands for a wide variety of manipulation and communication tasks. Besides being quite convenient, hands are extremely dexterous and expressive, with approximately 29 degrees of freedom (including the wrist). In his comprehensive thesis on whole-hand input, Sturman (1992) showed that the hand can be used as a sophisticated input and control device in a wide variety of application domains, providing real-time control of complex tasks with many degrees of freedom. He analyzed task characteristics and requirements, hand action capabilities, and device capabilities, and discussed important issues in developing whole-hand input techniques. Sturman suggested a taxonomy of whole-hand input that categorizes

input techniques along two dimensions:

- Classes of hand actions: continuous or discrete.
- Interpretation of hand actions: direct, mapped, or symbolic.

The resulting six categories describe the styles of whole-hand input. A given interaction task can be evaluated as to which style best suits the task. Mulder (1996) presented an overview of hand gestures in human-computer interaction, discussing the classification of hand movement, standard hand gestures, and hand-gesture interface design.

For several years, commercial devices have been available which measure, to various degrees of precision, accuracy, and completeness, the position and configuration of the hand. These include “data gloves” and exoskeleton devices mounted on the hand and fingers (the term *instrumented glove* is used to include both types). Some advantages of instrumented gloves include:

- Direct measurement of hand and finger parameters (joint angles, 3-D spatial information, wrist rotation)
- Provide data at a high sampling frequency
- Easy to use
- No line-of-sight occlusion problems
- Relatively low cost versions available
- Data that is translation-independent (within the range of motion)

Disadvantages of instrumented gloves include:

- Calibration can be difficult.
- Tethered gloves reduce range of motion and comfort.
- Data from inexpensive systems can be very noisy.
- Accurate systems are expensive.
- The user is forced to wear a somewhat cumbersome device.

Many projects have used hand input from instrumented gloves for “point, reach, and grab” operations or more sophisticated gestural interfaces. Latoschik and Wachsmuth (1997) present a multiagent architecture for detecting pointing gestures in a multimedia application. Väänänen and Böhm (1992) developed a neural network system that recognized static gestures and allows the user to interactively teach new gestures to the system. Böhm et al. (1994) extend that work to dynamic gestures using a Kohonen Feature Map (KFM) for data reduction.

Baudel and Beaudouin-Lafon (1993) developed a system to provide gestural input to a computer while giving a presentation. This work included a gesture notation and set of guidelines for designing gestural command sets. Fels and Hinton (1995) used an adaptive neural network interface to translate hand gestures to speech. Kadous (1996) used glove input to recognize Australian sign language as did Takahashi and Kishino (1991) for the Japanese Kana manual alphabet. The system of Lee and Xu (1996) could learn and recognize new gestures online.

Despite the fact that many, if not most, gestures involve two hands, most of the research efforts in glove-based gesture recognition use only one glove for input. The features that are used for recognition, and the degree to which dynamic gestures are considered vary quite a bit.

The HIT Lab at the University of Washington developed GloveGRASP, a C/C++ class library that allows software developers to add gesture recognition capabilities to SGI systems, including user-dependent training and one- or two-handed gesture recognition. A commercial version of this system is available from General Reality.

3.2.2 Body Suits

It is well-known that by viewing only a small number of strategically placed dots on the human body, people can easily perceive complex movement patterns such as the activities, gestures, identities, and other aspects of bodies in motion. One way to approach the recognition of human movements and postures is to optically measure the 3-D position of several such markers attached to the body and then recover the time-varying articulated structure of the body. The articulated structure may also be measured more directly by sensing joint angles and positions using electromechanical body sensors. Although some of the optical systems only require dots or small balls to be placed on top of a user's clothing, all of these body motion capture systems are referred to herein generically as "body suits."

Body suits have advantages and disadvantages that are similar to those of instrumented gloves: they can provide reliable data at a high sampling rate (at least for electromagnetic devices), but they are expensive and very cumbersome. Calibration is typically nontrivial. The optical systems typically use several cameras and process their data offline, their major advantage is the lack of wires and a tether.

Body suits have been used, often along with instrumented gloves, in several gesture recognition systems. Wexelblat (1994) implemented a continuous gesture analysis system using a data suit, "data gloves," and an eye tracker. In this system, data from the sensors is segmented in time (between movement and inaction), key features are extracted, motion is analyzed, and a set of special-purpose gesture recognizers look for significant changes. Marrin and Picard (1998) have developed an instrumented jacket for an orchestral conductor that includes physiological monitoring to study the correlation between affect, gesture, and musical expression.

Although current optical and electromechanical tracking technologies are cumbersome and therefore contrary to the desire for more natural interfaces, it is likely that advances in sensor technology will enable a new generation of devices (including stationary field-sensing devices, gloves, watches, and rings) that are just as useful as current trackers but much less obtrusive. Similarly, instrumented body suits, which are currently exceedingly cumbersome, may be displaced by sensing technologies embedded in belts, shoes, eyeglasses, and even shirts and pants. While sensing technology has a long way to go to reach these ideals, passive sensing using computer vision techniques is beginning to make headway as a user-friendly interface technology.

Note that although some of the body tracking methods in this section use cameras and computer vision techniques to track joint or limb positions, they require the user to wear special markers. In the next section only passive techniques that do not require the user to wear any special markers or equipment are considered.

3.3 Passive Vision-based Gesture Recognition

The most significant disadvantage of the tracker-based systems in section 3.2 is that they are cumbersome. This detracts from the immersive nature of a VE by requiring the user to don an unnatural device that cannot easily be ignored and which often requires significant effort to put on and calibrate. Even optical systems with markers applied to the body suffer from these shortcomings, albeit not as severely. What many have wished for is a technology that provides real-time data useful for analyzing and recognizing human motion that is passive and nonobtrusive. Computer vision techniques have the potential to meet these requirements.

Vision-based interfaces use one or more cameras to capture images, at a frame rate of 30 Hz or more, and interpret those images to produce visual features that can be used to interpret human activity and recognize gestures. Typically the camera locations are fixed in

the environment, although they may also be mounted on moving platforms or on other people. For the past decade, there has been a significant amount of research in the computer vision community on detecting and recognizing faces, analyzing facial expression, extracting lip and facial motion to aid speech recognition, interpreting human activity, and recognizing particular gestures.

Unlike sensors worn on the body, vision approaches to body tracking have to contend with occlusions. From the point of view of a given camera, there are always parts of the user's body that are occluded and therefore not visible, for example, the backside of the user is not visible when the camera is in front. More significantly, self-occlusion often prevents a full view of the fingers, hands, arms, and body from a single view. Multiple cameras can be used, but this adds correspondence and integration problems.

The occlusion problem makes full-body tracking difficult, if not impossible, without a strong model of body kinematics and perhaps dynamics. However, recovering all the parameters of body motion may not be a prerequisite for gesture recognition. The fact that people can recognize gestures leads to three possible conclusions: (1) the parameters that cannot be directly observed are inferred; (2) these parameters are not needed to accomplish the task; or (3) some are inferred and others are ignored.

It is a mistake to consider vision and tracking devices (such as instrumented gloves and body suits) as alternative paths to the same end. Although there is overlap in what they can provide, these technologies in general produce qualitatively and quantitatively different output which enable different analysis and interpretation. For example, tracking devices can in principle detect fast and subtle movements of the fingers while a user is waving his hands, whereas human vision in that case will at best get a general sense of the type of finger motion. Similarly, vision can use properties like texture and color in its analysis of gesture, whereas tracking devices do not. From a research perspective, these observations imply that it may not be an optimal strategy to merely substitute vision at a later date into a system that was developed to use an instrumented glove or a body suit—or vice versa.

Unlike special devices that measure human position and motion, vision uses a multipurpose sensor; the same device used to recognize gestures can be used to recognize other objects in the environment and also to transmit video for teleconferencing, surveillance, and other purposes. There is a growing interest in CMOS-based cameras, which promise miniaturized, low-cost, low-power cameras integrated with processing circuitry on a single chip. With its integrated processing, such a sensor could conceivably output motion or gesture parameters to the virtual environment.

Currently, most computer vision systems for recognition look something like Fig. 10.3. Analog cameras feed their signal into a digitizer board, or framegrabber, which may do a DMA transfer directly to host memory. Digital cameras bypass the analog-to-digital conversion and go straight to memory. There may be a preprocessing step, where images are normalized, enhanced, or transformed in some manner, and then a feature extraction step. The features—which may be any of a variety of 2-D or 3-D features, statistical properties, or estimated body parameters—are analyzed and classified as a particular gesture if appropriate.

Vision-based systems for gesture recognition vary along a number of dimensions, most notably:

- Number of cameras. How many cameras are used? If more than one, are they combined early (stereo) or late (multiview)?
- Speed and latency. Is the system real-time (i.e., fast enough, with low enough latency, to support interaction)?
- Structured environment. Are there restrictions on the background, lighting, speed of movement, and so forth?

- User requirements. Must the user wear anything special (e.g., markers, gloves, long sleeves)? Is anything disallowed (e.g., glasses, beard, rings)?
- Primary features. What low-level features are computed (edges, regions, silhouettes, moments, histograms, etc.)?
- Two- or three-dimensional representation. Does the system construct a 3-D model of the body part(s), or is classification done on some other (view-based) representation?
- Representation of time. How is the temporal aspect of gesture represented and used in recognition (e.g., via a state machine, dynamic time warping, HMMs, time-compressed template)?

3.3.1 Head and Face Gestures

When people interact with one another, they use an assortment of cues from the head and face to convey information. These gestures may be intentional or unintentional, they may be the primary communication mode or backchannels, and they can span the range from extremely subtle to highly exaggerated. Some examples of head and face gestures include:

- Nodding or shaking the head
- Direction of eye gaze
- Raising the eyebrows
- Opening the mouth to speak
- Winking
- Flaring the nostrils
- Looks of surprise, happiness, disgust, anger, sadness, etc.

People display a wide range of facial expressions. Ekman and Friesen (1978) developed a system called FACS for measuring facial movement and coding expression; this description forms the core representation for many facial expression analysis systems.

A real-time system to recognize actions of the head and facial features was developed by Zelinsky and Heinzmann (1996), who used feature template tracking in a Kalman filter framework to recognize thirteen head and face gestures. Moses, Reynard, and Blake (1995) used fast-contour tracking to determine facial expression from a mouth contour. Essa and Pentland (1997) used optical flow information with a physical muscle model of the face to produce accurate estimates of facial motion. This system was also used to generate spatiotemporal motion-energy templates of the whole face for each different expression. These templates were then used for expression recognition. Oliver, Pentland, and Bérard (1997) describe a real-time system for tracking the face and mouth that recognized facial expressions and head movements. Otsuka and Ohya (1998) model coarticulation in facial expressions and use an HMM for recognition.

Black and Yacoob (1995) used local parametric motion models to track and recognize both rigid and nonrigid facial motions. Demonstrations of this system show facial expressions being detected from television talk show guests and news anchors (in non-real time). La Cascia, Isidoro, and Sclaroff (1998) extended this approach using texture mapped surface models and nonplanar parameterized motion models to better capture the facial motion.

3.3.2 Hand and Arm Gestures

Hand and arm gestures receive the most attention among those who study gesture. In fact, many (if not most) references to gesture recognition only consider hand and arm gestures. The vast majority of automatic recognition systems are for deictic gestures (pointing), emblematic gestures (isolated signs), and sign languages (with a limited vocabulary and syntax). Some are

components of bimodal systems, integrated with speech recognition. Some produce precise hand and arm configuration, whereas others only coarse motion.

Stark and Kohler (1995) developed the ZYKLOP system for recognizing hand poses and gestures in real time. After segmenting the hand from the background and extracting features such as shape moments and fingertip positions, the hand posture is classified. Temporal gesture recognition is then performed on the sequence of hand poses and their motion trajectory. A small number of hand poses comprises the gesture catalog, whereas a sequence of these makes a gesture. Similarly, Maggioni and Kämmerer (1998) described the GestureComputer, which recognized both hand gestures and head movements. Other systems that recognize hand postures amidst complex visual backgrounds are reported by Weng and Cui (1998) and Triesch and von der Malsburg (1996).

There has been a lot of interest in creating devices to automatically interpret various sign languages to aid the deaf community. One of the first to use computer vision without requiring the user to wear anything special was built by Starner and Pentland (1995), who used HMMs to recognize a limited vocabulary of ASL sentences. A more recent effort, which uses HMMs to recognize Sign Language of the Netherlands, is described by Assan and Grobel (1997).

The recognition of hand and arm gestures has been applied to entertainment applications. Freeman, Tanaka, Ohta, and Kyuma (1996) developed a real-time system to recognize hand poses using image moments and orientation histograms, and applied it to interactive video games. Cutler and Turk (1998) described a system for children to play virtual instruments and interact with lifelike characters by classifying measurements based on optical flow. A nice overview of work up to 1995 in hand gesture modeling, analysis, and synthesis is presented by Huang and Pavlovic (1995).

3.3.3 Body Gestures

This section includes tracking full-body motion, recognizing body gestures, and recognizing human activity. Activity may be defined over a much longer period of time than what is normally considered a gesture; for example, two people meeting in an open area, stopping to talk, and then continuing on their way may be considered a recognizable activity. Bobick (1997) proposed a taxonomy of motion understanding in terms of:

- Movement—the atomic elements of motion.
- Activity—a sequence of movements or static configurations.
- Action—high-level description of what is happening in context.

Most research to date has focused on the first two levels.

The Pfinder system (Wren, Azarbayejani, Darrell, & Pentland, 1996) developed at the MIT Media Lab has been used by a number of groups to do body tracking and gesture recognition. It forms a 2-D representation of the body, using statistical models of color and shape. The body model provides an effective interface for applications such as video games, interpretive dance, navigation, and interaction with virtual characters. Lucente, Zwart, and George (1998) combined Pfinder with speech recognition in an interactive environment called Visualization Space, allowing a user to manipulate virtual objects and navigate through virtual worlds. Paradiso and Sparacino (1997) used Pfinder to create an interactive performance space where a dancer can generate music and graphics through their body movements, for example, hand and body gestures can trigger rhythmic and melodic changes in the music.

Systems that analyze human motion in VEs may be quite useful in medical rehabilitation (see chap. 49, this volume) and athletic and military training (see chap. 43, this volume). For example, a system like the one developed by Boyd and Little (1998) to recognize human gaits

could potentially be used to evaluate rehabilitation progress. Yamamoto, Kondo, and Yamagiwa (1998) describe a system that used computer vision to analyze body motion in order to evaluate the performance of skiers.

Davis and Bobick (1997) used a view-based approach by representing and recognizing human action based on “temporal templates,” where a single image template captures the recent history of motion. This technique was used in the KidsRoom system, an interactive, immersive, narrative environment for children. A nice online description of this project can be found at <http://vismod.www.media.mit.edu/vismod/demos/kidsroom/>.

Video surveillance and monitoring of human activity has received significant attention in recent years. For example, the W⁴ system developed at the University of Maryland (Haritaoglu, Harwood, & Davis, 1998) tracks people and detects patterns of activity.

4. SUGGESTIONS FOR SYSTEMS DESIGN

There has been little work in evaluating the utility and usability of gesture recognition systems. However, those developing gestural systems have learned a number of lessons along the way. Here a few guidelines are presented in the form of “dos and don’ts” for gestural interface designers:

- **Do inform the user.** As discussed in section 2, people use different kinds of gestures for many purposes, from spontaneous gesticulation associated with speech to structured sign languages. Similarly, gesture may play a number of different roles in a virtual environment. To make compelling use of gesture, the types of gestures allowed and what they affect must be clear to the user.
- **Do give the user feedback.** Feedback is essential to let the user know when a gesture has been recognized. This could be inferred from the action taken by the system, when that action is obvious, or by more subtle visual or audible confirmation methods.
- **Do take advantage of the uniqueness of gesture.** Gesture is not just a substitute for a mouse or keyboard. It may not be as useful for 2-D pointing or text entry but great for more expressive input.
- **Do understand the benefits and limits of the particular technology.** For example, precise finger positions are better suited to instrumented gloves than vision-based techniques. Tethers from gloves or body suits may constrain the user’s movement.
- **Do usability testing on the system.** Don’t just rely on the designer’s intuition (see chap. 34, this volume).
- **Do avoid temporal segmentation if feasible.** At least with the current state of the art, segmentation of gestures can be quite difficult.
- **Don’t tire the user.** Gesture is seldom the primary mode of communication. When a user is forced to make frequent, awkward, or precise gestures, the user can become fatigued quickly. For example, holding one’s arm in the air to make repeated hand gestures becomes tiring very quickly.
- **Don’t make the gestures to be recognized too similar.** For ease of classification and to help the user.
- **Don’t use gesture as a gimmick.** If something is better done with a mouse, keyboard, speech, or some other device or mode, use it—extraneous use of gesture should be avoided.
- **Don’t increase the user’s cognitive load.** Having to remember the whats, wheres, and hows of a gestural interface can make it oppressive to the user. The system’s gestures should be as intuitive and simple as possible. The learning curve for a gestural interface

is more difficult than for a mouse and menu interface because it requires recall rather than just recognition among a list.

- **Don't require precise motion.** Especially when motioning in space with no tactile feedback, it is difficult to make highly accurate or repeatable gestures.
- **Don't create new, unnatural gestural languages.** If it is necessary to devise a new gesture language, make it as intuitive as possible.

5. CONCLUSIONS

Although several research efforts have been referenced in this chapter, these are just a sampling; many more have been omitted for the sake of brevity. Good sources for much of the work in gesture recognition can be found in the proceedings of the Gesture Workshops and the International Conference on Automatic Face and Gesture Recognition.

There is still much to be done before gestural interfaces, which track and recognize human activities, and can become pervasive and cost-effective for the masses. However, much progress has been made in the past decade and with the continuing march toward computers and sensors that are faster, smaller, and more ubiquitous, there is cause for optimism. As PDAs and pen-based computing continue to proliferate, pen-based 2-D gestures should become more common, and some of the technology will transfer to 3-D hand, head, and body gestural interfaces. Similarly, technology developed in surveillance and security areas will also find uses in gesture recognition for virtual environments.

There are many open questions in this area. There has been little activity in evaluating usability (see chap. 34, this volume) and understanding performance requirements and limitations of gestural interaction. Error rates are reported from 1% to 50%, depending on the difficulty and generality of the scenario. There are currently no common databases or metrics with which to compare research results. Can gesture recognition systems adapt to variations among individuals, or will extensive individual training be required? What about individual variation due to fatigue and other factors? How good do gesture recognition systems need to be to become truly useful in mass applications?

Each technology discussed in this chapter has its benefits and limitations. Devices that are worn or held—pens, gloves, body suits—are currently more advanced, as evidenced by the fact that there are many commercial products available. However, passive sensing (using cameras or other sensors) promises to be more powerful, more general, and less obtrusive than other technologies. It is likely that both camps will continue to improve and coexist, often be used together in systems, and that new sensing technologies will arise to give even more choice to VE developers.

1. INTRODUCTION

A *motion interface* is the means by which a user travels through a virtual environment (VE). Motion interfaces are categorized as active or passive (Durlach & Mavor, 1995). Active motion interfaces are defined as *locomotion interfaces*, which require self-propulsion by a user. Passive motion interfaces transport a user through the VE without significant user exertion. They are further subdivided as inertial motion interfaces, where the body is moved as in a flight simulator on a Stewart platform, and noninertial motion interfaces, where the body is stationary as in the use of a joystick.

1.1 Features of Locomotion Interfaces

Ordinarily the use of our legs in walking is thought of as the meaning of locomotion, but a human-powered vehicle like a bicycle may be involved. Similarly, treadmills and stationary bicycles have served as locomotion interfaces. A locomotion interface approach that does not involve a physical device is walking in place. For greater generality, a more encompassing view of locomotion interface is taken to include any leg and arm combination for user self-propulsion, for example, rowing machines and Nordic skiing machines.

The key feature of locomotion interfaces that distinguishes them from passive motion interfaces is repetitive limb motion. Repetitive limb motion, or *gait*, results in self-propulsion. With such interfaces, tracking of a user's legs or body motion controls motion through a virtual environment. Due to repetitive limb motion, energy expenditure in gait is a key feature of locomotion interfaces. Some issues involved with these interfaces include:

- The effort in cycling the limbs is a basic physiological load.
- Body weight may have to be supported if the user is standing.

- The motion platform itself may require effort tied to a user's speed of motion. For example, a stationary bicycle may have a flywheel to simulate inertia and vanes to simulate viscous drag.

The energy extraction from the user by the locomotion interface can cause fatigue and affect decision-making processes, just as in the real world, where humans have to balance movement effort against movement goal.

Another feature of locomotion interfaces is the integration of proprioception with vision. Vision operates better for relative depth perception than for absolute distance judgments (see chap. 3, this volume). It has been shown that locomotion calibrates visual distance judgments (Reiser, Pick, Jr., Ashmead, & Garing, 1995). The implication is that appreciation of VE geometry and distance is enhanced by the ability to locomote. The features of energy extraction and sensorimotor integration are hypothesized to yield an increased sense of presence in the virtual environment (see chap. 40, this volume).

1.2 Workspace and Position Versus Rate Control

In passive-motion interfaces, a user is standing or seated, and manipulates some control or makes some motion that changes the user's position in the virtual environment. The amount of user motion typically controls the rate of moving through the virtual environment. An example is a joystick; the deflection angle from center is the rate command. Another example is a driving simulator; the amount by which the pedal is depressed controls the velocity of the vehicle. Rate control arises because the workspace of the control device is much smaller than the virtual space through which the user wishes to move. Because of the use of rate control rather than position control, repetitive motions are not required by the user to move through a virtual environment. Consequently, the user expends very little energy.

If such a device were used in position control mode, then the user would have to reindex to the center of the workspace before making the next excursion to move forward. This repeated cycling would according to our definition result in a locomotion interface. For example, repeated cycling of a joystick under position control would be like turning a crank. For haptic interfaces, the device's workspace directly matches that of the VE, and so position control may be used. Repeated cycling is not required because the workspaces match (scaling may be involved). More sophisticated controllers may use position control in central regions of the device's workspace for precise positioning and rate control near the workspace boundaries for slewing across larger distances.

In summary, the control mode and relation of the device workspace to the VE workspace leads to an approximate taxonomy for mechanical interfaces to VE systems, including:

- Rate control is the key feature of passive motion interfaces.
- Position control, where the device and VE workspaces match is the key feature of haptic interfaces.
- Position control with repeated cycling of the device (the *gait*) to cover the VE workspace is the key feature of locomotion interfaces.

1.3 Locomotion rendering

In the following section, different types of locomotion interfaces are surveyed that have been built to date. Notwithstanding the taxonomy and attempt at generality above, most of these locomotion interfaces involve walking while a few involve cycling.

Locomotion rendering may be defined similarly to haptic rendering, as the presentation of mechanical stimuli to simulate normal locomotion. Aspects of locomotion that might be rendered include the following:

1. *Forward motion.* Ideally, a user should be able to walk or run forward or backward at any speed. Some devices limit forward motion to a slow or moderate walk and constrain the step size. Other locomotion interfaces based on walking in place don't actually involve physical forward motion. When accelerating to a run, a user does not typically experience an inertial force because the locomotion interface keeps the body stationary with respect to the ground. One such device is capable of providing an artificial inertial force display.
2. *Turning.* Ideally, a user should be able to change the direction of walking arbitrarily. Some locomotion interfaces limit the range of turning, while other devices, which are essentially linear, use some control action to initiate turning that is somewhat artificial.
3. *Slope.* Arbitrary aspects of slope would be ideally displayed, such as walking on smooth slopes, including sideways traversal and uneven terrain such as stairs. Locomotion interfaces differ greatly in whether they address slope or to what extent.
4. *Obstacles.* Humans can't walk through real walls nor should they be able to walk through virtual walls. Wall constraints could be enforced merely by braking the locomotion interface, but certain devices display hitting a wall more directly to the body.
5. *Body postures.* Especially for walking simulators, there is an issue of the wide variety of postures and stepping patterns that one might adopt, such as crawling or sidling. What postures a locomotion interface can accommodate differ among the designs.

These aspects of locomotion rendering will serve to structure the discussion of locomotion interfaces below.

2. LOCOMOTION INTERFACES

A number of locomotion interfaces are derived from exercise machines, such as stationary bicycles, stair steppers, and treadmills. Others have been specifically designed toward a particular locomotion interface approach. The following is a taxonomy of locomotion interfaces along with a number of examples.

2.1 Pedaling Devices

Stationary bicycles represent a straightforward way to fashion a locomotion interface. Pedaling resistance can be achieved passively, by means of a friction brake, or more realistically by a flywheel and vanes to simulate inertia and viscosity. Simulating slope requires an electric motor to modulate the pedaling effort. Turning control is naturally achieved with handlebars. Position sensors on the pedals and on the handlebars measure the linear motion and direction of travel.

An elaboration is to place the bicycle on a motion platform. Brogan, Metoyer, and Hodgins (1998) employed a tilting platform with an up-down range of $+/- 12$ deg to represent hills for a racing bicycle simulator (Fig. 11.1A). The Sarcos Uniport is a unicycle on a turntable (Fig. 11.1B). The unicycle turns left or right based on user exertion against the seat, measured by load sensors. The user is therefore obtaining the appropriate vestibular cues regarding direction.

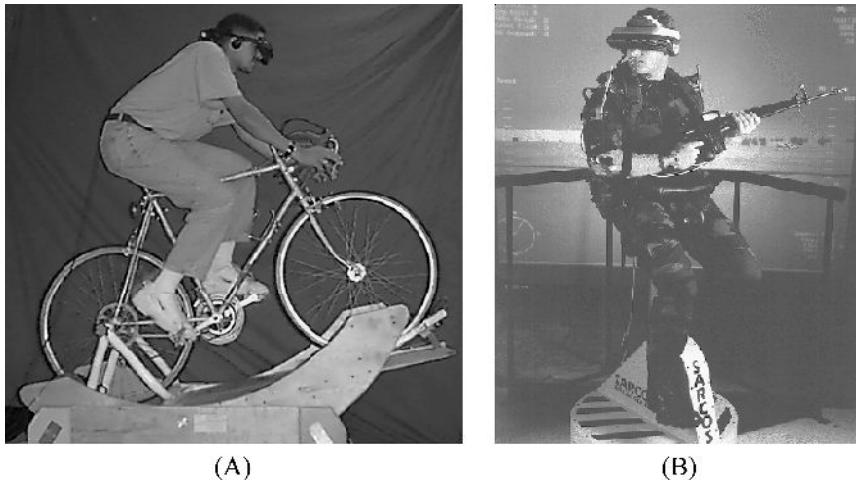

FIG. 11.1. (A) Bicycle simulator on tilt platform. Photo courtesy of D. Brogan, R. Metoyer, & J. Hodgins, College of Computing, Georgia Institute of Technology. (B) The Sarcos Uniport.

2.2 Walking in Place

A motion platform may be entirely avoided by measuring walking in place. A different set of muscles is employed versus walking forward, but an advantage is a potentially lower cost system.

The Gaiter system (Templeman, Denbrook, & Sibert, 1999) employs magnetic trackers attached to the thighs just above the knees and force sensors in the foot pads (Fig. 11.2). Forward motion and turning are controlled by mapping knee height, rate, and direction. The foot pad sensors aid in segmenting the steps. Magnetic trackers are also located at the waist, head, and a handgrip. The waist sensor controls the position and orientation of the body; the head sensor controls the gaze direction in conjunction with a head-mounted display (HMD) and the handgrip sensor is for auxiliary purposes.

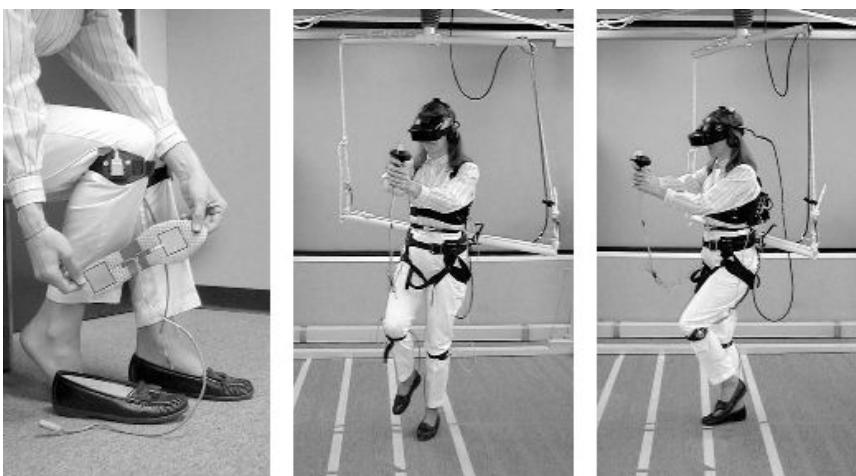

FIG. 11.2. The Gaiter system. Photo courtesy of J. Templeman.

Gestural knee actions, which are defined as excess motions that do not participate in physical displacement of the body, control the rate and direction of motion. Rocking the knee back then forward indicates walking backward. In addition to physically turning, it is possible to indicate turning while walking straight ahead and rocking the knees to the side.

In an alternative approach to a walking-in-place locomotion interface, Parsons et al. (1998) employ mechanical trackers on the ankles to trigger a step when the foot is raised enough. Slater, Steed, and Usoh (1995) inferred the footsteps by employing a neural network classifier on head bobbing as measured by a magnetic tracker; error rates of 10% were reported on correctly recognizing a step. They employ hand gestures to indicate going up or down a ladder.

With the foot simply being raised up and down, there is of course no sense of forward propulsion when walking in place. To give a sense of backward foot motion as if moving forward, one may use sliding between the feet and the ground. A series of different locomotion interface approaches by Iwata are summarized in Iwata (2000). One approach employed roller skates. The user was rigidly attached to a frame by a belt around the waist to absorb the forward reaction forces and to provide stability. Foot forces for climbing or descending were created by a single string belt for each foot, routed through pulleys to the bottom of each foot, and actuated by a DC motor. Subsequently, Iwata employed shoes with low-friction films on the soles. A brake pad on the toe allowed completion of the swing phase. The user was loosely constrained by a hoop frame. Grant and Magee (1997) utilized the amount of horizontal foot motion in a sliding-surface locomotion interface to drive the extent of forward motion.

2.3 Foot Platforms

A derivative of a stair-stepper exercise machine is individually programmable foot platforms, where each platform can be positioned in three dimensions. The Sarcos Biport (Fig. 10.3A) employs hydraulically actuated 3-degree-of-freedom (DOF) serial-link arms on which the user stands. The user's feet are attached to the platforms with releasable bindings. Force sensors are located near the attachment points and are employed in force control strategies and steering control. When the user lifts a foot, the attached arm must follow with zero force to avoid dragging the foot. When the user steps to contact a surface, the arm must be servoed to present a rigid surface.

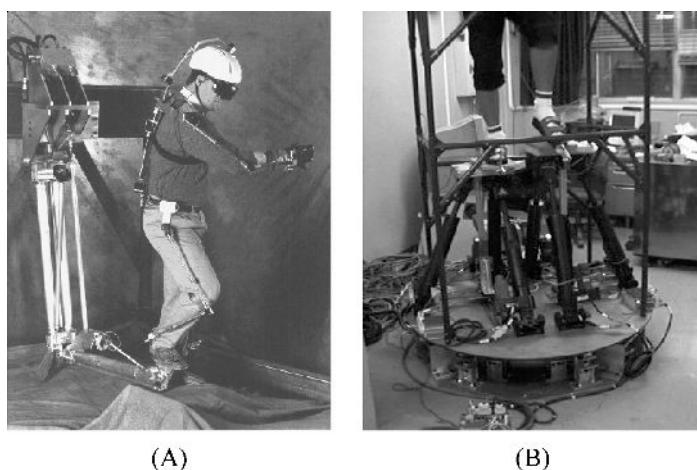

FIG. 11.3. (A) The Sarcos Biport. (B) The GaitMaster. Photo courtesy of H. Iwata.

A reverse centering motion is superimposed on the forward motion to attract the user back toward the center of the device. A foot mount permits the user to swivel left or right, and force sensors in the mounts signal the direction of motion. The platforms are servoed to follow the user's steps in a particular direction of motion. Moderate walking speeds can be supported. Speed limitations occur due to the structural stiffness of the present design. In addition to the presentation of uneven terrain, another advantage of such a device is the potential for simulating soft surfaces.

The Sarcos Biport's hydraulic arms are necessarily powerful to support the forces of walking. Safety is a major concern. A variety of safety devices have been implemented, including ceiling restraints, releasable bindings, and user-activated kill switches.

Iwata's GaitMaster (Fig. 10.3B) comprises two 3-DOF parallel drive platforms (Iwata & Yoshida, 1999). Each platform contains a passive spring-loaded yaw joint to allow some turning. The payload of each platform is 150 kg. A three-joint goniometer attaches a user's foot to the platform to measure foot motion.

The platforms are mounted on a turntable to accommodate turning. The platforms primarily accommodate forward or backward motion. The intent of this design is to avoid platform interference when stepping to walk in a sideways direction. This type of interference is a potential problem with the Sarcos Biport. Conversely, some modest oblique walking angles are possible with the Biport, which lead to more natural walking.

2.4 Treadmills

Initial research employed passive treadmills, where the belt motion is entirely caused by users pushing with their legs. The forward motion is directly indicated by the belt motion. The user has to brace against side bars or handle bars when pushing against the belt; handlebars allow turning control to be easily implemented. Passive treadmills are a low-cost and inherently safe platform, although the naturalness of locomotion is compromised. More recently, active treadmills have been employed where the belt speed is controlled by measurements of user position, either by optical or mechanical tracking.

2.4.1 *The Sarcos Treadport*

The original Sarcos Treadport is comprised of a large 4-by-8 foot treadmill and a 6-axis mechanical tether that acts as a position tracker (Christensen, Hollerbach, Xu, & Meek, 2000). The tether is actuated along its linear axis to be able to push and pull on the user. A second-generation Sarcos Treadport has been constructed (Hollerbach, Xu, Christensen, & Jacobsen, 2000) featuring a larger running surface (6 × 10 feet) and a fast tilt mechanism. Figure 10.4 shows the new Treadport in conjunction with a 3-wall CAVE (Cave Automatic Virtual Environment).

The Treadport's tether attaches to a user at the back of a body harness. The belt velocity is proportional to how far forward from center a user moves. Walking backward is also possible. An integral control term is added that gradually recenters the user to avoid the user getting too close to the front edge (Christensen, Hollerbach, Xu, & Meek, 2000). Natural forward motion speeds are supported: accelerations of 1 g and peak velocities of 12 mph. Due to the belt size, a variety of body postures can be supported including crouching and crawling.

Because the Treadport uses a linear treadmill, the issue of how to control turning arises. Body pose measurements from the mechanical tether are employed to control the rate of turning. Two control regimes are used. For stationary users, the amount of twist about the vertical axis controls the rate of turning. For rapidly walking or running users, the amount by which the user is displaced sideways from the treadmill center controls the rate of turning. To accommodate intermediate locomotion speeds, the two control regimes are blended. The use of rate control

FIG. 11.4. The second-generation Sarcos Treadport.

requires reindexing. The user has to move back to a center position to stop turning, then moves the opposite direction from center to turn the other way.

Treadmills can represent slope naturally by means of a platform tilt mechanism. Due to the platform mass and the slow actuation in commercial treadmills, the tilt cannot represent sudden slope changes. In the first-generation Sarcos Treadport, for example, the tilt rate is approximately 1 deg/sec. While this may suffice for an exercise function, the slow tilt rate is a limitation for virtual environments. The second-generation Treadport is specified for $+/- 20$ deg in one second, although the tilt is not currently operational.

An alternative is provided by the active mechanical tether on the Sarcos Treadport. The tether can push or pull along its linear axis at the small of the back in a roughly horizontal direction. When walking uphill, the component f of gravity force parallel to the slope opposing the user's motion is $f = m g \sin \theta$, where m is the user's mass, g is gravity, and θ is the slope angle. This extra effort in going uphill can be simulated by the tether pulling on the user with a force $f = m g \sin \theta$, requiring a greater user effort. For a user going downhill, the tether would push with that force, thereby requiring a lesser effort. User studies show the effectiveness of the mechanical tether force for slope display, but the empirical relation between walking on a slope and user-perceived equivalent pulling force was $f = 0.65 m g \sin \theta$, or two thirds of the expected force (Tristano, Hollerbach, & Christensen, 2000). It was hypothesized that the concentrated force application to just one point on the body rather than a distributed gravity load over the body was responsible for the fractional force perception.

When accelerating on treadmills, it has been found that runners exert 35% less energy than on the ground. The difference has been ascribed to an inertial force difference on the treadmill, essentially because the treadmill belt is servoed to keep the user's body stationary with respect to the ground. One approach is to vary the belt speed to decrease the difference from ground locomotion (Moghaddam & Buehler, 1993), but this difference can never be completely eliminated with this approach. Supposing a highly simplified dynamic model of the human as a cart with mass m , it would be predicted that the missing inertial force should be $f = ma$, where a is the acceleration. Christensen et al. (2000) utilized the active tether of the Sarcos Treadport to provide this simulated inertial force. User studies showed a preference

for such an inertial force display over conditions of no tether force, or of a springlike tether force. A fractional perception of roughly $f = 0.8 \text{ ma}$ was found, possibly due again to the lack of distributed force application over the body.

In the real world one cannot walk through walls, nor should one be able to walk through virtual walls. One alternative is to simply brake the locomotion interface, although the user might then stumble forward. The active tether of the Sarcos Treadport provides an alternative by applying a springlike penalty force to simulate hitting a wall. The treadmill is stopped simultaneously, but due to the active tether force the user does not stumble forward. This penalty force is similar to viscoelastic opposing forces applied by haptic interfaces when a user attempts to push into a hard surface.

Finally, it is desired to keep users away from workspace boundaries. When a user accelerates on a treadmill, it is possible to move off center because of limited bandwidth of the belt. Of course, it is not desirable to have users running off the end of a platform. In the Sarcos Treadport, an integral control term is added to draw the user back toward the center of the platform (Christensen et al., 2000). A software linear spring is also simulated by the active mechanical tether to provide a kinesthetic cue to the user about the amount of forward deviation from center. There are hard limit stops on the tether, which prevent movement beyond the front edge.

Another concern is sideways motion on the treadmill platform and the user potentially falling off the side. Hardware springs are provided on a base rotary joint and an attachment-end rotary joint on the mechanical tether of the Sarcos Treadport to provide kinesthetic cues about the amount of sideways deviation. The second-generation Sarcos Treadport has a large platform (6 × 10 feet) primarily to provide extra safety margins for sideways or forward motion without falling off. In addition, crawling is facilitated. Another reason for a larger belt is the use of a dead zone around a center position on the belt. If the user is stationary, small motions should not cause the belt to move; otherwise it would be impossible to stand still. While a dead zone prevents this, the dead zone does remove some useable area of the belt.

2.4.2 ATR Locomotion Interfaces

Two treadmill-style locomotion interfaces have been constructed at ATR by Noma, Sugihara, and Miyasato (2000). The ATLAS system (Fig. 10.5A) comprises a linear treadmill on a spherical joint that can pitch, yaw, and roll the platform. The pitching motion is the normal tilt motion found in many commercial treadmills. The yaw motion acts like a turntable to move the treadmill left and right, and is used for turning control. The roll motion allows the simulation of walking sideways along a slope. The belt area is 145 mm long and 55 mm wide, and the maximum belt speed is 4.0 m/sec. The yaw motion has a maximum rate of 1 rad/sec.

Motion control is achieved by optical foot tracking, employing a commercial video tracking system that tracks bright markers on the front of the subjects shoes at a 60-Hz rate. It was found that stance time was the best predictor of walking speed, and a curvilinear relation was established to generalize across all users. Turning is achieved by swiveling the treadmill in the direction in which the user is stepping. The lateral amount of foot motion is measured to estimate how much to rotate the platform. The platform cannot rotate continuously, and so must be reindexed to center beyond a certain angle. Noma et al. (2000) refer to this swiveling as turning cancellation, and to the function of a locomotion interface as motion cancellation in general. An HMD is employed for the visual display. A magnetic tracker is employed to detect head orientation.

The Ground Surface Simulator (GSS) is a system meant to simulate uneven or steplike terrain (Fig. 10.5B). The GSS employs a linear treadmill with a flexible belt that is deformed underneath by six vertical stages. The belt is 1.5 m long and 0.6 m wide. Each stage is 0.25 m

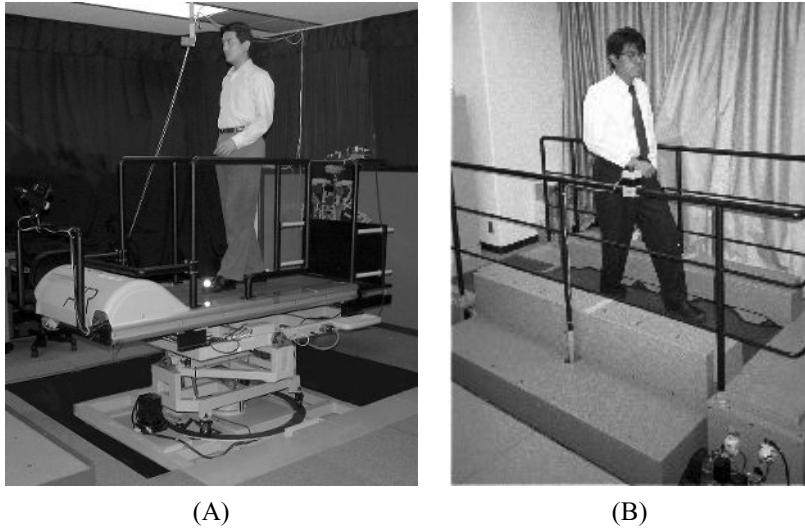

FIG. 11.5. (A) The ATLAS system. (B) The Ground Surface Simulator. Photos courtesy of H. Noma.

long and has a stroke of 6 cm at a speed of 6 cm/sec. There are rollers on the support surface of each stage. Because the geometry of the belt changes when deformed by the stages, an active belt tensioning system is employed. A slope of 5 deg can be presented by the GSS. Future plans call for mounting the GSS on a motion stage as for the ATLAS system.

2.4.3 *The Omni-Directional Treadmill*

The Omni-Directional Treadmill (ODT), designed by Virtual Space Devices, Inc., provides a two-dimensional treadmill surface designed to facilitate turning (Fig. 10.6A). A two-orthogonal belt arrangement creates the two-dimensional surface. A top belt is comprised of rollers whose axes are parallel to the direction of rotation of that belt. These rollers are rotated underneath

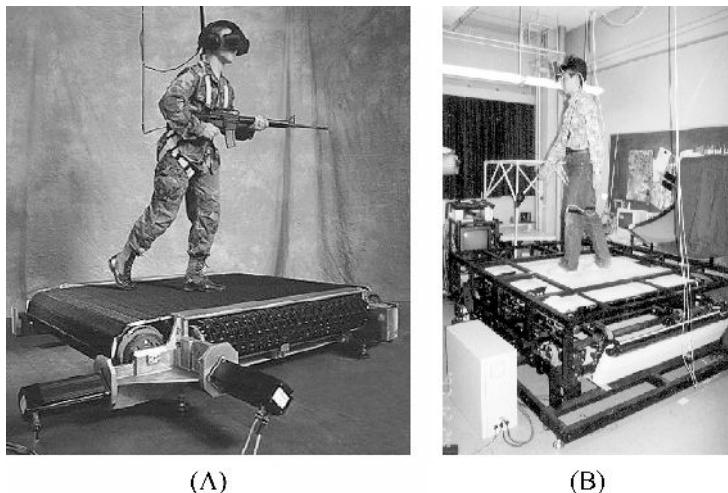

FIG. 11.6. (A) The Omni-Directional Treadmill. From <http://www.vsdevices.com/>. (B) The Torus treadmill. Photo courtesy of H. Iwata.

by another belt orthogonal to the first. The active surface is 1.3 m by 1.3 m, and the peak speed is 3 m/sec.

A mechanical position tracker on an overhead boom attaches to a harness worn by the user in order to control the treadmill. The boom is active and may exert a force up to 89 N. Both an HMD and a CAVE-like display have been employed for the visuals.

Some unsteadiness in walking on the roller surfaces has been reported (Darken & Cockayne, 1997). A mismatch between a user's walking direction and the centering motion of the belt could occur that causes the user to stumble. The mismatch presumably arises due to system lags and bandwidth limitations that permit the user to move off center. This type of mismatch would seem to be a potential problem for any two-dimensional motion stage.

2.4.4 The Torus Treadmill

Another two-dimensional treadmill design is Iwata's Torus Treadmill (Fig. 10.6[B]), which employs 12 small treadmills connected side-by-side to form a large belt to allow arbitrary planar motion (Iwata & Yoshida, 1999). The walkable area is 1 m by 1 m, and the maximum treadmill speed is 1.2 m/sec. Motion control is achieved by foot tracking employing magnetic trackers. An HMD is provided where a magnetic tracker senses head orientation.

In the initial implementation of the Torus Treadmill concept, the speed and area limitations limit walking to a slow speed and relatively short steps. A larger design in the future would presumably overcome such limitations.

3. DISCUSSION

Locomotion interfaces represent a relatively new field in which there are currently few systems and researchers. The thrust of current research may be described as exploring the design space of possible devices and approaches. Many of these designs represent initial explorations and have not been optimized in any sense, so that judging performance limitations is premature. Utility, functionality, cost, and safety are all issues that will need to be considered in choosing among the options.

3.1 Forward Motion Display

Both leg-based tracking and body-based tracking have been employed to measure how much forward or backward motion a user has produced. Leg-based tracking is readily accomplished where a mechanically tracked device is coupled to a user's feet, as for bicycles, foot platforms, and passive treadmill belts. Direct leg measurement can also be achieved by magnetic sensors (Templeman et al., 1999) or by optical tracking (Noma et al., 2000). The use of the stance time as an indicator of speed appears to be a viable method (Noma et al., 2000). Foot force sensors can aid the segmentation of gait (Templeman et al., 1999).

For body-based tracking, a mechanical tracker attached to the user's body is employed in the Sarcos Treadport (Hollerbach, Xu, Christensen, & Jacobsen, 2000) and in the Omni-Directional Treadmill (Darken & Cockayne, 1997). As mentioned earlier for a walking-in-place locomotion interface (Slater, Steed, & Usoh, 1995), steps can also be approximately inferred from measurements of head bobbing. The inaccuracy reported for this technique limits its utility, however.

Optical tracking is attractive as opposed to mechanical tracking because the user is relatively unencumbered. Magnetic tracking is known to suffer from sensitivity to environmental metal, which may not make it attractive around the heavy metal structures of many locomotion

interfaces. If one is to apply forces to the body, as with the Sarcos Treadport, then a mechanical connection is required.

Relative freedom of movement and unencumberance tend to be strengths of treadmill-style locomotion interfaces. For example, on the Sarcos Treadport a user can stride naturally and run at will. This kind of freedom has to be counterbalanced against movement restrictions due to optimizing some other aspect of locomotion rendering such as turning or uneven terrain. Foot platforms in particular impose some restrictions on forward motion speed.

Accelerating on a locomotion interface can never be the same as accelerating on the ground because the user's body is stationary, unless the missing inertial forces are applied to the body by some mechanical linkage such as the active mechanical tether of the Sarcos Treadport. In that sense, an active tether is demonstrably necessary to make ground and locomotion interface running the same. Psychological studies clearly show the preference of users for inertial force display (Christensen et al., 2000), but aside from preference it may be that displaying inertial force is not necessarily important for making the locomotion interface useful.

Walking-in-place simulators are a low-cost approach toward constructing locomotion interfaces. Comparisons with treadmill or foot platform systems should be made to determine the trade-offs in terms of loss of motion fidelity versus utility.

3.2 Turning Display

Turning intent can be measured through body tracking, leg tracking, or manipulation of a steering device. Steering bars are readily employed for turning control for stationary bicycles, and have also been employed in passive treadmills. Either rate control or position control in steering may be used.

Leg-based tracking is achieved optically by the ATLAS system (Noma et al., 2000). The amount of lateral motion in a step guides the swiveling of the treadmill by a turntable. A magnetic sensor on the knee is used in the Gaiter system (Templeman et al., 1999) to indicate turning by a rocking motion to the side; this represents a gestural control rather than a natural turning motion. Mechanical attachments of the legs to the foot platforms for the Sarcos Biport and for the GaitMaster (Iwata, 2000) guide turning. For the Sarcos Biport, force sensors on the attachment points are used to infer the direction of walking.

Body-based tracking can directly indicate the direction of tracking. For example, the magnetic trackers in walking-in-place locomotion interfaces (Slater et al., 1995; Templeman et al., 1999) measure rotation about the vertical axis. The Sarcos Uniport employs force sensors in the seat, and any sensed sideways twisting controls the rate of turning. The ODT and the Sarcos Treadport use mechanical tethers attached to body harnesses for direct sensing of motion direction.

The two-dimensional treadmill belt designs are attractive in terms of the naturalness of turning. Some control issues apparently must be addressed in the ODT because of reported unstable walking (Darken & Cockayne, 1997). In particular, a mismatch between the direction of a centering motion and the direction of a user's walking can result in a sideways force that causes the user to stumble. The initial implementation of the Torus Treadmill (Iwata & Yoshida, 1999) has led to slow gait and short steps, but this could presumably be remedied in a redesign. There is an issue of the mechanical design complexity of the Torus Treadmill concept and the speed capabilities of the main belt, which itself is the juxtaposition of many small treadmills. Speed constraints, complexity, and cost are particularly pertinent factors to be investigated when the utility of such designs is judged.

Another approach is using a turntable as in the Sarcos Uniport, the ATLAS system (Noma et al., 2000), and the GaitMaster (Iwata, 2000). By swiveling the treadmill in the direction of walking, the ATLAS system achieves a natural gait pattern in turning. Due to lags in rotation,

it is possible that footfall occurs at a slant relative to the desired walking direction, and so on the next step some correction by the user could be necessary. This might pose a problem when an HMD is employed, since users cannot see their orientation on the treadmill. In the GaitMaster, the user does not step into the turn, so the gait is not as natural as for the ATLAS.

The Sarcos Treadport is a linear treadmill without a turntable; hence turning is not as natural. Because of its width, some sideways motion is permissible, although a user would eventually have to recenter. At an obvious cost, the treadmill could be made even wider to accommodate sideways motion. Although rate control is currently used for turning, current research is addressing the use of proportional control within a certain angle. In proportional control mode, a user actually steps in the direction of desired motion, but again, a reindexing is eventually necessary.

The different turning approaches surveyed above may have implications for wayfinding (see chap. 24, this volume). Most natural locomotion occurs, of course, when visual, vestibular, and proprioceptive cues are consistent with normal turning, as in two-dimensional treadmills and the ATLAS system. The GaitMaster provides consistent vestibular and visual cues, although the proprioceptive cues are not veridical. The Sarcos Treadport provides only realistic visual cues. Interestingly, there have been no reported instances of simulator sickness (see chap. 30, 31 and 36, this volume) with the Treadport, even though the vestibular and visual cues are in conflict. This could be because the user is receiving proprioceptive cues for walking that although not realistic for turning, do indicate to users' sensory processes that they are moving.

For the Gaiter walking-in-place locomotion interface, learning to gesture with the knees to indicate turning is evidently an effective strategy (Templeman et al., 1999). Similarly, rate control for the Sarcos Treadport can be viewed as a form of gesturing. From observation of hundreds of people interacting with this system, ranging from elementary school children to adults of all ages, users have been found to adapt quite readily to this turning control mode. Often users discover how to control turning rapidly without instruction. Future research and experience will be required to decide how detrimental or effective different turning control modes are, particularly in the context of other tradeoffs. For example, the Sarcos Treadport excels at forward motion display at the cost of turning, whereas two-dimensional treadmills excel at turning at the cost of forward motion display.

Another issue is whether an active mechanical tether is used in conjunction with a CAVE display, as in the Sarcos Treadport. It has been argued that a tether is necessary for displaying inertial forces and unilateral constraints and is useful for displaying slope. The Treadport tether protrudes from the back of the treadmill and thus interferes with display screens if the treadmill is placed on a turntable. Two-dimensional treadmills also have problems providing the ability to apply forces in any direction. The overhead boom of the ODT would seem a better solution than the horizontal boom of the Treadport, but it might be difficult to get the same force output from such an arrangement.

3.3 Slope Display

Treadmills often are placed on tilting motion stages, so that walking up and down a smooth slope can be realistically displayed. The Sarcos Treadport is an example, but also the bicycle simulator of Brogan et al. (1998) has been placed on a tilting stage. The ATLAS system carries this concept one step further with a spherical joint mounting for the treadmill, which not only acts as a turntable and tilts but also rotates the treadmill sideways. This allows traversing sideways along a slope to be displayed.

The Sarcos Treadport can also simulate slope walking by pushing and pulling with a mechanical tether. Although the Treadport has a tilt capability, due to the large platform mass

the tilt speed is limited and sudden slope transients cannot be displayed. The fast-acting mechanical tether has been reported to simulate slope reasonably well (Tristano et al., 2000), and so may provide a lower-cost alternative to having a tilting stage. One difficulty with a tilting stage is that when a CAVE display is used, larger portions of the screens have to be projected. Also, the belt of the Sarcos Treadport is white to allow for the possibility of floor projection. A tilted platform may complicate correct imagery for the floor.

Displaying uneven terrain such as steps is a particular strength of foot platforms. Soft ground could even be displayed in principle. Unless the foot platform stages tilt, the biomechanics of walking on a smooth slope will not be veridical. The Ground Surface Simulator (Noma et al., 2000) displays uneven terrain through the use of vertical motion stages that deform a treadmill belt. The same comment about differences from smooth slope walking will apply unless the belt is very stiff and does not deflect much in its unsupported regions. For the Sarcos Treadport, if the mechanical tether is effective at displaying rapidly changing slopes, then its force profile might be fashioned to give the illusion of uneven terrain. This is a topic of current research.

3.4 Unilateral Constraint Display

Along with inertial force display, a mechanical tether is demonstrably necessary to display unilateral constraints. Simply braking the locomotion interface is only a vague simulation of hitting a wall. With the current harness attachment of the Sarcos Treadport, the sensation is more akin to being pulled from the back rather than hitting something with the front of the body. An attachment to a plate in front of the body might simulate hitting a wall more realistically. There have been light-hearted suggestions on swinging sandbags down from the ceiling. It seems, nevertheless, that hitting a wall is not something we want to simulate with complete fidelity!

3.5 Body Posture

Relatively unencumbered walking and diverse gaits are strengths of treadmills. Most locomotion interfaces surveyed here only support upright stance. If prone postures such as crawling are important, then a large treadmill surface such as the Sarcos Treadport is the most realistic option.

3.6 Visual Display

CAVE-like displays and HMDs have both been employed with locomotion interfaces. The use of HMDs is particularly appropriate when there are obstacles to the projection screens of CAVEs, such as motion platforms that rotate or tilt treadmills or mechanical tethers. There are more safety concerns with HMDs because users cannot see their positions on the locomotion interface, which could cause them to fall off a treadmill or to lose balance (see chap. 41, this volume). The inconvenience of wearing an HMD is sometimes cited. The usual criticism of poor visual quality of HMDs also applies. A further problem with HMD technology is the lack of economic drivers to improve quality and reduce cost. Simulator sickness might be more of a problem with HMDs than with CAVEs.

One advantage of HMDs over CAVEs is that objects can be projected between a user's hand and line of sight. In locomotion displays one is typically dealing with far-field vision, that is, objects and terrain that are beyond the arm's reach. Therefore, displaying the arm behind an object, which is a strength of HMDs and a weakness of CAVEs, is not as important. Safety

is facilitated by CAVEs, because users can see their positions, for example, on a treadmill belt and make appropriate adjustments. In a CAVE, users see their bodies, which might lead to a greater sense of immersion (see chap. 40, this volume), as opposed to HMDs where a user's body is occluded. The importance of self-vision is not yet clear. Economic drivers are very strong for improved CAVEs in the future because of the projection market, and so higher brightness, resolution, and image quality are to be expected.

There is not as much of an economic driver for stereoscopic projectors, which would be highly desirable for depth perception. Ground projection has been reported as being particularly important for CAVE displays. For the new Sarcos Treadport, the belt material was specified white to allow for the possibility of ground projection. Ideally, the ground projection should be in stereo for depth effects.

CAVEs can complicate the design of locomotion interfaces, because platform motion might interfere with the screens. As aforementioned, the mechanical tether of the Sarcos Treadport protrudes from the back, and so placement of a treadmill on a turntable is problematical. Such a tether on a 2-D treadmill is also problematic, and, as mentioned earlier, an overhead boom might be more appropriate but more difficult to design. If the platform tilts, then projection screens are covered or uncovered, and larger projected images might be required. There can be gaps between the screens and locomotion interfaces. The belt of a treadmill itself is a visual gap, unless there is floor projection. Issues of shadows cast by the user from a projector above and of visual deformation due to platform tilting would need to be addressed.

A final concern with visual displays is their cost, which can be on a par with mechanical displays. Quality HMDs are quite expensive. CAVEs require multiple high-quality projectors, special screens, and special mirrors. At the moment, special-purpose graphics engines are required to produce realistic displays, but the expense of graphics engines is expected to decline dramatically in the future. An indirect cost for CAVEs is the need for large rooms for placement of screens, mirrors, and projectors, including overhead space.

Besides vision, it would be desirable to include auditory displays for ambient sounds as well as footstep sounds. Stereophonic ambient sounds, for example, from walking in a forest, could aid the sense of immersion (see chap. 40, this volume) and spatial orientation (see chap. 24, this volume). In the haptics literature, it has been shown that the sound of contact can bias the perception of surface stiffness and material. Similarly, it is possible that different footstep sounds can bias the perception of the kind of ground one is walking on. Noise-cancelling headphones might be useful to filter out any sounds coming from a locomotion interface.

But why stop with audio? Olfactory displays are progressing, and it would be nice to smell the pine scent of forests we're walking through. Fans could be placed to simulate wind.

3.7 Safety

Because body weight and the forces of locomotion have to be supported, locomotion interfaces have to be powerful. Safety is potentially much more of a concern than with haptic interfaces. Programmable foot platforms are essentially powerful robot arms attached to the feet, and any malfunction could be painful (e.g., potential wishbone effect).

Dangers with treadmills are falling off the sides or stumbling. Ceiling restraints can help, as well as proprioceptive centering cues and sidebars. As mentioned above, the use of CAVEs is probably safer than HMDs. The active tether of the Sarcos Treadport is also a potential safety concern, although the tether forces are well within normal loads to the spine (Hollerbach et al., 2000).

Safety in locomotion interfaces will be enhanced through a judicious mixture of kill switches, watchdog timers, software constraints on motion, and hardware limit switches.

3.8 Locomotion and Haptics

Adding a haptic interface for manipulation to a locomotion interface will be quite a challenge because of the movement possible on a locomotion interface. A haptic interface would have to have a large workspace but be kept out of the way. Some sort of ceiling mount might be required.

One usually associates the forces experienced in manipulating via arms and hands with the term haptics. These days the term haptics seems to be generalized to include any force application to any part of the body. Thus Iwata (2000) has coined the term *foot haptics* for programmable foot platforms. Similarly, body haptics has been used to describe forces applied to the body by the active tether of the Sarcos Treadport. It is probably useful, though, to consider that locomotion interfaces are a distinct class of devices from traditional haptic interfaces.

3.9 Applications

Whereas concrete application areas for haptic interfaces are starting to emerge, such as for mechanical CAD interfaces and surgery training, concrete applications for locomotion interfaces are not well defined. Certainly, training is a strong candidate, such as in military rehearsals (Grant et al., 1997; Parsons et al. 1998) or fire fighter training (Iwata et al., 1999). Telecommunication and control of a remote mobile robot to serve as a physical avatar to allow one to experience walking in a remote place is an intriguing application suggested for the ATLAS (Noma et al., 2000). With terrain data now becoming available for moons and other planets of the solar system, one could simulate walking on Mars or Venus, which could serve an education function. Entertainment, exercise, recreation, and health rehabilitation are other suggested applications.

Finally, VE displays have a strong role to play in psychophysical research, because physical and visual stimuli are so conveniently synthesized. Rieser et al. (1995) towed a treadmill behind a car to decouple the optical flow from the kinesthetic sense of walking. Such decoupling could be much more conveniently achieved with a locomotion interface.

1. INTRODUCTION

Many of the design decisions of virtual environment (VE) applications are driven by the capabilities and limitations of users. These considerations affect both the design of hardware software. To be interactive, a VE software application must constantly present the current “view” of a computer-generated world and have that world quickly react to the user’s actions. To be convincing, the presentation must provide enough detail to make objects easily recognizable and enough objects to give the user the sense of being in the world. To be useful, the environment must respond to the user. The user’s location in the world should change when a navigation action is performed. Objects that the user can grab or nudge should move as expected. Manipulation of three-dimensional (3-D) interface elements, such as floating buttons, tabs, and sliders, should have the desired effect on the environment, perhaps by changing the appearance of an object.

An environment can be described as a set of geometry, the spatial relationship of the geometry to the user or users, and the change in the geometry in response to user actions and as time progresses. The set of geometry can be decomposed into geometric objects that may have a visual appearance, make a sound, or have an odor, taste, or texture to be felt. A geometric object can also be simply a point in space. This geometric environment is presented to each user utilizing output devices. Virtual environment systems usually provide a visual display, and many provide audio, although output for all of the far senses (i.e., sight, sound, and odor) has been shown to be effective (Dinh, Walker, Hodges, Song, & Kobayashi, 1999). Tactile and force feedback devices can also present an aspect of the world to the user and are currently in development. It is much more difficult, however, to mimic the touch sensation of arbitrary geometry than it is to provide a visual representation.

Given that a 3-D environment may occupy a large “space,” providing a convincing illusion that the user is in a realistic world requires many geometric objects that constantly react to

other objects and the users. However, current technology is not capable of handling the amount of information and processing needed to present such an environment. In addition, creating all of the pieces of the world at such a level of detail would be a significant effort. Luckily, many applications can be created with VE technology that do not require a full illusion, and a somewhat realistic world can be quite convincing. It is still a challenge, though, to create and process the description of an environment, which is the environment's model.

An environment model has at least three representations. One representation describes the model in a stored file. Another representation describes the model to a running application, which can be accessed and modified to produce complex behaviors that could not be described in the model itself. A final representation stores the model internally. This representation is optimized for the task of constantly supplying information to the output devices to render a view of the model, providing 3-D sound, and so on. At some point, the model is translated from one representation to another. For example, a file format that provides a stored model is the Virtual Reality Modeling Language (VRML; Ames, Nadeau, & Moreland, 1997). The Java3D package (Sowizral, Rushforth, & Deering, 2000) provides a run-time model for Java programs. Parts of the Java3D run-time model can be explicitly "compiled" to produce an optimized internal model at the cost of making modification of the environment model more difficult.

Some file representations are designed to translate easily to the internal representation, but cannot be easily translated to a model that can be modified at run time. Other file representations may translate quickly to a model that is easy to modify at run time, but require more processing to obtain an internal model that is optimized for interactive use. Over long execution times, a translation step from a file to an internal representation is cheap, as it occurs only once. On the other hand, if the run-time model is modified often, the translation from the run-time model to the internal model can become a critical performance bottleneck.

In this chapter, a discussion of how an environment model is described in terms of geometric primitives and behaviors is provided. This model is often used as the run-time representation. Next, this representation is related to common file formats used to describe a virtual environment, and to an internal representation that provides optimizations for efficient presentation of the model. Finally, a description of how the user can be incorporated into the model to provide an interface between the user and environment is provided.

2. GEOMETRY

For the most part, VEs are spatial in nature. A VE consists of properties associated with locations in three-space, such as sounds and appearance. A VE application, therefore, maintains a representation of spatial information and attempts to organize that information so that arbitrary views can be produced quickly and repetitively. Since visual perception is the primary channel used by sighted people to obtain information about the world around them, VE systems have focused on representing geometric models of visual objects and their placement in the environment.

A VE is usually described by low-level primitives such as polygons, lines, and text, and by higher level primitives such as spheres, boxes, cones, polygonal meshes, polyhedra, curves, and curved surfaces. Current graphics hardware renders low-level primitives, as well as polygonal meshes, very efficiently. However, many of the higher-level primitives, such as spheres, curves, and curved surfaces, cannot be precisely rendered quickly enough. Instead, they are converted to a polygonal representation when they are added to the environment. Advances in hardware, however, will likely allow higher level primitives to be rendered directly at sufficient speeds. A system that handles high-level primitives, by translating them to low-level primitives when

storing the model in the internal representation, will be best positioned to take advantage of this type of technological advance.

Although the visual appearance of an environment can be completely described, albeit approximately in some cases, by a set of polygons, lines, and text images, it is more useful to organize the geometry into separate groups that are related to each other. This network of geometries and relationships is known as a *scene graph*. The scene graph contains nodes that define geometric primitives and properties, relationships between geometry, and perhaps behaviors of the geometry. In this section, the geometric primitives used in VE applications, how these primitives are organized into a scene graph, what relationships the scene graph provides between groups of primitives, and what properties may be stored in the scene graph that determine the appearance of primitives and the environment, such as materials and light sources, are described.

2.1 Geometric Primitives

Current computer graphics systems are optimized to display convex polygons and lines, and are capable of rendering millions of polygons per second to the screen. Therefore, geometry is decomposed into, or approximated by, a set of polygons or lines. Text is often treated as a special primitive, although it can be crudely represented by a set of lines, a set of polygons, or more nicely represented by an image with “see-through” areas.

Geometric primitives are described by point coordinates in a 3-D coordinate system. By convention, the coordinate system is right-handed (when curling the fingers of the right hand from one positive axis to another, the outstretched thumb points in the direction of the third positive axis). Whenever a group of primitives describe an object that has a particular orientation (for example, a tree generally grows “upward”), convention assigns the *y* coordinate axis to represent the “up” direction, the *x* coordinate axis to represent the “right” direction, and the *z*-axis to represent the “back” direction. This coordinate system is a remnant of models developed for display on a computer monitor, where the *x*-axis is the horizontal axis of the monitor, and the *y*-axis is the vertical axis of the monitor. (If only monitors had been placed face up on or in a desk—then the coordinate system convention might match the *z*-up convention of mathematicians and physicists!)

Polygons, also known as faces, are described by a list of coplanar points in three-space. Each pair of points on the list (and the pair containing the first and last points) defines an edge of the polygon. Graphics systems, however, may only be able to render convex polygons, and may just render triangles, as they are simple to process. Concave polygons or polygons with four or more edges are usually decomposed into triangles before they are rendered. Often, a graphics system needs to be instructed to spend the time to convert concave polygons correctly. Polygons are shown filled with some color or pattern, but are considered infinitely thin, meaning that, if they are viewed from the side, they will be invisible. Lines, however, are of a given width regardless of the viewing angle.

In addition to allowing for polygons and lines, modeling systems will generally allow users to create higher level geometries, such as boxes, spheres, cones, and cylinders. These shapes may be converted to polygons by the modeling system or may be stored as their shapes, and must be converted to a polygonal representation by the rendering system. Unfortunately, a polygonal representation is often a rough approximation of the shape. This is especially true of shapes with curved lines or surfaces. Since a computer image is an approximation itself, the error in the shape representation may be hidden by the error introduced in using discrete pixels to define an image. If the rendering system has the shape description, it can translate the shape to a representation that is as accurate as possible given its visibility, at the cost of extra processing time. In general, a more accurate representation requires more polygons or

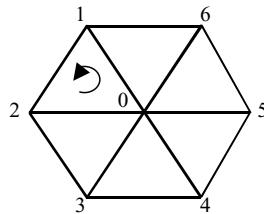

FIG. 12.1. A polygonal surface.

lines. Current modeling packages can produce polygonal representations of their models, but note that the primary application for modeling packages is to produce high-quality animation frames or still images. Thus, they often produce many more polygons than can be handled by an interactive rendering system. What's worse, some of these packages do not allow the user to control the polygonalization algorithm to put a greater weight on fewer polygons.

An environment generally consists of a set of geometric objects, where each object is described by a set of solids or lines, and each solid is described by a set of surfaces, which, in turn, are described by a set of edge-connected polygons (see Fig. 12.1). The viewpoint is assumed to always be outside of a solid. With this assumption, the rendering system can limit the polygons they draw to those on surfaces that face the viewer, since surfaces that don't face the viewer are on the other side of a solid and are obscured by the front surface of the solid. This technique is known as *back-face culling*. However, when the assumption fails (the viewpoint moves inside of a solid), then the effect of back-face culling is that the surfaces disappear altogether (all surfaces are facing away from the viewpoint). At the cost of deciding if the viewpoint is inside an object, a rendering system may display an “inside” color instead. However, this technique is expensive for arbitrary solids and large numbers of objects.

In order for the back-face culling technique to work, polygons of a surface must have a “front” and a “back.” By convention, the order of the points that describe the polygon determines the front and back sides of the polygon: if the viewer is on the front side, then the points are given in counterclockwise order. If the points are given in clockwise order from the point of view of the viewer, the viewer is on the back side of the polygon (as shown in Fig. 12.1).

Surfaces can be approximated as a set of polygons, but surface representation methods that require less information can be loaded into the application faster and transmitted faster from the application to the graphics rendering system. One such method represents a surface that is defined by a set of height values along a regular grid. This method can represent terrain that contains no caves or outcroppings (i.e., all bumps go up, all holes go down). This method allows a surface to be described by the coordinates of the corners, the distance between grid points, and a height value for each grid point, roughly one third of the information needed if only points were used. In addition, the representation can be shrunk further using algorithms that can quickly approximate these surfaces with fewer polygons when the viewpoint is far away (Lindstrom et al., 1996).

A polygon mesh also describes a surface using less information than the same surface given as a set of distinct polygons. Graphics systems generally support meshes of triangles or quadrangles. A mesh is described by a list of polygons, where each successive polygon shares one edge completely with the previous polygon, and therefore shares two points. For example, a triangle mesh can be described by three points for the first triangle, then one more point for the next triangle, another point for the third triangle, and so on. A surface described in this manner uses roughly one third fewer points to describe a surface and does not have the restrictions of the elevation map. In fact, an elevation map will likely be translated to a triangle mesh before it is rendered.

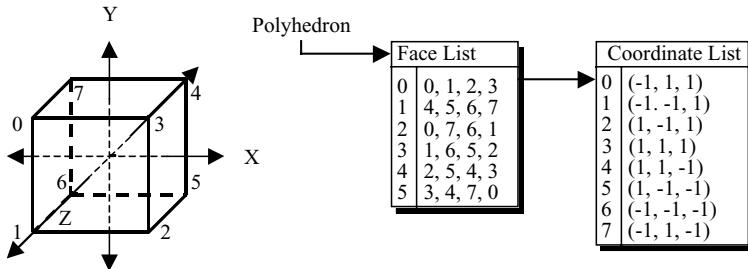

FIG. 12.2. Face and coordinate lists for a cube.

When a polyhedron is specified by a set of face polygons, each being described by a set of coordinates in three-space, many of the same coordinates are given more than once. This is a result of the surface polygons' common edges. To avoid storing redundant information, the geometric model is very often given as a set of labeled coordinates, and a set of faces that list the labels of the coordinates that describe the face's edges. This storage scheme is shown in Fig. 12.2 for a $2 \times 2 \times 2$ cube centered at the origin. Note that the order of the coordinates for each face are given in counterclockwise order from the point of view of being outside of the cube. A similar strategy can be used to store coordinates of a list of line segments.

Graphics hardware vendors tend to describe the performance of their display system in terms of how many polygons per second can be drawn. However, this measurement does not tell the full story. Depending on the hardware architecture, a graphics system may be polygon-bound or fill-bound. If a system is fill-bound, then the number of polygons that can be displayed to the screen is heavily dependent on how much screen space each polygon takes when rendered. In other words, the time taken to fill each polygon dominates the rendering time. If a system is polygon-bound, then the changes to the number of polygons have a more significant effect to rendering time than the size of the polygons. This difference in architecture has a profound effect on how models should be designed and built for VE applications. If a VE application will use a polygon-bound system, then the model should contain as few polygons as possible, no matter how large they are individually. Mostly flat surfaces could be replaced by single polygons, for example. If the system used is fill-bound, however, this change in the model will not have much of an effect on the rendering time. In fact, a system may be fill-bound because it is designed to handle many polygons in parallel, and works best when polygons take about the same amount of time to fill because the parallel processing is balanced. If this is the case, it would be a good idea to break up a large polygon (or, more precisely, one that will appear prominently on the display) into a set of smaller, coplanar polygons.

2.2 The Scene Graph

One could represent the geometric model of a VE with just a set of polygons, lines, and text. However, when a particular object, such as a chair, table, or vase, moved in the environment, then all of the coordinates of the polygons that represent the moving object would need to be changed, or transformed, in the same way. In addition, if the vase was conceptually “on top of” the table, the coordinates of the vase should move when the table moves. A more efficient representation of the model would group geometric primitives together into geometric objects, and would define “attachment” relationships between the objects.

An environment model, therefore, can be represented by a coordinate system graph, which is a directed acyclic graph. Each node of a coordinate system graph contains a set of geometric primitives, which usually represent a conceptual object or object part. The geometry of a node is

described in terms of a local coordinate system. The edges of the graph define a transformation between the coordinate system of one node to the coordinate system of another node. Conceptually, the coordinate system of one node (the child) is contained in the coordinate system of another (the parent). If the parent's coordinate system is transformed, the child's coordinate system is transformed as well (unbeknownst to the child), but if the child's coordinate system is transformed, the parent's coordinate system is unaffected, and the child's transformation is visible in the parent's coordinate system.

A coordinate system graph does not contain cycles because it is unclear how a change in the relationship between objects in the cycle should change the relationships between the other objects in the cycle. Should all of the transformations be changed equally, or should just one other edge change? If just one edge changes, which one should it be? For example, if five marbles represented in a coordinate system graph were placed next to each other, and the graph contained edges between adjacent marbles to keep them spaced evenly, and an edge between the outer marbles to maintain a certain length for the marble line, how should the marbles move if the distance between the outer marbles changes? Or if the distance between two adjacent marbles changes? Should the marbles adjust to space out evenly again, or should just one other distance change?

Coordinate system transformations are described by a 4×4 matrix that operates on homogeneous coordinates, where a location in space is given by the 4-tuple (i.e., x, y, z, 1). A set of locations is transformed from one coordinate system to another by multiplying each location by the matrix transformation between the coordinate systems. Matrix transformations can be combined by multiplying them together, but matrix multiplications are not commutative, and a change in the order in which the transformations are given will change the total transformation (unless the transformations are all the *identity matrix*, which does nothing).

A matrix transformation in a coordinate system graph is often described as a combination of scale changes along the major axes, x, y, and z, rotations about the major axes, and translations along the major axes. However, the transformation may include shears, mirrors, or other affine transformations. Standard 3-D matrix transformations and the use of these transformations in a coordinate system graph are described in more detail by Foley, van Dam, Feiner, and Hughes (1996). Some systems or file formats (such as VRML) may describe the rotation component as a certain rotation around a given vector. This representation, known as a *quaternion*, describes a rotation more efficiently, and is better for interpolating between two rotations (smoothly changing from one rotation to another without experiencing gimbal lock). However, an extra step is required to incorporate a rotation in this form into a 4×4 matrix transformation (Watt & Watt, 1992).

A coordinate system graph is usually represented as a tree, where the root node contains geometry in a "world" coordinate system, and the child nodes have local coordinate systems that relate to the world coordinate system. Therefore, points in the geometry of a child node can be transformed to the world coordinate system. Points further down a subtree of the root node can be transformed to their parent's coordinate system, and then to its grandparent's coordinate system, and so on until it is in the world coordinate system. Similarly, a point in the world coordinate system can be transformed to the local coordinate system of a descendant node by applying the inverse of each transformation on the path to that node. When rendering a scene for the display, geometry must be transformed to the world coordinate system, then transformed to a descendant node representing the coordinate system of the viewer, where the origin is at the eye point.

The coordinate system graph is a type of *scene graph*, as it describes the scene for an environment. Other types of scene graphs have nodes that do not represent geometry and do not associate a transformation for every edge in the graph. For example, the VRML file format (Ames et al., 1997) and the Cosmo3D run-time library (Eckel, 1998) provide a scene graph with

many types of nodes, one of which is the “transform” node that defines a spatial relationship between geometry attached to it and the geometry it is attached to. Edges are still used to group geometry by defining, directly or indirectly, rigid attachments. Other nodes in the graph define light sources, appearance properties, and different types of grouping.

2.3 Material Properties

Surfaces in the real world have many properties that affect how they appear beyond their position and orientation. They may be rough or smooth. They may be dyed or painted with different colors, or they may contain grains. They may have fine detail that is too expensive to model geometrically, such as the texture of skin or hair. At a great distance, even features like brick grooves, windowsills, or door handles might be considered fine detail. These features can be described by their contribution to the color of a pixel on the display, if the feature is visible at all. In addition to the various properties of the face, this contribution will be affected by the light sources and global lighting model that is in effect for the environment.

The appearance of a face under a given lighting configuration is generally described by properties of the face as a whole and properties of the points on the face. Properties given to the entire face include the color of the face under no light, the color response to a diffuse light, the color response to a specular (mirror) reflection, and the transparency of the face. Properties of individual points on a face can be given by an image or texture map, which contains color and transparency information for points on a two-dimensional (2-D) grid. The color information of the image map may be combined with the face properties or may override them (the fountain scene in Fig. 12.3 uses texture maps for the floors and ceilings). As a whole, the material properties define a contribution of certain values of red, green, and blue to a pixel on the display, if the face is visible at that point on the display.

2.4 Lighting and Shading

The appearance of a geometric primitive depends not only on its material properties, but also on how light sources in the environment are positioned. An environment is assumed to have a

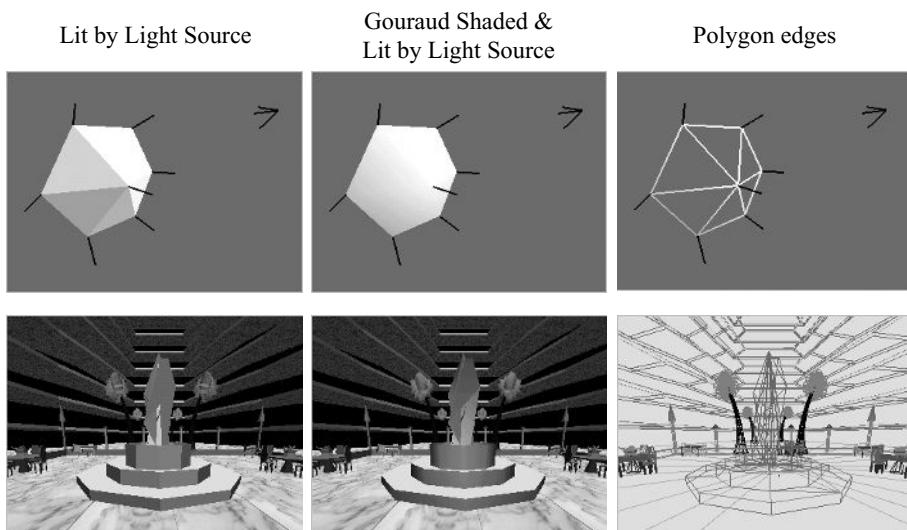

FIG. 12.3. The effects of a lights sources and Gouraud shading.

certain amount of low-level ambient light, and the material definition given to a face describes the color to use for the interior of the face in the absence of any light sources. For each light source that does exist, a proportional amount of diffuse color, from the material definition, is added to particular pixel colors for parts of the face that are visible. The amount of diffuse color is dependent on the incident angle of the ray from the light source onto the face. Light sources can be given at infinity, where all light rays are parallel and travel in a certain direction, or can be given a position from which the rays emanate. Systems that render the display at interactive rates generally do not consider obstructions to light rays, and therefore no shadows are shown. The left two screen-shots in Fig. 12.3 demonstrate the effect of light sources. The location of the light source for the six triangles in the top left image is shown in the top right corner of the image.

Light sources can be included as a node or with geometry in the scene graph, but the rendering system must only use the location and direction of the light in the coordinates in which objects are rendered. The coordinate system transform that is usually used to define a node's position in the world or relative to another node may include nonrigid transformations, such as scales and shears, which do not preserve angles or distances.

In the images on the left of Fig. 12.3, each polygon was considered individually. If a group of polygons approximates a single, curved surface, the interior of each polygon can be shaded so that the surface appears curved rather than faceted. When the color of a pixel is calculated, the normal used in the lighting calculations is the normal to the *surface* at the point which is projected to that pixel, rather than the normal to the polygon. Calculating a new normal for each pixel drawn when filling a polygon on the image can take a significant amount of time, however. The most common technique for "smooth shading," or Gouraud shading, uses the normal to the surface at each vertex of the polygons that make up the surface. Normal vectors for the interior pixels of the polygon are interpolated from the normal vectors at the corners (the value is a weighted average of the vertex normal vectors, based on the relative distance from each vertex). The middle images of Fig. 12.3 use the Gouraud shading technique. The images on the right show the edges of the polygons that are being drawn in the other images. The black lines in the top images show the normal vectors for each vertex. Foley et al. (1996) describe the Gouraud and other shading algorithms in more detail.

3. BEHAVIOR

A dynamic environment can be represented by a set of objects that have particular behaviors. These behaviors may be given as part of the stored model of the object, may be defined by the execution of the application code, or may be some combination of the two. An object may have a set of behaviors that it follows given its current context. These behaviors can be roughly categorized as *environment-independent behaviors*, which do not consider the current state of the other objects in the environment, and *environment-dependent behaviors*, which do consider other objects. Environment-independent behaviors include changes to the object that are solely based on the passing of time, or *time-based behaviors*, and changes that occur in a particular sequence, or *scripted behavior*. Environment-dependent behaviors include *event driven behaviors*, which respond to events initiated by users or other objects, and *constraint maintenance behaviors*, which react to changes of other objects to maintain defined constraints, such as relative placement, gravity, or penetration limits (see Fig. 12.4). The following subsections describe each type of behavior in more detail, concluding with a subsection on interactive behaviors encapsulated into *interactor* objects.

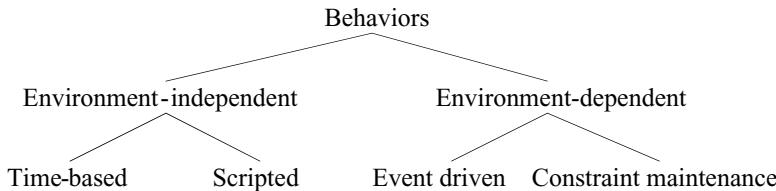

FIG. 12.4. Categories of behavior specification in virtual environments.

3.1 Time-based

An object's behavior may describe a change in one of the object's properties over time or at a certain point in time. Object properties that may be changed include the object's position, orientation, color, and visibility. A circling airplane may follow a particular path as it flies around a town, where its position and orientation are determined by the amount of time that has passed from when it began flying. A distant mountain may change from a detailed model displayed during daylight hours, to a simpler model for dawn and dusk, to being invisible at night.

Time-based behaviors may be defined to use wall-clock time, also known as absolute time, which is the time frame of the user; or a time frame that is transformed from wall-clock time. Behaviors usually have a start and end time. A behavior may change a property continually over the time between start and end times. For convenience, the time values used to define such a change usually are zero at the start time and one at the end time. If a behavior should last, say, 5 minutes, then the behavior can be scaled appropriately.

Time frames can be used like one-dimensional coordinate system frames. A time frame can define a translation (time 0 to a start time) and a scale (time 1 to an end time). Time frames can be related to the wall-clock time, or they can be organized hierarchically, like a coordinate system graph. For example, in the Mirage system (Tarlton & Tarlton, 1992), an *activity* consists of the change of an object's property from a $t = 0$ to a $t = 1$ value. A single activity can be set to begin and end at certain times, or be combined with other activities by becoming siblings of a parent activity. The relationship between a parent activity and its children may specify that the child activities occur simultaneously, or one after the other. The parent activity will have a relationship with wall-clock time that will have it occur at a certain time and pace. With this structure, an activity could flow at various speeds, and could even be paused or reversed.

For example, Fig. 12.5 shows an activity hierarchy where a "Rolling Wheel" activity consists of a "Rotating Wheel" activity and a "Moving Wheel" activity. These child activities may be combined for a coordinated motion by making no transformation from the parent time frame to

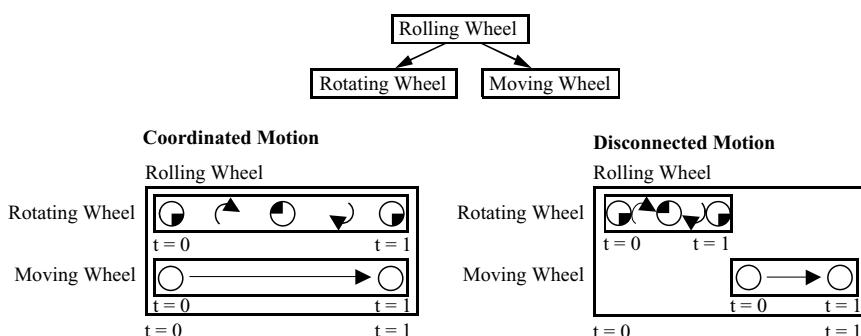

FIG. 12.5. Activity combinations (Adapted from Tarlton & Tarlton, 1992, with permission).

the time frame of each child, as is shown on the diagram on the left. Alternatively, the motions can be performed one after the other by transforming the 0 to 0.5 time values of the Rolling Wheel activity to the 0 to 1 time values of the Rotating Wheel activity, and transforming the 0.5 time values of the Rolling Wheel activity to the 0 to 1 time values of the Moving Wheel activity. This is shown in the diagram on the right of Fig. 12.5. The left structure of the figure produces a rolling wheel, and the right structure produces a wheel that rotates and then slides.

Individual activities may specify an instantaneous change in an object's property at the activity's start time, or may specify a continuous change of a property based on the time value. The continuous change may be given as a function of the time value, or may simply be specified as an *interpolation* between a starting and ending property value. Different interpolation methods may be used depending on the property type. For example, a linear interpolation is often used for position changes, while a color change may be a linear interpolation of colors in HSV (hue, saturation, value) space, having been transformed from RGB (red, green, blue) space. Other interpolation methods can be used to produce a different transition between values. For example, an "ease-in, ease-out" method slowly increases the rate a value changes until the halfway point, then slowly decreases the rate back to zero, at which point the new value should be obtained. A common animation technique is to define particular property values, such as position and orientation, for objects at certain moments in time. A set of these values are known as a *key frame*, which define the start and ending values of interpolation activities that follow one another. (See Watt and Watt [1992] for a detailed description of how interpolation is used in animating object movements.)

3.2 Scripted

A scripted behavior defines a set of steps to be taken in order. The run-time system may make a new step every time it renders an image to the display, or one step after a specified number of image frames. The speed of the behavior, therefore, is directly tied to the frame rate of the application. Scripted behaviors may not appear smooth, because they are not tied to a constant passage of time. However, a scripted behavior can provide a transition or animation that shows every step to the user while completing as fast as possible. If the behavior is time-based, there is a chance that a step will not be seen when it occurs between the times an image frame is rendered.

3.3 Event-driven

The behavior of an object may be specified as a reaction to an event that occurs in the environment. An event may represent a user's action, such as pressing a button, or it may represent an incidence in the environment, such as the collision of two objects. Alternatively, it may represent a change to the property of another object, such as the other object's appearance or mass.

Events can be stored in a global *event queue* (which may actually be many queues), and dispatched to objects that have expressed an interest in them, or can be stored locally in an object's *out field*, and *routed* to the *in field* of other objects when such a route has been set up. Generally, systems that are designed to support event response in application code use the event queue model, whereas systems that use only behaviors defined in a file description, such as VRML (Ames et al., 1997), will use event routes. However, the Java3D package (Sowizral et al., 2000) uses an event route network, which eases the incorporation of VRML models into its run-time system. The event route model is not as flexible as the event queue model, as a route must have a single source, whereas an event can come from anywhere. It is not difficult

for an object to listen for events from an event queue that come from any object, but it is difficult for an object to set up routes from many objects.

3.4 Constraint Maintenance

It is sometimes easier to describe a behavior declaratively, stating a set of relationships that should be maintained, rather than defining a procedure to enforce the relationships. This is akin to specifying what result you want, but not how to get the result. The positional relationship between a parent and child in a coordinate system graph is an example of a declarative constraint: The child should have a certain position in relation to the parent. Of course, the simplicity of describing a behavior with constraints comes with a cost. The run-time system must ensure that the constraints are maintained, and must deal with situations where the behavior is overconstrained or underconstrained. In addition, it is difficult to design a system of constraints of any complexity, as one change can have far-reaching, and sometimes puzzling, effects.

Constraints can be specified for any set of properties of the objects in the environment. For example, the TBAG tool kit (Elliot, Schechter, Yeung, & Abi-Ezzi, 1994) is a graphics library and run-time system that provides “constrainable” program objects that describe relationships between values that should be maintained. The TBAG tool kit uses the SkyBlue constraint satisfaction algorithm (Sannella, 1992) to generate the values that satisfy given constraints as best as possible. However, two types of constraints are found more often than others in VE run-time support systems: geometric constraint maintenance and physics-based motion.

A geometric constraint uses properties such as attachment and spatial relationships with other objects. Using the coordinate system graph as part of a scene graph, a run-time system automatically maintains a spatial relationship between child and parent objects in the graph. The run-time system may also maintain a direct spatial relationship between two objects that are not a child or parent of the other in the scene graph. For example, objects that represent 3-D interface components (buttons, menus, etc.) may be automatically arranged adjacent to each other so that they do not overlap even if components are moved or scaled. In another example, the WALKEDIT system (Bukowski & Sequin, 1995) allows users to quickly position objects to construct rooms with furniture, books, and other items. This task is facilitated by the enforcement of spatial constraints that come from abstract relationships or associations. Picture frames are constrained to vertical surfaces; cups sit on horizontal surfaces such as desks or floors, and so on.

A run-time system can reasonably maintain a list of one-way constraints, where a change in one property results in a change in another property, but not vice versa. For example, a change in the position of a parent node in the scene graph affects the position of the child node in the environment, but a change in the child node’s position does not affect the parent node’s position. It is much more difficult to support two-way constraints, or constraint dependencies that contain cycles, as a solution must be found by solving a system of simultaneous equations, and it may be over- or underconstrained (a solution does not exist, or many possible solutions exist). A run-time system that needs to enforce two-way constraints can implement constraint satisfaction algorithms such as SkyBlue.

A virtual environment can look more “realistic” if the objects in the environment follow the physical laws of the real world. Real-world objects have mass, may be rigid or flexible, solid or fluid, will fall at a constant acceleration when not supported, will move and twist when pushed by some force, and so on. However, simulating a world with many objects that obey such laws, and producing an accurate view of the objects at interactive rates, is a job beyond the ability of most computers in existence today. Therefore, current run-time systems generally do not try to enforce physical laws, but a few provide assistance to applications for a small subset of the

objects in the environment. Objects may be given properties such as mass, velocity, angular velocity, acceleration, and angular momentum. In addition, some run-time systems can report when collisions occur between the geometries of two objects, or a separate support library can be used, such as I-COLLIDE (Cohen, Lin, Manocha, & Ponamgi, 1995). It is usually up to the application, however, to determine how objects might change form or trajectory due to a collision.

3.5 Interactors

As is true of 2-D graphical applications, a 3-D environment may contain geometric objects that belong to a class that interact with the user and other objects in a well-defined way. In 2-D interfaces, these objects are called widgets, components, or interactors, and include buttons, menus, scrollbars, and pointers. Each class of objects encapsulates an interactive behavior, parameterized to allow for multiple uses. Buttons, for example, have the same behavior when “pressed” by the mouse pointer, but have different labels and reactions to user actions. Since the number of ways a user interacts with a VE can be large and the interaction between 3-D objects complex, the implementation of such interactor classes is important to facilitate the development of interactive VE applications.

A 3-D interactor is generally a geometric object with a defined behavior when certain events occur and certain properties of the environment and objects in it change. For example, a 3-D button might react to the collision of a ray or associated hand object. Figure 12.6 shows a VE application with several 3-D interactors. An interactor can be defined as a specialized node in the scene graph, as is done in the VRML file format using PROTO nodes (Ames et al., 1997). These specialized nodes can be given fields to store state, and *in* and *out* connection points for event routes. A system, such as the Virtuality Builder II (VB2) (Gobbetti & Balaguer, 1993), which uses a constraint satisfaction algorithm, can enforce constraints between fields internal to an interactor node and between fields of different interactors. In addition, one-way constraints can constrain field values to user input, such as hand position.

An interactor framework that uses event routes to connect interactors together can be difficult to wire in, especially if the interactor reacts to a property for a set of objects (the hand position of any of a group of users, for example). In the Simple Virtual Interactor Framework and Toolkit (SVIFT), an extension to the SVE library, interactor classes can themselves identify the set of events and property changes that they are interested in, based on the parameters given at instantiation and the behavior desired (Kessler, 1999). For example, a “narrator” interactor may look for any “description” property that is stored with any object added to the scene graph and observe the gaze direction of the user. If the user looks in the direction of an object with a description for a set amount of time, the narrator object would display or “read” the

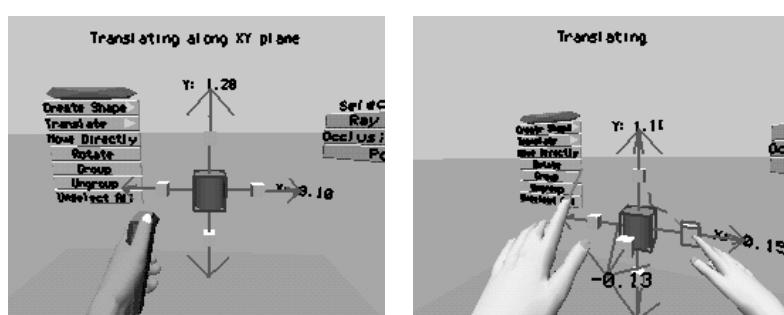

FIG. 12.6. Interactors in a shape manipulation task.

description. Figure 12.6 contains a set of SVIFT interactors, including buttons, menus, tabs that can be grabbed and moved (or bestow the grab and move ability to another object), constraint maintainers (to keep the manipulated object on a particular plane, for example), and selectors. The figure on the left is using a ray selector interactor, and the figure on the right is using a “poking” selector. Since the other interactors in the environment are defined to respond to any “selection” event that has them as the selected object, they can work with either selection mechanism.

4. FILE FORMATS

In the previous sections, the vocabulary with which VEs are described was defined. The geometry and behavior of a VE application may be given procedurally, using this vocabulary as a basis. A VE application may contain code that constructs geometry using a low-level graphics library, such as OpenGL, or a high-level library such as Java3D. The application may also contain a step-by-step procedure for how geometry changes over time or as a reaction to the user’s actions.

A geometric model can generally be described more efficiently by its geometric primitives and properties, such as vertices, colors, and so on, than by giving a procedure for building the geometry. A file format can be designed to describe geometry and spatial relationships between geometries, and therefore allow for clear and concise descriptions of a geometric model. It becomes the task of a file loader and the run-time system to translate the model from the stored representation to the run-time model, and ultimately to the internal model for efficient rendering.

A file format might also allow simple, object-based behaviors to be defined. However, complex behaviors and behaviors involving many objects are usually best left to a programming language to describe the behavior procedurally. For example, the Alice system (Pausch et al., 1995) uses geometries that are described by model files, but object and environment behaviors are described using Python scripts.

Files that describe geometric models may be intended to be read and edited directly by developers, such as those defined by VRML (Ames et al., 1997), or be intended to be created and modified only by modeling applications, such as those defined by the Multigen OpenFlight format (MultiGen, Inc. 1998). A format that will be edited by a developer must define an organization of geometric primitives and components that match the developer’s conceptual model of the environment’s construction. In addition, it should use descriptive keywords and allow components to be named. A model format that is not intended to be edited by a person can be more compact, even though it can still be read. For example, the Wavefront obj format defines a single geometric object using vertices, vertex normals, texture coordinates, faces, and face materials, each of which are defined using a short keyword (“v” for a vertex, “vn” for a vertex normal, etc.). Numbers are represented as a series of numeric characters, rather than being stored as a binary value, allowing the file to be read (and edited if necessary). A Wavefront material file supplements an obj file to provide the definition of face materials.

5. INTERNAL MODEL

The internal model representation of the environment is designed to provide the rendering performance required for VE applications. The run-time representation of a geometric model could be passed directly to the low-level graphics library and audio libraries to present to the

user, but the run-time representation is not likely to be the most efficient representation to use, especially for visual components. An internal representation, therefore, can be created that provides a more efficient transfer to the graphics hardware, and therefore allows for faster performance of the system.

The goal of almost all rendering optimizations is to reduce the amount of information passed from a software application to the rendering hardware. These optimizations can be automatic or application-assisted. One type of automatic optimization generates additional representations of a geometry from a run-time or stored model that uses less information to define the geometry. Another computes extra information that allows for run-time selection of parts of the geometry that can be ignored. Automatic optimizations include primitive sorting for reduced state changes, display list generation, and culling faces for the render list based on the user's viewpoint. Application-assisted optimizations include switching between different levels of detail and using "billboarded" geometries, described later. This section describes these optimizations in more detail. Many of these are implemented, for example, by the IRIS Performer tool kit, described by Rohlff and Helman (1994).

5.1 Primitive Sorting

A graphics rendering system uses a current *graphics state* to determine how primitives will appear when they are rendered. The current graphics state includes the coordinate system, material properties, current texture image, and global properties such as fog and light sources. When describing each primitive of a model to be rendered, an application could specify all properties of the graphics state required to render the primitive correctly. However, more often than not, a primitive is part of a greater whole and shares most of its properties with other primitives. For example, a set of triangles that describes the surface of a hood for a car model will share the same material and lighting properties, and will share the same lighting properties with the triangles that describe the hubcap. Repeating the current state for every polygon on a particular surface would be quite inefficient.

Systems that generate an internal model for rendering efficiency, such as the Performer tool kit, provide a framework that allows primitives to be sorted by their graphics state. Primitives that have the same material and global properties will appear together, while those with similar properties will be close to each other, and so on. This modified list will be used to describe the model to the renderer, and state changes will only be given when necessary. The result of this optimization is that much of the redundancy of the model is removed.

The most optimal list of primitives would be a sorted list of all of the primitives. However, this list would need to be updated whenever one of an object's properties changes. For example, since all of the primitives would need to have a common coordinate system, all of the primitives of an object would need to be transformed to a common, world coordinate system, taking into account the coordinate system transformations between the object and its parent and ancestors. If the object were to move, however, through the change of one of these transformations, all of the primitives in the list that are part of the object would need to be updated with a new position. This would be a bookkeeping nightmare. Instead, lists of primitives that are sorted are usually limited to individual objects, as described in the next section. However, Durbin, Gossweiler, and Pausch (1995) describe a system that provides a list of primitives for each object which is either just the primitives of the object, or one that includes the primitives of the object and its children, if the children have not changed their state in a prescribed time. In this system, when a child changes its state and its primitives are part of a parent, the parent returns to its individual list until its children do not change for some specified time. Therefore, object trees that do not change often are rendered more efficiently (perhaps dramatically so, if the objects share many properties).

5.2 Display Lists

Another method to reduce the transfer of geometry and property changes through the graphics system is to, instead, create *display lists* representing the graphics commands required to create the geometry and to make property changes. A display list can be created and transferred once through the graphics system, then referred to by a unique ID each time the commands should be executed by the graphics system. The graphics system may perform the sorting optimization. Display lists can contain the commands to create a geometric object, or may simply consist of the commands to set up a particular material with a texture image to be used for a variety of primitives.

Like a sorted primitive list, a display list is only useful as long as the properties of the primitives do not change. When one property of a single primitive changes, the list needs to be recreated. Since this can cause delays, the Performer library does not use display lists for most primitives. Systems that do use display lists and sort primitives must catch changes to properties and perform a regeneration of the list, or simply prevent the change.

5.3 Face and Object Culling

Two common methods to reduce the amount of information transferred to the rendering system involve omitting faces that cannot be seen by the user. One method, *back-face culling*, makes the assumption that face primitives define the surface of a solid object and that the face will only be viewed from outside of the object. Therefore, the face is only rendered when the user's eye point is on the front side of the primitive, which is generally defined to be the side of the face for which the list of vertices is given in a counterclockwise manner. If the viewer is on the back side of the face, it is not rendered. If the object is one that the viewer can be inside of, such as a room, the faces must be made to be two-sided, usually by giving the same list of face vertices twice, in opposite orders. The back-face removal technique is usually a feature of the low-level graphics library.

The other method to reduce the amount of faces rendered involves the higher level representation of the objects in the environment. Objects are checked for an intersection or containment in the user's view volume frustum, which defines the volume of the environment that the user would see if there were not obstructing objects. This volume is defined by the position of the user's viewpoint and viewing window in the environment, and the near and far clipping planes. If an object is found to be outside of the viewing frustum, it is simply not rendered, saving the rendering system the effort of determining that each face of the object falls outside of the rendered display.

This method depends on having a simple geometric representation of each object that is a good approximation of the volume the object occupies. Common representations include spheres and boxes. It is easy to check for intersections between spheres and other spheres or plane-based volumes, but sphere boundaries often contain much more empty space than space occupied by the object. In addition, to make intersection checking fast, spheres must be defined in a common coordinate system, as nonuniform scale and shear transformations will change the spheres into nonaligned ellipsoids that are much more difficult to work with. A box volume can be aligned to a single world axis for easier intersection testing or aligned with the local coordinate system of the object it represents for a more accurate approximation (objects are often defined so that their widest length is parallel to a major axis).

Since a scene graph defines a hierarchy of objects, this hierarchy can be exploited for more effective view volume culling. The parent of a group of child objects might have a bounding volume that contains the geometry of the parent and the geometries of the group. Therefore, if the parent object's bounding volume is outside of the viewing volume, so are all of its

children, and that whole subtree can be omitted from the rendering of the current frame. If the environment is sparsely populated by objects, then a more effective bounding volume hierarchy may be constructed separately from the scene graph based on grouping the closest objects, and then grouping the closest groups together, until one group contains all objects.

5.4 Level-of-Detail Switching

The amount of detail necessary for an object's description depends on how much detail the user can possibly notice. If the object is far away or in a foggy or low-light environment, the user will not notice much detail, while if the object is near by on a clear day, most detail will be perceived. A method of reducing the amount of information transferred to the rendering system involves selecting the object geometry from a list of progressively less detailed representations that has the least detail but will appear very similar to the object at its full detail. That object is used, potentially saving the wasted effort of rendering detail geometry that would not be noticed. This method of omitting detail can work for all presentation mediums involving the distance senses. Sights, sounds, and smells diminish in intensity and detail based on distance or other factors. In general, the application must supply different levels of detail for an object and give some measure of how it compares to a full detail model. A common approach, as seen in the *level of detail node* (LOD) of the VRML file format, is to associate a representation with a range of distances from the user's eye point for which that representation should be used. A system, such as Performer, can also automatically determine when an object's geometry is so small that it does not occupy enough of the screen to be noticed, and therefore can be omitted completely.

5.5 Billboard Geometry

A common technique that is used to reduce the amount of detail needed for a geometric model is to use an image containing a picture of the detail. This technique works well for distant objects, as the absence of depth to parts of the model is not noticed. However, this technique alone will not work for objects that can be viewed from all directions, such as trees or clouds. Another technique can be used, in addition to an image, to give the appearance of depth to a model if the model can be assumed to appear the same from all directions. This technique is known as *billboarding*. The image is placed on a flat polygon, but the polygon automatically always faces the viewer, or always orients to the viewer while keeping one axis aligned (such as the "up" axis for standing objects). For example, a tree image will remain upright, but will appear to have a trunk and crown from any point of view (except from directly above or below). The tree will appear to be three dimensional, if a bit too symmetrical. This technique can be combined with changing the image based on the rotated angle to give an approximation of an object that is not symmetric around one or more axes.

6. INCLUDING THE USER

When creating 2-D images for interface and content, computer applications use a standard location for the viewer: some distance in front of the computer screen. In fact, the viewer is mathematically assumed to be at a great distance from the screen, as raised buttons appear the same whether they are on the left, right, top, or bottom. The geometric model of these applications is two dimensional, or an ordered composite of 2-D image layers, all of which are in front of the viewer. However, when the geometric model becomes truly three dimensional, the viewer can be placed in the model itself, giving the user a presence in the 3-D environment.

This allows users to view a 3-D model from any perspective, to get closer and even “fly” through the model. Including a representation of the user in the 3-D model itself clearly specifies the point of view for the image rendered for the user, and it allows the behavior of the model to affect the view: When the user is “attached” to a moving airplane object, the viewpoint moves with it. In addition, geometry can be “attached” to the user so that it moves when the view changes (through mouse manipulations or tracking device movements), as in a “head’s up display.” Finally, the user model can describe the type of display being used and specify the window in the 3D world that matches the display image edges. The image may be like glasses into the virtual world, moving as if attached to the user’s head (a head-mounted display [HMD]), or a window into the world that moves independently of the user’s head (a “fish tank,” workbench, or handheld display). Figure 12.7 shows three different representations of the user (Kessler, Bowman, & Hodges, 2000). These three representations will be described in more detail below.

Placing a representation of the user in the 3-D model of a VE not only provides a convenient way to specify the user’s view of the world, but it also allows for a unified method for handling the user’s visible representation in the world and interaction with the world. Geometric objects can be given for important parts of the user’s body, such as the arms and hands, which may be controlled by any positional input device (e.g. mouse, joystick, or 6-degree-of-freedom tracker) or scripted animations. The direct interaction of the user with the world can be handled just as the interaction between any two or more objects is handled. The following sections describe how the user can be represented in the environment model, how tracking input devices can control the user model, and finally, how the user model can generate the viewing parameters for the various display devices that the user may be utilizing.

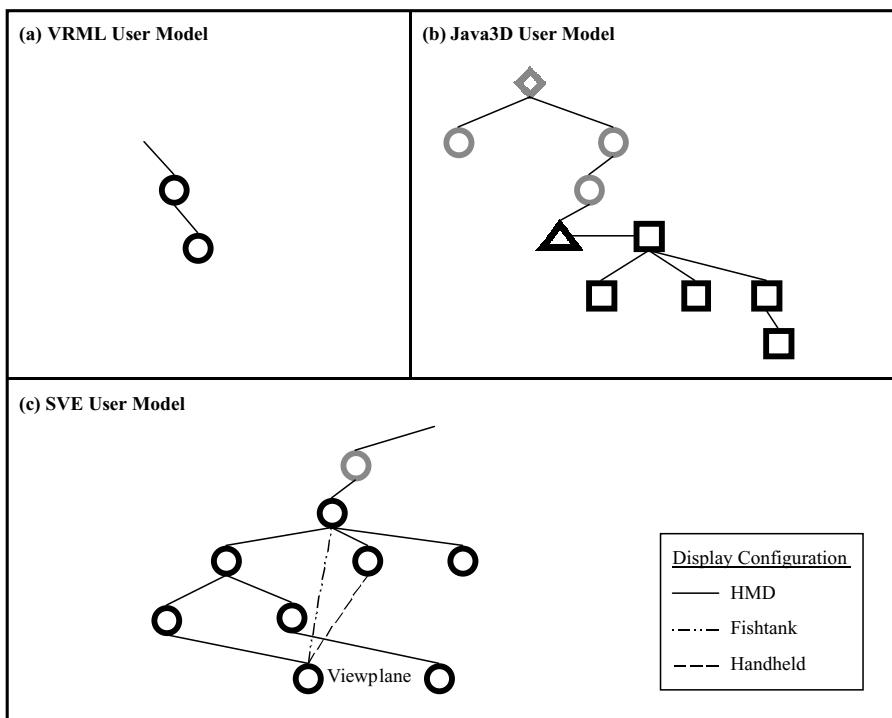

FIG. 12.7. User model in the scene graph for VRML and the Java3D and SVE libraries.

6.1 User Model

The simplest representation of a user in a 3-D environment includes a location, gaze direction, and “up” direction for the view. However, this “viewpoint” method conceptually places the user outside of the environment. A better method, common to most VE systems, is to represent the user by one entity or a group of entities in the environment model, which can be “attached” to other entities of the model and be manipulated like other entities. This method allows the user’s viewpoint to follow an object that she is “in,” such as an airplane or car. The VRML file format provides an example, shown in Fig. 12.7a, where the user is represented by a *Viewpoint* node (Ames et al., 1997). The Viewpoint node can be attached to a *Transform* or other *Group* node, which means that the user’s viewpoint will change as the positions of the Transform nodes further up the tree change. The *NavigationInfo* node describes how the user’s viewpoint can change within the coordinate system of the Viewpoint node, including the speed, and constraints on movement.

The viewpoint representation of the user also fails to include other important information, such as the position of the two eyes for stereo viewing; the position of hands, feet, torso, and other body parts; and the movement of digits. Information about the user is used to help determine the view presented, to provide a visible representation of the user in the environment, to allow direction interaction with the geometric objects in the environment, and to provide input to gesture recognition algorithms. Given that this information is spatial in nature and that it is all about one subject (the user, of which there may be more than one in the environment), it is natural to include the user data in the environment model.

Figure 12.7 shows the user representation in three different 3-D environment models, the VRML file format (Ames et al., 1997), the Java3D scene graph (Sowizral et al., 2000), and the SVE coordinate system graph (Kessler et al., 2000). In addition to the viewpoint being associated with a Viewpoint node in the VRML file format, an attached NavigationInfo node describes the size of the user’s avatar in the environment. The VRML avatar is described as having a width, given as a radius from the user’s position, a height, and a maximum step size. The width is used to determine collisions between the user and geometry in the world, the height is used to describe the distance the user should be above the ground if following the terrain, and the step size is used to determine if a height difference in the terrain is too large to allow the user to pass over it.

The representation of the user in the Java3D scene graph is similar to the VRML format. The location of the user in the 3-D environment is defined by the ViewPlatform node, which can be placed in the scene graph so that the user automatically moves with objects. However, Java3D has two additional program objects, the *PhysicalBody* and *PhysicalEnvironment* objects, which define the positions of the user’s head, eye(s), and hands in the environment. These objects encapsulate the transformation from the ViewPlatform coordinate system to a “coexistence” coordinate system and describe the locations of user body parts in that coexistence coordinate system. The application programmer can use the calculated positions of the various body parts in *Behavior* nodes to define interactions between the user and the environment, and to have separate geometric objects follow the user’s movements and provide a visible representation of the user in the environment.

In contrast to Java3D, the SVE coordinate system graph associates a separate geometric object in the coordinate system graph for each important body part, as is shown in Fig. 12.7c. A *User* object represents the user as a whole and can be attached to the environment model at any place, like the Viewpoint and ViewPlatform nodes. Attached to the User are a *Head* object and two *Hand* objects. Attached to the Head object are two *Eye* objects. Other user objects, such as feet, palms, finger joints, and so forth can be added to the representation as needed. The next section describes how the relationship between the physical locations of the user’s body

parts, if tracked, and location of a geometric object in the environment is maintained. These user objects may not have a geometry defined for them, simply representing a location in the world, or may have a geometry or child objects with geometry to give a visible representation of the user in the environment. An advantage to this user model is that the interaction of the user with the world can be handled in the same way as interactions between any set of objects in the environment are handled.

6.2 Incorporating Tracking Information

Tracking devices generally report the position and orientation of a “tracker” in relationship to a particular reference frame. If the tracker is at the end of a set of mechanical linkages, then the reference frame is the base of the linkages. If the tracker is an electromagnetic device, then the reference frame is the “transmitter” part of the device (often placed on the desk or hung above the user).

Information from the tracking device can be used in raw form or adjusted by a given offset to relate the tracking reference frame to the world coordinate system of the environment. This information can be used to determine the position of the viewer or be used to determine how the user interacts with the scene. However, if the tracking information is to be used in a coordinate system other than the world coordinate system, then the reference frame offset must be carefully calculated and updated when the scene graph changes. In fact, two offsets might need to be maintained: a transformation between the tracker reference frame and the environment, and a transformation between the tracking device and the reference point of the associated user’s body part. For example, the transmitter may be mounted above the user’s head, and a head tracker may be mounted on an HMD such that it is a few centimeters above and behind the top of the head and tilted.

The user model of Java3D defines a set of coordinate systems between the ViewPlatform node in the scene graph representation of the user’s position (or, more precisely, the position of the user’s feet, screen, or eye), and the user’s head, eyes and hands. The ViewPlatform node defines where its origin is in “coexistence” coordinates, based on whether it represents the user’s feet, screen, or eye. The PhysicalEnvironment object defines a transformation from the coexistence coordinates to the tracker reference frame, the “tracker base” (the first offset discussed above). Finally, the PhysicalBody object defines a transformation from the head position to the head tracker position (the second offset discussed above). As discussed in the next section, this model supports a variety of display configurations. The particular display configuration used can be defined separately from the Java3D scene graph, since the necessary parameters are in the View object and associated objects (shown as squares in Fig. 12.7b).

In the SVE library, tracking information is introduced into the user model to control a body part (or any other object in the environment) by adding two new geometric objects. One object is used to represent the reference frame itself, and it is set to be the child of the controlled object’s parent. The other new object represents the tracker and is placed as a child of the reference frame object. The controlled object is then set to be the child of the tracker object. The tracker object’s coordinate system transformation is set to the raw tracking information each frame. By initializing the coordinate system transform of the reference frame object correctly, the controlled object will move around its previous parent correctly. An added benefit to having a new reference frame object for each tracker is that different tracking devices can be used simultaneously, even if their tracker bases are at different locations and the tracker reference frames do not match. If a correction needs to be made for how the tracker is attached to the body part it is tracking (e.g., if it is 90 degrees off), then a correction can be placed in the transformation from the tracker to the controlled object. The SVE model

provides the application with spatial information such as tracker reference frame and tracker position in the same way it provides spatial information about any other object, simplifying the implementation of user interaction and environment behaviors.

6.3 Viewing Model

One of the main tasks of the user model is to define the parameters necessary to generate the user's current view so that it can be rendered to the user's display. The VRML Viewpoint node provides a common representation for the user's view: that of a camera in the environment. The Viewpoint node provides a location, orientation, and a field of view for a camera model, which defines how geometry is projected onto the display toward an eye point. Two viewpoints can be used with a camera model when generating the images for a head-mounted display. In this case, however, precision requires that the optics of the display be accounted for, as described by Robinett and Holloway (1995). For example, the standard assumptions that each eye is centered on the image and that the display plane is perpendicular to the gaze direction are generally not quite correct.

The main assumption of the camera model is that the eye point is related to the display image by a constant offset. When the eye moves relative to the display, then the camera model no longer applies. This is the case for "fish tank" display configurations (Deering, 1992), which include desktop monitors and projected images on horizontal workbenches or on walls. For these configurations, the user model provides the position of the user's eye (or eyes, if a stereo image is displayed), and the location in the environment of the window that defines the view seen from each eye point. For example, the Java3D scene graph supports both HMD and fish tank display configurations by storing transformations in the PhysicalEnvironment, ViewPlatform, and Scene3D objects that relate the tracker reference frame (the "tracker base") to the displayed image. For HMD configurations, this relationship changes constantly. For fish tank configurations, it is constant. Regardless, the view is determined by the relationship between the screen and the eye point (which is controlled by the tracker that moves in the user model's tracker reference frame).

Following the philosophy that spatial objects in the user's environment should be represented by geometric objects in the coordinate system graph, the SVE user model includes a *Viewplane* object that represents the outline of the display. In SVE, a view is defined by one or two Eye objects, a Viewplane object, and the edges of the display, given in the coordinate system of the Viewplane object. Since the Eye objects and the Viewplane object are in the same coordinate system graph, they can be related spatially and determine the viewing parameters. Obviously, if the Viewplane and Eye are placed in the graph so that they can move independently, then this model can support fish tank display configurations as well as HMD configurations. In fact, since the Viewplane and the Eye can be moved independently of the tracker reference frame, the SVE user model supports a third display configuration: handheld displays (Rekimoto, 1997). In this configuration, the window to the virtual world is rendered to a handheld display that moves with the user's hand motions.

The Viewplane object is the representation of the projection plane for the default view of the environment and is placed in the coordinate system graph differently depending on the display configuration, as shown in Fig. 12.7c. For HMD configurations, the Viewplane object is positioned to correspond to the optical projection plane of the HMD (with window extent values that provide the correct vertical and horizontal field of view angles for the HMD) and is attached to the Head object. For fish-tank displays, the view plane represents the actual monitor screen in the real-world configuration. Therefore, the view plane does not move with the user's head but stays stationary in the user's reference frame. Thus, the Viewplane object is attached to the User or Workspace object. For fish tank displays, the view plane must be positioned

carefully so that the position difference, or disparity, between left and right views of an object is correct (objects at the view plane should have no disparity, whereas objects further in front of or behind the view plane should have larger disparities).

7. SUMMARY

Virtual environment applications present 3-D environments to a user that is located in the environment. In this chapter, a description of how the environment is defined in terms of three representations was provided. One representation defines the model in a file or set of files. The format of these files is designed to provide a concise, geometrically organized description of geometric primitives and simple behaviors. Another representation is used by the application at run time to modify the environment, effect behavior of the objects in the environment, and to make the environment react to user interactions. The final environment representation is an internal representation that, when possible, distills the description of the environment to the information that is strictly necessary for processing, and provides that information to a rendering system to produce the image for the display. Many of the techniques described in this chapter are given in terms of a visual result, but they could also be adapted to the presentation for other senses, such as sound and smells.

1. INTRODUCTION

Applications of virtual environments (VEs) are becoming increasingly interactive, allowing the user to not only look around a three-dimensional (3-D) world, but also to navigate the space, manipulate virtual objects, and give commands to the system. Thus, it is crucial that researchers and developers understand the issues related to 3-D interfaces and interaction techniques. In this chapter, the space of possible interaction techniques for several common tasks is explored and guidelines for their use in VE applications are offered. These guidelines are drawn largely from empirical research results.

1.1 Motivation

Interaction (communication between users and systems) in a 3-D VE can be extremely complex. Users must often control 6 degrees of freedom (DOFs) simultaneously, move in three dimensions, and give a wide array of commands to the system. To make matters worse, the standard and familiar input devices such as mice and keyboards are usually not present, especially in immersive VEs.

Meanwhile, VE applications are themselves becoming increasingly complicated. Once a technology only for interactively simple systems (those in which interaction is infrequent or lacks complexity) such as architectural walkthrough (Brooks et al., 1992) or phobia treatment (Hodges et al., 1995), VEs are now proposed for use in domains such as manufacturing, design, medicine, and education. These domains will require a much more active user, and therefore a more complex user interface.

One of the main concerns with the advent of these complex applications is interaction performance, defined broadly. Two aspects of performance will be considered in this chapter: task performance and technique performance with human effects. Task performance refers to

the quality of task completion, such as time for completion or accuracy. It is usually measured quantitatively. Technique performance refers to the qualitative experience of the user during interaction, including ease of use, ease of learning, and user comfort. These factors are all related to the concept of usability. The focus is on design of interaction techniques (ITs) that maximize performance and the use of such techniques in interactively complex VE applications. This is an extremely important topic. Since VEs support human tasks, it is essential that VE developers show concern for human performance issues when selecting interaction techniques and metaphors for their systems. Until recently, however, most VE interaction design was done in an ad hoc fashion, because little was known about the performance characteristics of VE interaction techniques. Here, a wide range of techniques for the most common VE tasks (travel, selection, manipulation, and system control) is presented. Perhaps more importantly, a large number of design guidelines are provided. These guidelines are taken, where possible, from published empirical evaluation of VE interaction techniques (and in many other cases from personal experience and observation of user interaction within VE applications), and are meant to give VE developers practical and specific ways to increase the interaction performance of their applications. The guidelines are summarized in Table 13.1.

1.2 Methodology

Many of the results in this chapter stem from the use of a particular methodology (Bowman & Hodges, 1999) for the design, evaluation, and application of interaction techniques, with the goal of optimizing performance. In order to understand the context in which the guidelines presented here were developed, the parts of this methodology relating to design are briefly discussed.

Principled, systematic design and evaluation frameworks (e.g., Price, Baecker, & Small, 1993) give formalism and structure to research on interaction, rather than relying solely on experience and intuition. Formal frameworks provide not only a greater understanding of the advantages and disadvantages of current techniques, but also better opportunities to create robust and well-performing new techniques, based on the knowledge gained through evaluation. Therefore, several important design and evaluation concepts are elucidated in the following sections.

1.2.1 *Initial Evaluation*

The first step toward formalizing the design of interaction techniques is to gain an intuitive understanding of the tasks involved with VE interaction and current techniques available for these tasks. This is accomplished through experience using ITs and through observation and evaluation of groups of users. Often in this phase, informal user studies or usability tests are performed in which users are asked what they think of a particular technique or observed trying to complete a given task with the technique under study. These initial evaluation experiences are drawn upon heavily for the process of creating taxonomies and categorizations of interaction techniques (see section 1.2.2). It is helpful to gain as much experience of this type as possible so that informed decisions can be made in the next phase of formalization.

1.2.2 *Taxonomy and Categorization*

The next step in creating a formal framework for design and evaluation is to establish a *taxonomy* of interaction techniques for each interaction task (i.e., travel, selection, manipulation, and system control; see Fig. 13.1). Such taxonomies partition the tasks into separable subtasks, each of which represents a decision that must be made by the designer of a technique. Some of these subtasks are related directly to the task itself, whereas others may only be

TABLE 13.1
Summary of Guidelines for the Design of VE Interaction Techniques

<i>Generic Guidelines (sec. 3)</i>	<i>Travel Guidelines (sec. 4.1.2)</i>	<i>Selection Guidelines (sec. 4.2.2)</i>	<i>Manipulation Guidelines (sec. 4.3.2)</i>	<i>System Control Guidelines (sec. 4.4.5)</i>
Practice user-centered design and follow well-known general principles from HCI research.	Make travel tasks simple by using target-based techniques.	Use the natural virtual-hand technique if all selection is within arm's reach.	Reduce the number of degrees of freedom to be manipulated if the application allows it.	Reduce the necessary number of commands in the application.
Use HMDs or SIDs when immersion within a space is a performance requirement. Use workbench displays when viewing a single object or set of objects from a third-person point of view.	If steering techniques are used, train users in strategies to acquire survey knowledge. Use target-based or route-planning techniques if spatial orientation is required but training is not possible.	Use ray-casting techniques if speed of remote selection is a requirement.	Provide general or application-specific constraints or manipulation aids.	When using virtual menus, avoid submenus and make selection at most a 2-D operation.
In SIDs, design the system to minimize the amount of indirect rotation needed.	Avoid the use of teleportation; instead, provide smooth transitional motion between locations.	Ensure that the chosen selection technique integrates well with the manipulation technique to be used.	Allow direct manipulation with the virtual hand instead of using a tool.	Indirect menu selection may be more efficient over prolonged periods of use.
Use an input device with the appropriate number of degrees of freedom for the task.	Use physical head motion for viewpoint orientation if possible.	Consider multimodal input for combined selection and command tasks.	Avoid repeated, frequent scaling of the user or environment.	Voice and gesture-based commands should include some method of reminding the user of the proper utterance or gesture.
Allow two-handed interaction for more precise input relative to a frame of reference.	Use non-head-coupled techniques for efficiency in relative motion tasks. If relative motion is not important, use gaze-directed steering to reduce cognitive load.	If possible, design the environment to maximize the perceived size of objects.	Use indirect depth manipulation for increased efficiency and accuracy.	Integrate system control with other interaction tasks.
Use absolute devices for positioning tasks and relative devices for tasks to control the rate of movement.	Consider integrated travel and manipulation techniques if the main goal of viewpoint motion is to maneuver for object manipulation.			
Take advantage of the user's proprioceptive sense for precise and natural 3-D interaction.	Provide wayfinding and prediction aids to help the user decide where to move, and integrate those aids with the travel technique.			
Use well-known 2-D interaction metaphors if the interaction task is inherently one- or two-dimensional.				
Use physical props to constrain and disambiguate complex spatial tasks.				
Provide redundant interaction techniques for a single task.				

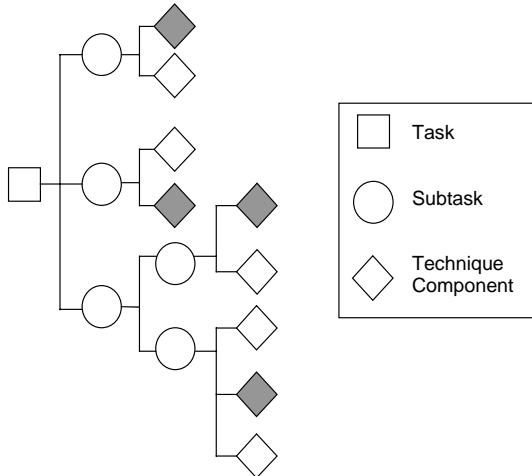

FIG. 13.1. General taxonomy format.

important as extensions of the metaphor on which the technique is based. In this sense, a taxonomy is the product of a careful task analysis. Once a task has been broken down to a sufficiently fine-grained level, listing possible methods (technique components) for accomplishing each of the lowest level subtasks completes the taxonomy. An interaction technique is made up of one technique component from each of the lowest level subtasks, such as the shaded components in Fig. 13.1.

Ideally, the taxonomies established for universal tasks need to be correct, complete, and general. Any IT that can be conceived for the task should fit within the taxonomy. Thus, the subtasks will necessarily be abstract. The taxonomy will also list several possible technique components for each of the subtasks but will not claim to list each conceivable component. For example, in an object-coloring task, a taxonomy might list touching the virtual object, giving a voice command, or choosing an item in a menu as choices for the color application subtask. However, this does not preclude a technique that applies the color by some other means, such as pointing at the object.

One way to verify the generality of taxonomies is through the process of *categorization*—defining existing ITs within the framework of the taxonomy. If existing techniques for the task fit well into a taxonomy, one can be surer of its correctness and completeness. Categorization also serves as an aid to evaluation of techniques. Fitting techniques into a taxonomy makes explicit their fundamental differences, thus the effect of choices can be determined in a more fine-grained manner.

1.2.3 Guided Design

Taxonomies and categorization are good ways to understand the low-level makeup of ITs and to formalize the differences between them, but once they are in place, they can also be used in the design process. A taxonomy can be thought of not only as a classification but also as a design space. In other words, a taxonomy informs or guides the design of new ITs for the task, rather than relying on a sudden burst of insight.

Since a taxonomy breaks a task down into separable subtasks, a wide range of designs can be considered quite quickly, simply by trying different combinations of technique components for each of the subtasks. There is no guarantee that a given combination will make sense as a complete interaction technique, but the systematic nature of the taxonomy makes it easy to generate designs and to reject inappropriate combinations.

Categorization may also lead to new design ideas. Placing existing techniques into a design space allows designers to see “holes” that are left behind—combinations of components that have not yet been attempted. One or more of the holes may contain a novel, useful technique for the task at hand. This process can be extremely useful when the number of subtasks is small enough and the choices for each of the subtasks are clear enough to allow a graphical representation of the design space, as this makes the untried designs quite obvious (Card, Mackinlay, & Robertson, 1990).

1.3 Universal Interaction Tasks

What user tasks need to be supported in immersive VEs? At first glance, there appear to be an extremely large number of possible user tasks—too many, in fact, to think about scientific design and evaluation for all of them. However, as Foley (1979) has argued for two-dimensional (2-D) interaction, there is also a set of “universal” tasks (simple tasks that are present in most applications, which can be combined to form more complex tasks) for 3-D interfaces. These universal tasks include *navigation*, *selection*, and *manipulation*.

Navigation refers to the task of moving the viewpoint within a 3-D space, and includes both a cognitive component (wayfinding), and a motor component (travel, also called viewpoint motion control; see chap. 24, this volume). Selection refers to the specification of one or more objects from a set. Finally, manipulation refers to the modification of various object attributes (including position and orientation, and possibly scale, shape, color, texture, or other properties). Selection may be used on its own to specify an object to which a command will be applied (e.g., “delete the selected object”), or it might denote the beginning of a manipulation task.

These simple tasks are the building blocks from which more complex interactions arise. For example, the user of a surgery simulator might have the task of making an incision. This task might involve approaching the operating table (navigation), picking up a virtual scalpel (selection), and moving the scalpel slowly along the desired incision line (manipulation). One class of complex tasks, *system control*, involves the user giving commands to the system. For example, this might be accomplished by bringing a virtual menu into view (manipulation) and then choosing a menu item (selection). However, system control is so ubiquitous in VE applications that the design of system control techniques can be considered separately.

This chapter is targeted at developers and researchers who produce complete VE applications. It provides background information, a large set of potential techniques for universal interaction tasks, and guidelines to help in the choice of an existing technique or the design of a new technique for a particular system. Use of these guidelines should lead to more usable, useful, efficient, and effective virtual environments.

1.4 Performance Requirements

In order to determine whether or not a VE interaction technique exhibits good performance, metrics must be defined that capture performance. Metrics allow the performance of a technique to be quantified, the performance of competing techniques compared, and the interaction requirements of an application specified. Listed below are some (but certainly not a complete set) of the most common performance metrics for VE interaction, including metrics for task performance and technique performance. For each individual interaction task, the metrics may have slightly different meanings.

1. *Speed*. This refers to the classic quantifier of performance: task completion time. This efficiency metric will undoubtedly be important for many tasks, but should not be the only measurement considered.

2. *Accuracy.* Accuracy is a measurement of the exactness with which a task is performed. For travel or manipulation tasks, this will likely be measured by the distance of the user or object from the desired position or path. For selection, one might measure the number of errors that were made. Often, required accuracy is held constant in experiments while speed is measured, but the speed/accuracy trade-off should be fully explored, if possible.

3. *Spatial awareness.* A user's spatial awareness is related to his knowledge of the layout of a space and his own position and orientation within it. This may be an important performance requirement in large, highly occluded, or complex virtual environments. Most often, movement within the space (travel) affects spatial awareness, but other interaction tasks may also affect this metric.

4. *Ease of learning.* This is commonly discussed in the human-computer interaction (HCI) community, and refers to the ease with which a novice user can comprehend and begin to use a technique. It may be measured by subjective ratings, or the time for a novice to reach some level of performance, or by characterizing the performance gains by a novice as exposure time to the technique increases.

5. *Ease of use.* This is another HCI concept that may be difficult to quantify. It refers to the simplicity of a technique from the user's point of view. In psychological terms, this may relate to the amount of cognitive load induced upon the user of the technique. This metric is usually obtained through subjective self-reports, but measures of cognitive load may also indicate ease of use.

6. *Information gathering.* One of the goals of many immersive VEs is for the user to obtain information from or about the environment while in it. The choice of interaction techniques may affect the user's ability to gather information, and so measurement of this ability can be seen as an aspect of technique performance.

7. *Presence.* Another goal of VEs is to induce a feeling of presence ("being there," or immersion within the space) in users (see chap. 40, this volume). This quality is purported to lend more realism to a VE system, which may be desirable in systems for entertainment, education, or simulation. Presence may be affected by the interaction techniques in a system. It is usually measured by subjective reports and questionnaires (Slater, Usoh, & Steed, 1994; Witmer & Singer, 1998).

8. *User comfort.* Most of the interaction techniques discussed herein require activity on the part of the user (e.g., moving the arm, turning the head). It is important in systems that require a moderate to long exposure time that these motions do not cause discomfort in the user. Discomfort can range from classic simulator sickness to eye strain to hand fatigue and so on (see chaps. 29–32, this volume). Although VEs in general may induce some level of discomfort, this may be increased or decreased depending on the interaction techniques and input devices chosen. Comfort measurements are usually user self-reports (Kennedy et al., 1993).

9. *Expressiveness.* Virtual environment interaction techniques may be general in nature or quite domain-specific. The choice depends in part on the system's need for expressiveness. Expressiveness refers to the generality and flexibility of use of a given technique. For example, a travel technique that allows 3-D flying is more expressive than one that restricts the user to 2-D movement on a ground plane. Increased expressiveness is not always desirable because constraints can help to guide a user's actions. It is important for each application to carefully specify the level of expressiveness needed for a given interaction task.

10. *Unobtrusiveness.* An interaction technique is obtrusive if it interferes with the user's ability to focus on the task at hand. This metric will be most important for applications that

have repeated and frequent use of the same interaction technique. Such a technique will be required to be unobtrusive so users do not become quickly frustrated.

11. *Affordance*. Finally, a technique's performance can be described by the affordances that it presents for a task. An affordance (Norman, 1990) is simply a characteristic of a technique or tool that helps the user understand what the technique is to be used for and how it is to be used. For example, voice commands in general have little affordance because the user must know what the commands are. Listing the available commands on screen is an affordance that aids the user. Like expressiveness and unobtrusiveness, affordance is an innate characteristic of a technique that is not easily measured. Nonetheless, it must be taken into consideration when choosing techniques for a VE application.

2. NATURALISM VERSUS MAGIC

A common misconception about VEs is that, in order to be effective, they should work exactly the way the real world works, or at least as close as is practically possible (interaction with a VE application should be “natural”). The very term *virtual reality* promotes such a view—that virtual reality should be the same as “real reality.” In fact, this is not always the case. It may be very useful to create VEs that operate quite differently from the physical world.

In chapter 11 (this volume), locomotion devices for VEs are discussed. These devices usually strive to reproduce a realistic or natural mode of travel. There are several advantages to such techniques. Natural mappings are present, so users can easily perform tasks based on principles they are familiar with from daily life. Also, this simulation of the physical world may create a greater sense of immersion or presence (see chap. 40, this volume) in the virtual world. Finally, realism may enhance the user experience.

However, there is an alternative to the naturalistic approach, which we'll call “magic” (Smith, 1987). In this approach, the user is given new abilities, and non-natural methods for performing tasks are used. Examples include allowing the user to change his scale (grow or shrink), providing the user with an extremely long arm to manipulate faraway objects, or letting the user fly like a bird. Magic techniques are less natural, and thus may require more explanation or instruction, but they can also be more flexible and efficient if designed for specific interaction tasks.

Clearly, there are some applications that need naturalism. The most common example is training, in which users are trained in a VE for tasks that will be carried out in a physical environment. Such applications have the *requirement* of natural interaction. On the other hand, applications such as immersive architectural design do not require complete naturalism—the user only has the goal of completing certain tasks, and the performance requirements of the system do not include naturalism.

This discussion focuses on techniques involving some magic or nonrealism, in the interest of optimizing performance. Such techniques may enhance the user's physical, perceptual, or cognitive abilities, and take advantage of the fact that the VE can operate in any definable fashion. No possible techniques are excluded from consideration as long as they exhibit desirable performance characteristics (task and technique performance).

3. GENERIC VE INTERACTION GUIDELINES

When attempting to develop guidelines that will produce high-performance VE interaction, both generic guidelines that inform interaction design at a high level, and specific guidelines for

common tasks (i.e., travel, selection, manipulation, and system control) should be considered. The next two sections will cover these areas. The guidelines presented in this section are not intended to be exhaustive, but are limited to those that are especially relevant to enhancing performance and those that have been verified through formal evaluation. A large number of VE-specific usability guidelines can be found in Gabbard and Hix (1998).

3.1 Existing HCI Guidelines

The first thing to remember when developing interaction for VEs is that interaction is not new. The field of HCI has its roots in many areas, including perceptual and cognitive psychology, graphic design, and computer science, and has a long history of design and evaluation of 2-D computer interfaces. Through this process, a large number of general-purpose guidelines have been developed that have wide applicability to interactive systems, and not just the standard desktop computer applications with which everyone is familiar. This existing knowledge and experience can be leveraged in interaction design of virtual environments. If VE design does not meet these most basic requirements, then VE systems are sure to be unusable. Furthermore, the application of HCI principles to VEs may lead to VE-specific guidelines as well. These guidelines are well-known, if not always widely practiced, so they are not reviewed in detail here.

Practice user-centered design and follow well-known general principles from HCI research.

Two important sources for such general guidelines are Donald Norman's *The Design of Everyday Things* (Norman, 1990) and Jakob Nielsen's usability heuristics (Nielsen & Molich, 1992). These guidelines focus on high-level and abstract concepts such as making information visible (how to use the system, what the state of the system is, etc.), providing affordances and constraints, using precise and unambiguous language in labeling, designing for both novice and expert users, and designing for prevention of and recovery from errors.

Following such guidelines should lead to a more understandable, efficient, and usable system. However, because of their abstract nature, applying these principles is not always straightforward. Nevertheless, they must be considered as the first step toward a usable system.

3.2 Choice of Devices

A basic question one must ask when designing a VE system regards the choice of input and output devices to be used. Currently, little empirical data exists about relative interaction performance, especially for VE display devices. There are, however, a few general guidelines that can be posited here.

3.2.1 Display Devices

Three common VE display devices, as described in chapter 3 (this volume), are head-mounted displays (HMDs), spatially immersive displays (SIDs, semisurrounding projected stereo displays, such as the CAVETM), and desktop stereo displays, such as the Responsive Workbench. These display types have very different characteristics, and interaction with these displays is likely to be extremely different as well.

Use HMDs or SIDs when immersion within a space is a performance requirement.

Use workbench displays when viewing a single object or set of objects from a third-person point of view.

These two guidelines are based on the essential difference between display types. HMDs and SIDs encourage an egocentric, inside-out point of view, and are therefore appropriate for first-person tasks such as walk-throughs or first-person gaming. Workbench displays support

an outside-in point of view and therefore work well for third-person tasks such as manipulating a single object or arranging military forces on a 3-D terrain near the surface of the workbench. If objects are spatially located near to the user in a SID or workbench setup, however, there may be problems involving the user's hand occluding objects that should actually be in front of the hand.

In SIDs, design the system to minimize the amount of indirect rotation needed.

Most projected VEs do not completely surround the user. For example, a standard CAVE configuration places graphics on four surfaces of a six-sided cube (floor and three walls). Thus, the ceiling and back wall are not displayed. This means that for users to view parts of the VE directly behind or above them, they must rotate the environment indirectly, using some input device (e.g., pressing a button to rotate the scene 90 degrees rather than simply turning her head). In an application in which immersion is important, this indirect rotation will likely break the illusion of presence within the space to some degree. Recent research (Bakker, Werkhoven, & Passenier, 1998; Chance, Gaunet, Beall, & Loomis, 1998) has shown that physical turning produces better estimates of turn magnitude and direction to objects (indicating superior spatial orientation) than does indirect turning. One way to alleviate this problem is to adopt a vehicle metaphor for navigation so that the user is always facing the front wall and using the side walls for peripheral vision. With a steering wheel for choosing vehicle direction, indirect rotation seems much more natural. Note that fully immersive SIDs, such as a six-sided cube or spherical dome, do not suffer from this problem.

3.2.2 Input Devices

Input devices and their differences have been studied more extensively than display differences. Common VE input devices include 6-DOF trackers, continuous posture-recognition gloves, discrete event gloves, penlike devices, simple button devices, and special-purpose devices such as the Spaceball or force-feedback joysticks.

Use an input device with the appropriate number of degrees of freedom for the task.

Many inherently simple tasks become more complex if an improper choice of input device is made. For example, toggling a switch is inherently a 1-degree-of-freedom task (the switch is on or off). Using an interaction technique which requires the user to place a tracked hand within a virtual button (a 3-DOF task) makes it overly complex. A simple discrete event device, such as a pinch glove, makes the task simpler. Of course, one must trade off the reduced degrees of freedom with the arbitrary nature of the various actions the user must learn when using a pinch glove or other such device. In general, designers should strive to reduce unnecessary DOFs when it is practical (Hinckley, Pausch, Goble, & Kassell, 1994). If only a single input device is available, software constraints can be introduced to reduce the number of DOFs the user must control (see section 4.3.2).

Use physical props to constrain and disambiguate complex spatial tasks.

This guideline is related to the previous discussion about degrees of freedom. Physical props can help to reduce the number of DOFs that the user must control. For example, the pen-and-tablet interaction metaphor (Bowman, Wineman, Hodges, & Allison, 1998) uses a physical tablet (a 2-D surface) and a tracked pen. A 2-D interface is virtually displayed on the surface of the tablet, for tasks such as button presses, menu selection, and 2-D drag and drop (see Fig. 13.2). The physical props allow the user to do these tasks precisely, because the tablet surface guides and constrains the interaction to two dimensions.

Physical props can also make complex spatial visualization easier. For example, in the Netra system for neurosurgical planning (Goble, Hinckley, Pausch, Snell, & Kassell, 1995), it was found that surgeons had difficulty rotating the displayed brain data to the correct orientation when a simple tracker was used to control rotation. However, when the tracker was embedded

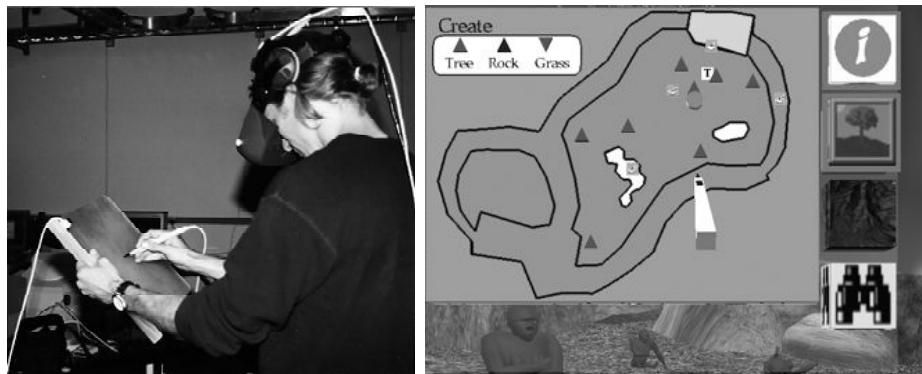

FIG. 13.2. Physical (*left*) and virtual (*right*) views of a pen-and-tablet system.

within a doll's head, the task became much easier because the prop gave orientation cues to the user.

Use absolute devices for positioning tasks and relative devices for tasks to control the rate of movement.

This guideline is well-known in desktop computing, but not always followed in virtual environments. Absolute positioning devices such as trackers will work best when their position is mapped to the position of a virtual object. Relative devices (devices whose positional output is relative to a center position that can be changed), such as joysticks, excel when their movement from the center point is mapped to the rate of change (velocity) of an object, usually the viewpoint. Interaction techniques which use absolute devices for velocity control or relative devices for position control will perform less efficiently and easily. Zhai (1993) has extended this idea by comparing isometric and isotonic devices in a 3-D-manipulation task.

3.3 Interacting in Three-dimensional Space

By its very nature, 3-D (also called spatial) interaction is qualitatively and quantitatively different than standard 2-D interaction. As discussed in the previous section, the choice of 3-D input devices can be quite important, but there are also other general principles related to the way 3-D interaction is implemented in software.

Take advantage of the user's proprioceptive sense for precise and natural 3-D interaction.

Proprioception is a person's sense of the location of the parts of his body, no matter how the body is positioned. For example, a driver can easily change gears without looking, because of his knowledge of his body and hand position relative to the gearshift. Mine, Brooks, and Sequin (1997) discuss how to take advantage of this sense in VEs by providing body-centered interactions. One possibility is to give users a virtual tool belt on which various tools (e.g., pointer, cutting plane, spray paint, etc.) can be hung. Because users know where the various tools are located on their body, they can interact and choose tools much more efficiently and easily without looking away from their work.

Use well-known 2-D interaction metaphors if the interaction task is inherently one- or two-dimensional.

It seems to be an unspoken rule among VE application developers that interaction techniques should be new and unique to virtual environments. This is as much a myth as the concept discussed earlier that all interaction should mimic the real world. In fact, there are many 2-D interaction metaphors that can be used directly in or adapted for use in virtual environments. Pull-down or pop-up menus, 2-D buttons, and 2-D drag-and-drop manipulation have all been

implemented in VEs with success (e.g., Bowman, Hodges, & Bolter, 1998). With these interaction techniques, issues related to reducing the number of DOFs the user must control often arise. When 2-D interaction metaphors are used, the provision of a 2-D surface for interaction (such as the pen-and-tablet metaphor discussed above) can increase precision and efficiency.

Allow two-handed interaction for more precise input relative to a frame of reference.

Most VE interfaces “tie one hand behind the user’s back,” allowing only input from a single hand. This severely limits the flexibility and expressiveness of input. By using two hands in a natural manner, the user can specify arbitrary spatial relationships, not just absolute positions in space. However, it should not be assumed that both hands will be used in parallel to increase efficiency. Rather, the most effective two-handed interfaces are those in which the nondominant hand provides a frame of reference in which the dominant hand can do precise work (Hinckley, Pausch, Profit, Patten, & Kassell, 1997).

Provide redundant interaction techniques for a single task.

One of the biggest problems facing evaluators of VE interaction is that the individual differences in user performance seem to be quite large relative to 2-D interfaces. Some users seem to comprehend complex techniques easily and intuitively, whereas others may never become fully comfortable. Work on discovering the human characteristics that cause these differences is ongoing, but one way to mitigate this problem is to provide multiple interaction techniques for the same task. For example, one user may think of navigation as specifying a location within a space and therefore would benefit from the use of a technique where the new location is indicated by pointing to that location on a map. Another user may think of navigation as executing a continuous path through the environment and would benefit from a continuous steering technique. In general, “optimal” interaction techniques may not exist even if the user population is well-known, so it may be appropriate to provide two or more techniques, each of which have unique benefits. Of course, the addition of techniques also increases the complexity of the system, and so this must be done with care and only when there is a clear benefit.

4. TECHNIQUES AND GUIDELINES FOR COMMON VE TASKS

4.1 Travel

Travel, also called viewpoint motion control, is the most ubiquitous and common VE interaction task—simply the movement of the user within the environment. Travel and wayfinding (the cognitive process of determining one’s location within a space and how to move to a desired location—see chap. 24, this volume) make up the task of navigation. Chapter 11 (this volume) presents locomotion interface devices, which are physical devices supporting travel tasks, so in this section the focus is on passive movement, in which the user remains physically stationary while moving through the virtual space.

There are three primary tasks for which travel is used within a virtual environment. *Exploration* is travel which has no specific target, but which is used to build knowledge of the environment or browse the space. *Search tasks* have a specific target, whose location may be completely unknown (naïve search) or previously seen (primed search). Finally, *maneuvering tasks* refer to short, precise movements with the goal of positioning the viewpoint for another type of task, such as object manipulation. Each of these three types of tasks may require different travel techniques to be most effective, depending on the application.

4.1.1 Technique Classifications

Because travel is so universal, a multitude of techniques have been proposed (see Mine [1995] for a survey of early techniques). Many techniques have similar characteristics, so it

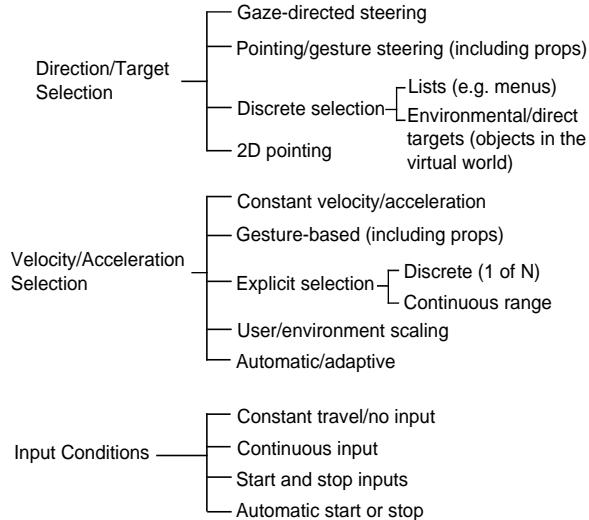

FIG. 13.3. Taxonomy of passive, first-person travel techniques.

will be useful to present classifications of techniques rather than discussing each technique separately.

A simple taxonomy of passive movement techniques was described in Bowman, Koller, and Hodges (1997) and is reproduced in Fig. 13.3. This taxonomy partitions a travel task into three subtasks: direction or target selection, velocity and/or acceleration selection, and conditions of input (specifying the beginning and end of movement).

Most techniques differ only in the direction or target specification subtask, and several common technique components are listed in the taxonomy. Gaze-directed steering uses the orientation of the head for steering, whereas pointing gets this information from the user's hand. The orientation of other body parts, such as the torso or foot, could also be used. Physical devices, such as a steering wheel, provide another way to specify direction. Other techniques specify only a target of motion, by choosing from a list, entering coordinates, pointing to a position on a map, or pointing at the target object in the environment.

The velocity/acceleration selection subtask has been studied much less than direction or target selection, but several techniques have been proposed. Many systems simply default to a reasonable constant velocity. Gesture-based techniques use hand or body motions to indicate velocity or acceleration (e.g., speed depends on the distance of the hand from the body). Again, physical props such as accelerator and brake pedals can be used. Velocity or acceleration could be chosen discretely from a menu. Finally, velocity and acceleration may be automatically controlled by the system in a context-sensitive fashion (e.g., depending on the distance from the target or the amount of time the user has been moving; Mackinlay, Card, & Robertson, 1990).

The conditions of input may seem trivial, but this simple subtask can have an effect on performance. Generally, the user simply gives a single input, such as a button press, to begin moving, and another to stop moving. There may also be situations when it is appropriate for the system to automatically begin and/or end the motion, or when the user should be moving continuously.

Another way to classify travel techniques relates to the amount of control that the user has over viewpoint motion. *Steering techniques* give the user full control of at least the direction of motion. These include continuous steering, such as gaze-directed or pointing techniques, and

discrete steering, such as a ship steering technique in which verbal commands are interpreted to give the user control of the ship's rudders and engines (William Walker, personal communication, 1999). On the other end of the control spectrum, *target-based techniques* only allow the user to specify the goal of the motion, whereas the system determines how the viewpoint will move from the current location to the target. This requires the use of a selection technique (see section 4.2). *Route-planning techniques* represent a middle ground. Here the user specifies a path between the current location and the goal, and then the system executes that path. This might be implemented by drawing a path on a map of the environment or placing markers using some manipulation technique and having the system interpolate a spline between these control points.

Finally, there is a class of techniques that do not fit well into the above classifications that use manual manipulation to specify viewpoint motion. Ware and Osborne (1990) identified the "camera in hand" metaphor, where the user's hand motion above a map or model of the space specifies the viewpoint from which the scene will be rendered, and the "scene in hand" metaphor, in which the environment itself is attached to the user's hand position. Both of these techniques are exocentric in nature, but manual viewpoint manipulation can also be done from a first-person perspective. Any direct object manipulation technique (see section 4.3) can be modified so that the user's hand movements affect the viewpoint instead of the selected object. The selected object remains fixed in the environment, and the user moves around that object using hand motions. Such a technique might be extremely useful for maneuvering tasks where the user is constantly switching between travel and manipulation.

4.1.2 Guidelines for Designing Travel Techniques

Make simple travel tasks simple by using target-based techniques.

If the goal of travel is simply to move to a known location, such as moving to the location of another task, target-based techniques provide the simplest metaphor for the user to accomplish this task. In many cases, the exact path of travel itself is not important; only the goal is important. In such situations, target-based techniques make intuitive sense and leave the user's cognitive and motor resources free to perform other tasks. The use of target-based techniques assumes that the desired goal locations are known in advance or will always coincide with a selectable position in the environment. If this is not true (e.g., the user wishes to obtain a bird's-eye view of a building model), target-based techniques will not be appropriate. Users of these techniques should also pay attention to the guideline regarding teleportation below.

Use physical head motion for viewpoint orientation if possible.

Almost all immersive VE systems use head tracking to render the scene from the user's point of view. Since viewpoint motion control involves both viewpoint position and orientation, it makes sense to use the head tracking information for setting viewpoint orientation. However, in certain applications, especially those in which the user is seated, it might be tempting to specify viewpoint orientation indirectly, for example, by using a joystick. It has been shown (Chance, Gaunet, Beall, & Loomis, 1998) that such indirect orientation control, which does not take advantage of proprioception, has a damaging effect on the spatial orientation of the user. Therefore, when it is important for the user to understand the spatial structure of the environment, physical head motion should always be used.

Avoid the use of teleportation; instead, provide smooth transitional motion between locations.

Teleportation, or "jumping," refers to a target-based travel technique in which velocity is infinite, that is, the user is moved immediately from the starting position to the target. Such a technique seems very attractive from the perspective of efficiency. However, empirical results (Bowman et al., 1997) have shown that disorientation results from teleportation techniques.

Interestingly, all techniques that used continuous smooth motion between the starting position and the target caused little disorientation in this experiment, even when the velocity was relatively high. This effect may be lessened if a common reference, such as a map or World-in-Miniature showing the current position is used, but even with these techniques smooth transitional motion is recommended, if practical.

If steering techniques are used, train users in strategies to acquire survey knowledge. Use target-based or route-planning techniques if spatial orientation is required but training is not possible.

Spatial orientation (the users' spatial knowledge of the environment and their position and orientation within it) is critical in many large-scale VEs, such as those designed to train users about a real-world location. The choice of interaction techniques can affect spatial orientation. In particular, evaluation (Bowman, Davis, Hodges, & Badre, 1999) has shown that good spatial orientation performance can be obtained with the use of steering techniques, such as pointing in the desired direction of motion, where the user has the highest degree of control. Steering techniques only produce high spatial orientation, however, if sophisticated strategies are used (e.g., flying above the environment to obtain a survey view, moving in structured patterns). If such strategies are not used, steering techniques may actually perform worse, because users are concentrating on controlling motion rather than viewing the environment. Techniques where the user has less control over motion, such as target-based and route-planning techniques, provide moderate levels of spatial orientation due to the low cognitive load they place on the user during travel—the user can take note of spatial features during travel because the system is controlling motion.

Consider integrated travel and manipulation techniques if the main goal of viewpoint motion is to maneuver for object manipulation.

Manual viewpoint manipulation techniques use object manipulation metaphors (see section 4.3) to specify viewpoint position. Such techniques have been shown experimentally (Bowman, Johnson, & Hodges, 1999) to perform poorly on general travel tasks such as exploration and search. However, such techniques may prove quite useful if the main goal of travel is to maneuver the viewpoint during object manipulation. Manual viewpoint manipulation allows the use of the same technique for both travel and object manipulation tasks, which may be intermixed quite frequently in applications requiring complex manipulation.

Use non-head-coupled techniques for efficiency in relative motion tasks. If relative motion is not important, use gaze-directed steering to reduce cognitive load.

Relative motion is a common VE task in which the user wishes to position the viewpoint at a location in space relative to some object. For example, an architect wishes to view a structure from the proposed location of the entrance gate, which is a certain distance from the front door—movement must be relative to the door and not to any specific object. A comparison of steering techniques (Bowman et al., 1997) showed that a pointing technique performed much more efficiently on this task than gaze-directed steering. This is because pointing allows the user to look at the object of interest while moving, whereas gaze-directed steering forces the user to look in the direction of motion. Gaze-directed steering performs especially badly when motion needs to be away from the object of interest. Thus, techniques that are not coupled to head motion support relative-motion tasks. Non-head-coupled techniques include not only steering techniques such as pointing, but also manipulation-based techniques. For example, a technique in which the user grabs the object of interest then uses hand motion to move the viewpoint about it was shown to produce very efficient performance on a relative motion task in a small unpublished user study performed by the author. On the other hand, gaze-directed steering is slightly less cognitively complex than either pointing or manipulation techniques, so it may still be useful if relative motion is not an important task in an application.

Provide wayfinding and prediction aids to help the user decide where to move, and integrate those aids with the travel technique.

The design of interaction techniques for travel assumes that the user knows where to go and how to get there, but this is not always the case. Wayfinding aids (e.g., Darken, 1996) may be needed, especially in large-scale VEs where the user is expected to build survey knowledge of the space. Such aids include maps, signposts, compass markings, and paths. During travel, the user may need to know whether the current path will take them to the desired location. Predictor displays (Wickens, Haskell, & Harte, 1989) have long been used in aircraft simulation to show the pilot the result of the current heading, pitch, and speed. Such displays might also be useful in other VEs that involve high-speed 3-D motion.

4.2 Selection

Selection is simply the task of specifying an object or set of objects for some action. Most often, selection precedes object manipulation (see section 3.3), or specifies the object of some command (see section 3.4), such as “delete the selected object.” In interactively complex VEs, selection tasks occur quite often, and therefore efficiency and ease of use are important performance requirements for this task.

4.2.1 Technique Classifications

The most obvious VE selection technique is again the one that mimics real-world interaction—simply touching the desired object with a virtual hand. Within this general metaphor, there are several possible implementations, however. The virtual hand could simply be a rigid object controlled by a single 6-DOF tracker, or it could be controlled by a glove that recognizes a multitude of different hand postures for more precision. Another issue relates to the precision of selection. Can the user only select at the object level, or can specific points on an object’s surface be selected? Finally, there is the issue of selection feedback. Most systems present simple graphical (e.g., highlight the object) or audio feedback to indicate touching, but haptic feedback (see chaps. 5 and 6) more closely simulates real-world touching and allows the user to select objects without looking at them.

No matter how implemented, this simple virtual hand metaphor suffers from a serious problem: The user can only select objects in the VE that are actually within arms reach. In many large-scale VEs, especially in the design or prototyping application domains, the user will wish to select remote objects—those outside of the local area surrounding the user. Therefore, a number of “magic” techniques have been developed for object selection. These fall into two main categories: arm extension and ray casting.

Arm-extension techniques still use a virtual hand to select objects via touching, but the virtual hand has a much greater range than the user’s physical hand. The simplest example is a technique that linearly maps the physical hand movements onto the virtual hand movements, so that for each unit the physical hand moves away from the body, the virtual hand moves away N units. The Go-Go technique (Poupyrev, Billinghurst, Weghorst, & Ichikawa, 1996) takes a more thoughtful approach. It defines a radius around the user within which the physical hand is mapped directly to the virtual hand. Outside that radius, a nonlinear mapping is applied to allow the virtual hand to reach quite far into the environment, although still only a finite distance (see Fig. 13.4). Other techniques allow infinite arm extension, such as an indirect technique that uses two buttons to extend and retract the virtual hand. Such techniques are generally less natural and induce more cognitive load.

Ray-casting techniques move away from the object touching metaphor and instead adopt a pointing metaphor. A ray emanates from the user, with the user controlling its orientation

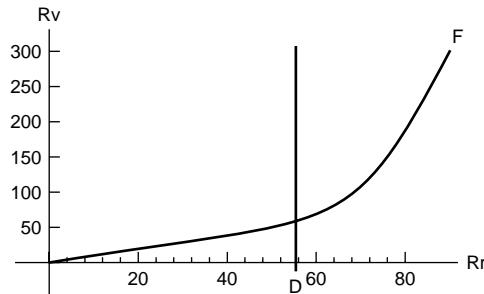

FIG. 13.4. Mapping function for Go-Go technique.

only, and the first object the ray intersects may be selected. The ray may be linear, or it may be cone-shaped so that small objects are more easily selected at a distance. The most common implementation of ray casting is to attach the ray to the user's virtual hand so that simple wrist movements allow pointing in any direction (Mine, 1995). Another class of techniques uses gaze direction for ray casting so that an object can be selected by placing it in the center of one's field of view. Finally, some techniques use a combination of eye position and hand position for selection (Pierce et al., 1997), with the ray emanating from the eye point and passing through the virtual-hand position (see Fig. 13.5). This is often called occlusion, or framing, selection.

Bowman and Hodges (1999) defined a taxonomy of selection techniques, which is presented at the top of Figure 13.6. Note that besides the subtask discussed thus far (indication of object), there are also feedback and indication to select subtasks. The latter refers to the event used to signal selection to the system, such as a button press, gesture, or voice command.

Finally, it should be noted that all of the techniques presented herein are designed for single-object selection only. Selection of multiple objects simultaneously has not been the subject of much research, but techniques from 2-D interfaces may work reasonably well in three dimensions. These include sequential selection with a modifier button pressed and rubberbanding, or "lassoing." Techniques such as rubberbanding, which must be extended to specify a 3-D volume, will present interesting usability challenges.

4.2.2 Guidelines for Designing Selection Techniques

Use the natural virtual hand technique if all selection is within arms reach.

The simple virtual-hand metaphor works well in systems where all interaction with objects is local. This usually includes VE applications implemented on a workbench display, where most objects lie on or above the surface of the table.

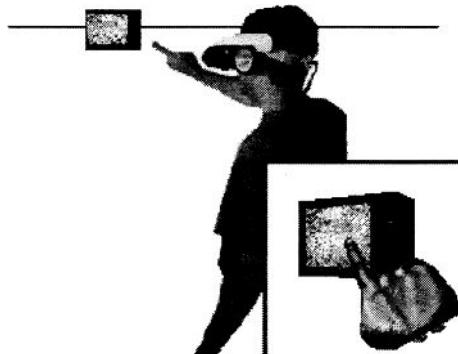

FIG. 13.5. Occlusion selection.

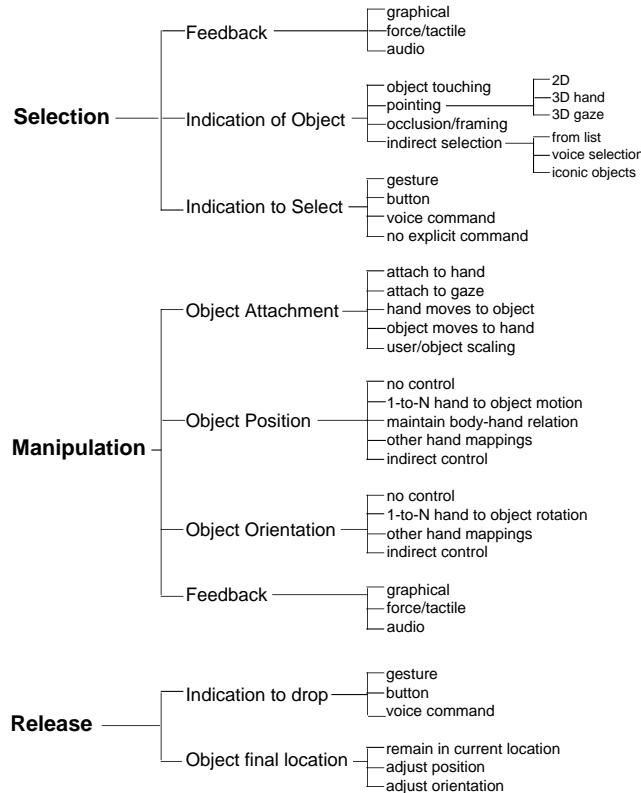

FIG. 13.6. Taxonomy of single-object selection and manipulation techniques.

Use ray-casting techniques if speed of remote selection is a requirement.

Evaluation (Bowman & Hodges, 1999) has shown that ray-casting techniques perform more efficiently than arm-extension techniques over a wide range of possible object distances, sizes, and densities. This is due to the fact that ray-casting selection is essentially 2-D (in the most common implementation, the user simply changes the pitch and yaw of the wrist).

Ensure that the chosen selection technique integrates well with the manipulation technique to be used.

Selection is most often used to begin object manipulation, and so there must be a seamless transition between the selection and manipulation techniques to be used in an application. Arm-extension techniques generally provide this transition, because the selected object is also manipulated directly with the virtual arm, and so the same technique is used throughout the interaction. As discussed below, however, it is possible to integrate ray-casting techniques with efficient manipulation techniques.

Consider multimodal input for combined selection and command tasks.

When selection is used in combination with system control tasks, it may be more efficient and natural to use multimodal interaction (Bolt, 1980; chap. 21, this volume). For example, one may point at an object and then give the voice command “Delete.”

If possible, design the environment to maximize the perceived size of objects.

Selection errors are affected by both the size and distance of objects, using either ray-casting or arm-extension techniques (Bowman & Hodges, 1999). These two characteristics can be combined in the single attribute of visual angle or the perceived size of an object in an image. Unless the application requires precise replication of a real-world environment,

manipulating the perceived size of objects will allow more efficient selection (Poupyrev, Weghorst, Billingham, & Ichikawa, 1997).

4.3 Manipulation

Manipulation goes hand in hand with selection. Manipulation refers broadly to modification of the attributes of the selected object. Attributes may include position, orientation, scale, shape, color, or texture. For the most part, research has only considered the manipulation of the position and orientation of rigid objects, although some special-purpose applications include object deformation or scaling. Object manipulation tasks have importance in such applications as design, prototyping, simulation, and entertainment, all which may require environments that can be modified by the user.

4.3.1 *Technique Classifications*

The most common object manipulation technique is a natural one, in which the selected object is rigidly attached to the virtual hand and moves along with it until some signal is given to release the object. This technique is simple and intuitive, but certain object orientations may require the user to twist the arm or wrist to uncomfortable positions, and it does not use the inherent dexterity of the user's fingers. Recent research, then, has focused on more precise and dexterous object manipulation using fingertip control (Kitamura, Yee, & Kishino, 1998). This can be simulated to a degree using a rigid virtual hand if a clutching mechanism is provided. Researchers have also proposed two-handed object manipulation techniques, which often use the nondominant hand as a reference (e.g., a pivot point for rotation) and the dominant hand for fine, precise manipulation.

As with selection, natural manipulation techniques suffer from limitations of reach. Also, manipulating large objects within arms reach may occlude the user's view. Therefore, techniques for remote manipulation are also important, and several categories of such techniques have been proposed.

Arm-extension and ray-casting selection techniques can also be used for object manipulation. Arm-extension metaphors simply attach the object to the virtual hand and allow the user to control it using physical-to-virtual hand mapping (Poupyrev et al., 1996). Ray-casting techniques may attach the object to the ray itself, which allows intuitive, but limited and imprecise, manipulation (Bowman & Hodges, 1997). Because ray casting is so efficient as a selection mechanism, several researchers have attempted to increase the utility of ray casting for manipulation. One idea is to select using ray casting and then move the virtual hand to the selected object for direct manipulation (Bowman & Hodges, 1997). Another set of techniques scales the user or the environment so that the virtual hand, which was originally far from the selected object, is actually touching this object so that it can be manipulated directly (Pierce et al., 1997).

Another metaphor, called the world-in-miniature (WIM, Stoakley, Conway, & Pausch, 1995), solves the remote object manipulation problem by giving the user a small handheld copy of the environment. Direct manipulation of the WIM objects causes the larger environment objects to move as well. This technique is usually implemented using a small 3-D model of the space, but a 2-D interactive map can also be considered a type of WIM.

All of the techniques in the preceding section can be implemented in a general way—that is, allow objects to be positioned and oriented anywhere in the space—but most applications will benefit from the addition of special manipulation aids and constraints. One way to do this is through the use of snapping or gridlines (Mine, 1995) such that objects can only end in a discrete number of positions or orientations, or line up with other objects. Physical simulation

can also be used, including gravity and impenetrable objects, so that manipulation results in a realistic configuration of objects. Physical simulation may be compute-intensive, however. Finally, objects themselves can be given intelligence (Bukowski & Sequin, 1995) so that coffee cups rest on their bottom surface and paintings hang on walls, for example.

The taxonomy presented by Bowman and Hodges (1999) also addresses object manipulation and release of objects after manipulation (see Fig. 13.6). The size of the manipulation taxonomy indicates that the design space is quite large. New techniques can be created using the process of guided design by combining components for each of the lowest level subtasks.

4.3.2 Guidelines for Designing Manipulation Techniques

Reduce the number of degrees of freedom to be manipulated if the application allows it.

Provide general or application-specific constraints or manipulation aids.

These two guidelines address the same issue: reducing the complexity of interaction from the user's point of view. This can be done by considering the characteristics of the application (e.g., in an interior design task, the furniture should remain on the floor) by off-loading complexity to the computer (using constraints or physical simulation), or by providing widgets to allow the manipulation of one or several related DOFs (Conner et al., 1992; Mine, 1997). This also relates to the guideline concerning the DOFs of the input device to be used.

Allow direct manipulation with the virtual hand instead of using a tool.

Tools, such as a virtual light ray, may allow a user to select objects from great distances. However, the use of these same tools for object manipulation is not recommended due to the fact that positioning and orienting of the object is not direct—the user must map desired object manipulations to the corresponding tool manipulations. Manipulation techniques that allow the direct positioning and orienting of virtual objects with the user's hand have been shown empirically to perform more efficiently and to provide greater user satisfaction than techniques using a tool (Bowman & Hodges, 1999). For efficient selection and manipulation, then, a 2-D selection metaphor such as ray casting must be combined with a hand-centered, direct manipulation technique. This is the basis of techniques such as HOMER (Bowman & Hodges, 1997) and Sticky Finger (Pierce et al., 1997).

Avoid repeated, frequent scaling of the user or environment.

Techniques that scale the user or the world to allow direct manipulation have some desirable characteristics. The user's perception of the scene does not change at the moment of selection, and small physical movements can allow large virtual movements (Pierce et al., 1997). However, experimental data shows a correlation between the frequent use of such techniques and discomfort (dizziness and nausea) in users (Bowman & Hodges, 1999). Techniques that scale the user or environment infrequently and predictably should not suffer from these effects.

Use indirect depth manipulation for increased efficiency and accuracy.

Indirect control of object depth (e.g., using joystick buttons to move an object nearer to or farther away from the user) is completely unnatural and requires some training to be used well. However, once this technique is learned it provides more accurate object placement, especially if the target is far from the user (Bowman & Hodges, 1999). This increased accuracy leads to more efficient performance as well. Moreover, these techniques do not exhibit the arm strain that can result from the use of more natural arm-extension techniques.

4.4 System Control

Many of the other interactions found in VE applications fall under the heading of system control. This category includes commands, mode changes, and other modifications of system state. Often, system control tasks are composites of the other universal tasks. For example,

FIG. 13.7. Virtual pull-down menu (*left*), pen-and-tablet menu (*center*), and rotary menu (*right*).

choosing a menu item is a selection task, whereas dragging an object to a trash can for deletion is a manipulation task.

There has been little empirical evaluation of VE system control techniques, and no formal classification of which the author is aware. Therefore, in this section several categories of techniques are focused on including menus, voice commands, tools, and gestures.

4.4.1 Virtual Menus

Menus are the most common forms of system control found in VEs, and many of the virtual menu systems that have been developed are simple adaptations of menus from 2-D desktop systems.

The most simple menu system is a series of labeled buttons that appears in the virtual environment. These may be at a specific location in the environment, or they may be attached to the user for greater availability from any location. Slightly more complex are pull-down menus, which appear only as a label and whose items are revealed when the label is selected (Jacoby & Ellis, 1992). Pop-up menus have also been implemented, so that the menu appears at the location of the user's hand for easy access. Other implementations use menus on a virtual surface, such as in the pen-and-tablet metaphor or on the surface of a workbench display. Mine (1997) developed a rotary menu system in which items are chosen by rotating the wrist. This takes advantage of the fact that menu selection is essentially a one-dimensional task, so menu selection is done by changing only 1 DOF. TULIP menus (Bowman & Wingrave, 2001) map menu items to fingers, which are selected using Pinch Gloves. Figure 13.7 shows three example virtual menu systems.

Many virtual menu systems have faced a set of common problems. One is that the resolution of text, especially in HMDs, is low, so menus and labels must contain few items and take up considerable display space due to large font sizes. Also, input using trackers is imprecise, so menu items must be large and few submenus can be used. For a command-intensive application such as immersive design, these problems force designers to think of creative ways to issue commands.

4.4.2 Voice Commands

The use of voice as a command input is very popular in virtual environments. Voice has many advantages, including its simple input device (a microphone), freedom to use the hands for other operations, and flexibility of voice input to specify complex commands. Voice also has disadvantages, including limited recognition capability, forcing the user to remember arbitrary command utterances, inappropriateness for specifying continuous quantities, and the distraction to other users in the same room.

Voice has most often been used to implement simple, discrete commands such as "Save," "Delete," or "Quit," but it has also been used in more complex menu hierarchies. Darken (1994)

combined voice input with visual menus so that recall of command names was eliminated. Currently, much voice research is focused on multimodal interaction (Bolt, 1980), where voice and gesture or other input modalities are combined to form a richer and more precise interaction.

4.4.3 Gesture Commands

Many of the earliest VE systems used gloves as input, and glove gestures to indicate commands. Gesture recognition is covered in detail in chapter 10 (this volume). Advantages of using gestures include the flexibility and number of degrees of freedom of the human hand, the lack of a need for traditional input devices, and the ability to use two hands. However, gestures suffer from many of the same problems as voice, including forced user recall and poor recognition rates. For these reasons, most production VE systems use menu or button systems, or only primitive- and limited-gesture commands.

4.4.4 Virtual Tools

Since having a large command space proves problematic for VE applications, developers have looked for ways to reduce the number of commands needed. One way to do this is through the use of virtual tools. Tools are common in many desktop applications as a more direct way to indicate an action to the system. For example, instead of selecting an area of the screen and choosing an “erase” command, the user can simply select an eraser tool and directly erase the desired areas.

There have been similar efforts in virtual environments. One example is Mine’s ISAAC system (Mine, 1997), which makes use of a wide variety of tools to perform interactive modifications to a geometric scene. The Virtual Tricorder (Wloka & Greenfield, 1995) is a multipurpose tool that changes appearance and function depending on system mode and state.

4.4.5 Guidelines for Designing System Control Techniques

Unlike the other three universal interaction tasks, there has been very little evaluation of VE system control techniques. Therefore, most of the guidelines below are drawn from experience and intuition. Much more research is needed in this area.

Reduce the necessary number of commands in the application.

In many cases, system control in VEs is awkward and distracts from the actual task at hand. If users are struggling with the menu interface, for example, their domain-specific goals will take much longer to realize. This seems to affect immersive VEs more than traditional desktop applications because of the narrow field of view (see chap. 3, this volume), fatigue from spatial interaction (see chap. 41, this volume), and adverse effects of extended VE use (see chaps. 29–32, this volume). Developers need to look closely at what commands are absolutely necessary and what actions can be done using direct manipulation or virtual tools instead.

When using virtual menus, avoid submenus and make selection at most a 2-D operation.

Input to VEs (usually based on 6-DOF trackers) can be quite imprecise. Requiring users to navigate more than one level of menus can lead to frustration and inefficiency. The same holds for menu systems that require 3-D input. The use of a physical surface such as the pen-and-tablet metaphor can alleviate some of these problems, as can a 1-D solution such as rotary menus.

Indirect menu selection may be more efficient over prolonged periods of use.

In a usability study of two handheld virtual menu systems (Bowman, Hodges, & Bolter, 1998), it was found that menu item selection for novice users was more efficient when the items were touched directly with a stylus. However, as users became more expert with the menu system, a technique using joystick buttons to navigate the menu performed better, because users could “click ahead” of the system and no large hand movements were needed.

Voice and gesture-based commands should include some method of reminding the user of the proper utterance or gesture.

Lack of affordances is a major problem for most gesture and voice command systems, unless the number of commands is very small. Therefore, small visual reminders of the allowed words or gestures (Darken, 1994) may greatly enhance performance.

Integrate system control with other interaction tasks.

If the user thinks of the command subsystem as a completely separate component, the level of presence (see chap. 40, this volume) in the VE may decrease and the level of distraction may increase with the use of the system control technique. As much as possible, system control should seem a part of the environment in which the user is working. For example, pull-down menus attached to the user's view seem unnatural and detached from the environment, whereas a handheld menu seems part of the environment. Also, if the devices and widgets used for system control can also be used for travel, selection, or manipulation, the use of these techniques will not be as distracting to the user.

5. EVALUATION AND APPLICATION

This chapter has focused on the design of VE interaction techniques with high performance, but design is not the end of the story. Evaluation and application are also necessary components to the entire process of determining the appropriate interaction techniques for a VE application.

Following the guidelines and principles in this chapter should lead to interaction techniques that are well suited for the performance requirements of VE applications. However, because of the youth of this research area, one cannot guarantee performance levels no matter how many guidelines are followed. For this reason, evaluation and assessment of VE interaction is essential. Chapter 34 (this volume) covers the topic of usability evaluation in detail. Application designers need to test their systems with members of the intended user population to ensure that required performance levels are met.

For those who are designing new VE interaction techniques and performing basic research, the aspect of application must be kept in mind. Future research should focus on developing techniques that meet the performance requirements of current and proposed real-world VE applications. For examples of such applications, see chaps. 42–55 (this volume).

6. CONCLUSIONS

This chapter has been intended as a practical guide both for researchers and developers of interactive VE applications. It is essential to remember that most of the guidelines and principles presented here are the results of formal evaluation and that further guidelines should also be the product of careful testing.

This chapter emphasized the concept of performance, with a broad definition. In this area, user comfort, satisfaction, ease of use, and other subjective parameters are in some cases more important than more traditional performance variables such as speed and accuracy. Application developers must carefully consider the performance requirements of their systems before choosing interaction techniques.

Another consideration is the required naturalism of the interface. Certain applications need interaction that closely matches interaction in the physical environment. However, other applications with different requirements may benefit from the use of magic techniques that extend the user's real-world capabilities.

Finally, the issue of standards should be addressed. There has been a great deal of discussion about the possibility of a standard interface or set of interaction techniques for VEs, much like

the desktop metaphor for personal computers. Time may prove the author wrong, but the current situation appears to suggest that it will not be fruitful to pursue a standardized interface for VE interaction. Most of the types of VE applications that are currently in use or that have been proposed are highly specialized and domain-specific, and they exhibit a wide range of interaction performance requirements. There is currently no killer application for VEs that promises to put an HMD in every home. Furthermore, evaluation has shown time and time again that the optimal interaction technique is nonabsolute, but is instead application- and task-dependent. For these reasons, the author advocates the development of VE interaction techniques that are optimized for particular tasks and applied to particular systems.

7. ACKNOWLEDGMENTS

The author would like to thank the following people for their help, support, and discussion regarding the issues in this chapter: Larry Hodges, Donald Allison, Drew Kessler, Rob Kooper, Donald Johnson, Albert Badre, Elizabeth Davis, Ivan Poupyrev, Joseph LaViola, Ernst Kruijff, Mark Mine, Matthew Conway, Jeffrey Pierce, Andrew Forsberg, Ken Hinckley, the other members of the 3DUI mailing list, and Dawn Bowman.

1. INTRODUCTION

The purpose of this chapter is to examine the technological challenges inherent in the design of multisensory virtual environments (VEs). In this context, multisensory VEs are viewed as closed-loop systems comprised of humans, computers, and the interfaces through which continuous streams of information flow. More specifically, VEs are distinguished from other

simulator systems by their capacity to portray three dimensional (3-D) spatial information in a variety of modalities, their ability to exploit users' natural input behaviors for human-computer interaction, and their potential to "immerse" the user in the virtual world. Accordingly, the primary objective of multisensory VEs is to provide users with salient and meaningful information that affords veridical perception and permits adaptive, goal-directed behavior in the VE, ultimately enhancing operator efficiency in a wide variety of application domains, including training, information visualization, product development and testing, entertainment, medicine and health care, and teleoperation. However, despite significant advances in human-computer interface (HCI) technology over the past decade (e.g., head-mounted displays [HMDs], spatial audio displays, and haptic interfaces), compelling and useful multisensory VEs are sparse, and the purported advantages of the technology have yet to be realized.

The goal of this chapter is to address the technological challenges involved in designing and implementing multisensory virtual environments. Whereas other authors (Barfield & Furness, 1995; Durlach & Mavor, 1995; Melzer & Moffitt, 1997) have addressed these issues in detail, their approach has typically involved the decomposition of the VE into modality-specific technologies linked to various perceptual systems—e.g., chapters such as "The Design of Multidimensional Sound Interfaces" (Cohen & Wenzel, 1995) and "The Auditory Channel" (Durlach & Mavor, 1995). While the unisensory treatment is pedagogically convenient, it fails to provide an obvious framework within which multisensory VEs can be conceived and constructed. The approach used herein will be guided by two major themes: appropriate problem specification and selection; and critical evaluations of contemporary VE technologies as they relate to human perceptual and perceptual-motor capabilities.

There are several factors entwined in the specification and selection of a suitable problem. First, it should be well defined, i.e., it should be bounded by a finite set of rules, which constrain the types of events and interactions that may occur. Second, it should be inherently multisensory, meaning that it should mimic a real or fictitious environment that naturally demands a multimodal interface for achieving veridical perception, coordinated behaviors, and a sense of presence (see Held & Durlach, 1991, 1992; Sheridan, 1992; Steuer, 1992; and chap. 40, this volume, for reviews of the concept of presence). These requirements connote a highly interactive and immersive environment. Third, the problem should be nontrivial to the extent that it represents both an interesting and utile means of discussing the challenges associated with the design of multisensory virtual environments. It is clear that these three requirements do not uniquely specify a virtual environment. Indeed, there are numerous candidates, for example, surgical simulation, tactical air combat, planetary exploration, and atomic and molecular visualization. However, many of these require domain-specific expertise for both the design and use of the virtual environment. In order to make this discussion more generally accessible, a domain has been selected that satisfies the requirements set forth above and is both broadly understood and commercially attractive: the game of baseball.

Before providing an examination of some of the technological challenges involved in designing a multisensory virtual baseball environment, it will be instructive to consider several key parameters affecting the fidelity of VE interface technologies: (1) spatial resolution; (2) temporal resolution; (3) computational complexity; and (4) synchronization. The intent is not to enumerate exhaustively the manner in which these factors impact all possible display and control interfaces, but rather to introduce the concepts and terminology necessary to facilitate an analysis of the appropriateness of current technologies and their integration to support several of the key aspects of the game.

Spatial resolution refers to the fineness of spatial detail that can be discriminated in an image, without reference to a particular modality. The spatial resolutions of the most common perceptual systems (e.g., sight, hearing, and touch) have been well documented in texts on human perception (see Coren, Ward, & Enns, 1999; Sekuler & Blake, 1990) and elsewhere

in this book (see chaps. 3–7, this volume), whereas Barfield and his colleagues (1995) have provided a direct comparison between human perceptual capabilities and current VE technology. The analysis provided by Barfield, Hendrix, Bjorneseth, Koczmarek, & Lotens (1995) raises a number of issues: (1) there exist numerous inter- and intra-modality discongruities in spatial resolution with respect to both perceptual systems and VE technologies; (2) capabilities of prevailing VE technologies and human perceptual systems are often mismatched; and (3) the effectiveness of multisensory VE for supporting veridical perception will depend to some extent on the number and magnitude of these disparities.

Temporal resolution is the time-domain analogue of spatial resolution, that is, the smallest temporal interval that can be discriminated by a perceptual system. This parameter is important for effective interaction of humans and VE technologies, as discrepancies may generate errors in perception that are manifested in modality-specific ways. For example, temporal mismatches between the human auditory system and spatial audio displays may result in inadequate spatial resolution and mislocalization of virtual sounds; comparable discrepancies in haptic displays may result in failure to accurately depict object properties such as texture and rigidity; and in the case of vision, insufficient temporal resolution can produce flicker (Durlach & Mavor, 1995). Additionally, when excessive time delays exist between a user's control inputs and concomitant changes in the displays (see Wloka, 1995), perceptual-motor disruptions may result.

Computational complexity occurs as the result of the spatial and temporal resolution requirements imposed by the perceptual capabilities of the human observer and the mathematical models required to specify the entities in the VE and their interactions. The virtual concert hall serves as a convenient example of the complexities involved in the implementation of an acoustic model. In any hall, there are perceptible higher order acoustic reflections off of the walls and other large objects within the space. However, given the state of current audio display technology, even first-order reflections are computationally expensive, meaning that only auditory models of the most trivial virtual worlds can be achieved in real time. Similar examples are easily found in other modalities. Two of the anticipated consequences of inadequate or underspecified models are the diminution of presence (see chap. 40, this volume) and, in the case of training simulators (see chap. 43, this volume), the acquisition of inappropriate behaviors. On the other hand, the primary cost associated with the implementation of a more fully specified model is the introduction of excessive time delay, which may result in perceptual adaptations and negative aftereffects (Held & Durlach, 1991; Held, Efsthathoy, & Greene, 1966; Welch, 1986; chaps. 31, 37–39, this volume), degraded perceptual-motor skills (Poulton, 1974; Ricard, 1994, 1995; chap. 38, this volume), and even sickness (Hettinger & Riccio, 1992; Kennedy, Lane, Lilienthal, Berbaum, & Hettinger, 1992; chap. 30, this volume).

Synchronization is one of the key issues in the design of multisensory virtual environments. First, user motion must be synchronized with its portrayal in the VE or severe degradations in system usability may ensue (Friedmann, Starner, & Pentland, 1992; see chap. 34, this volume). Furthermore, the spatial and temporal attributes of objects, events, and their interactions in the VE must often be exquisitely coupled due to the relatively large variations in spatial and temporal resolutions across sensory modalities (see chap. 21, this volume). In the real world, spatial coordination of the senses is achieved by sensory integration and intersensory and sensorimotor coordination, which develop over the life span of the human (Gregory, 1987). Intersensory mismatches induced by lack of spatial or temporal synchronization in the VE may occasion unintended perceptual illusions (see chapter 22, this volume), or ineffective perceptual-motor interactions with objects in the VE (see chap. 13, this volume). These may result in undesirable behavioral adaptations and skill acquisitions, which may be inappropriately transferred to behaviors in the real environment (Kozak, Hancock, Arthur, & Chrysler, 1993; see chaps. 29–33, 37–39, this volume). They may also lead to simulator sickness (Kennedy, Lane, Lilienthal, Berbaum, & Hettinger, 1992; see chap. 30, this volume).

2. TECHNOLOGICAL CHALLENGES INVOLVED IN DESIGNING A MULTISENSORY VIRTUAL ENVIRONMENT

One means of facilitating discussion of designing an immersive multimodal baseball environment would be to organize the following sections according to the key perspectives of the game: hitter, pitcher, fielder, umpire, and spectator. Each of these roles is unique in its requirements for providing users with a compelling and authentic simulation. However, due to the structural limitations imposed hereupon (this being a book *chapter*, and not a *book*), this discussion will concentrate primarily on the act of hitting, delving into other roles only as required, for example, to discuss displays for sensory modalities not typically required of the hitter.

2.1 The Hitter

The act of hitting consists of establishing a stance, gripping the bat, reading the pitch, swinging the bat, and running the bases. Indeed, it is a complex perceptual-motor task that demands input from the visual, tactile and kinesthetic, and auditory modalities. Perhaps one of the most complex aspects of simulating the act of hitting involves the haptic and tactile representation of the bat, and the muscular stimulation that results from the holding and swinging thereof. Clearly, the apparatus required to provide this information does not currently exist. Consider, for example, the trivial case in which the batter does not swing at all (i.e., a ball or a called strike). To create the illusion of holding the bat would require a means by which a multidimensional array of forces could be presented to the batter, including the force on the bat due to gravity, which affects the perception of the bat's weight and the batter's postural control, as well as the forces involved in grasping. While a crude representation of the latter may be possible with current tactile display technology (cf. Kaczmarek & Bach-Y-Rita, 1995; Kontarinis & Howe, 1995; see chaps. 5–6, this volume), it is difficult at this time to conceive of a stable or elegant kinesthetic apparatus to affect the former. Along these lines, Hannaford and Venema (1995) have identified several formidable challenges for the realization of high-fidelity kinesthetic simulation, including specification of contact with rigid surfaces and the complexities involved in the real-time modeling of physically energetic processes.

Given the problems associated with generating a realistic simulation of grasping, holding, and swinging a virtual bat, a more practical solution may involve the combination of a real baseball bat (i.e., a "prop") with a glove-based tactile interface. In this case, the forces experienced by grasping and swinging the bat would be real, whereas those generated by hitting a virtual baseball would be displayed through force-reflecting actuators in the gloves. A variety of techniques may be employed to portray contact information (Durlach & Mavor, 1995), including shape-changing, vibrotactile, and electrotactile actuators. Moreover, the haptic perception of contact with a virtual baseball may be enhanced by providing the hitter with a realistic auditory contact cue (i.e., the so-called crack of the bat), which may also be varied to convey the type of contact made with the bat (e.g., hit squarely on the barrel, up tight on the hands, etc.). The overall effectiveness of this contact display, however, would depend on accurate tracking of bat position in relation to the position of the virtual baseball, precise collision detection models, and synchronization between resultant visual, haptic, and auditory contact information.

As with other VE applications (e.g., medical, military, teleoperation), accurate tracking of object position and orientation is essential to the overall effectiveness of the system. In the case of the hitter, position and orientation trackers would be required to track the location of the bat and various parts of the hitter's body, including hands, arms, feet, hips, shoulders, eyes, and head, and data from the trackers would be used to update the multimodal display of objects in the environment. Specifically, data from the position and orientation trackers would be used

collectively as inputs to determine whether the pitch was hit or missed, and, if hit, its trajectory and distance.

While significant advances in tracking technologies have occurred over the last several decades, (see Durlach & Mavor, 1995, for review; see chaps. 8–9, this volume), the spatial and temporal resolution required of tracking a hitter's swing are extreme and constrain the types of tracking technologies that may be employed. For example, Anderson (1993) has estimated that sampling rates of approximately 1000 Hz are required to track a baseball bat in a virtual batting cage in which the hitter swings at a virtual pitch displayed in an HMD. Accordingly, trackers of the electromagnetic variety, which range from 60 to 120 Hz, would be ineffective, and if employed would ultimately lead to an unusable virtual environment. One potential solution, noted by Durlach and Mavor (1995), would be to use optical tracking systems and/or inertial trackers that are capable of 1000 Hz sampling rates; however, the former are often cost prohibitive, whereas the accuracy of the latter has been noted to suffer from "drift," thus requiring continuous calibration. A similar state of affairs exists for accurate eye tracking (see chap. 9, this volume), which may also require bandwidths in the 1000 Hz range (Inchingolo & Spanio, 1985). Unfortunately, current noninvasive eye-tracking technologies tend to have much lower sampling rates and often suffer from suboptimal accuracy (see Borah, 1998, for review).

Given the sensitive perceptual-motor couplings required for the act of hitting, substantial errors in tracking, whether caused by inadequate sampling rates, interference, or suboptimal resolution, will disrupt the display of information to the hitter, subsequently rendering the task unachievable. This line of reasoning follows from the recognition that the act of hitting can be viewed as a high gain, closed-loop tracking task, which is particularly susceptible to the deleterious effects of time delay and perturbations (see Jagacinski, 1977; Pew & Rupp, 1971; Poulton, 1974; Ricard, 1994). For example, in the case of continuous tracking tasks, increases in time delay must be accompanied by decreases in gain in order to maintain tracking stability. If not, unstable tracking will occur, which in the case of hitting may be exhibited by swinging too high, low, early, or late. Conversely, if the hitter's gain is too low, tracking of the pitch will be sluggish, resulting in increased tracking error and poor hitting performance.

Position and orientation tracking of other aspects of the hitter's body—head, shoulders, and hips—may not be as severely constrained by bandwidth requirements; however, issues such as encumbrance, susceptibility to obfuscation and interference, and accuracy, may limit their effectiveness for supporting the hitting scenarios. Despite these caveats, potential candidates for body-position tracking may include commercially popular electromagnetic trackers (Ascension Flock of Birds and Fastrak), optical systems, and mechanical trackers, each of which vary in degree of accuracy, resolution, range, sampling rate, interference, and latency (Durlach & Mavor, 1995; Meyer, Applewhite, & Biocca, 1992; Nixon, McCallum, Fright & Price, 1998; Piantanida, Bowman, & Gille, 1993; Pimentel & Teixeira, 1993; Sutherland, 1970). For example, the position of the key body joints (e.g., ankles, knees, hips, hands, shoulders, head) could be tracked with either active or passive markers in conjunction with the appropriate optical systems (see Durlach & Mavor, 1995) or by wearing a suit that contains goniometers—mechanical trackers—at the body joints of interest. Electromagnetic trackers would also be appropriate for tracking body positions that do not require high sampling rates, but limitations such as interference and range should be recognized (Nixon et al., 1998). To summarize, the technological challenge imposed by tracking position and orientation information for the act of hitting are substantial. In all likelihood, the tracking system would comprise a collection of mechanical, inertial, optical, and electromagnetic trackers. Given that hitting is a tightly coupled, closed-loop system, any degradation of the temporal and spatial accuracy of the tracking information would severely impact the user's ability to hit the virtual pitch.

Of course, since the batter is not going to hit what cannot be seen, several important considerations exist for the selection of an appropriate visual display for the act of hitting. In addition to reading the pitch, detecting the pitcher's release, and predicting the ball's trajectory, the visual display must permit the interpretation of hitting signs from the coach, survey of the defensive configuration, and determination of ball's location and trajectory after being struck. Ideally, the visual display should endeavor to match the capabilities of the human visual system, that is, a 210-degree horizontal \times 125-degree vertical field of view and resolution on the order of 0.5–1 minute of arc, allowing for depth perception resolution of 10 seconds of arc, and temporal resolution that exceeds critical flicker-fusion thresholds. In addition, to enhance the sense of presence and realism, the visual display should be capable of realistic color (approximately 300 chromaticities/luminance level) and photopic daylight luminance levels ($0.314 - 3.14 \times 10^6$ cd/m²). Unfortunately, current VE visual display technologies are incapable of matching the capabilities of the human visual system (Barfield et al., 1995; Durlach & Mavor, 1995; see chap. 3, this volume).

Another important consideration is the actual display medium, that is, whether visual display should be head mounted, boom mounted, surface projected, or even retinally displayed. While HMDs have been used extensively in VEs, they suffer from narrow fields of view, insufficient resolution, small exit pupils, and problems resulting from size, weight, and fit. The latter severely limits this technology's usability, especially for long or extended sessions. In addition, weight and associated inertial liabilities have been noted as a factor contributing to simulator sickness and disorientation (see chap. 30, this volume). Moreover, since the ability of an HMD to support goal-oriented behavior is intimately tied to the performance of the tracking system, any deficiencies in the tracking data will only serve to exacerbate problems resulting from the HMD's limitations. Finally, sliding into base while wearing an HMD may prove unsafe for both user and apparatus.

An alternative to HMDs is the employment of an off-head or projected display, which is capable of producing relatively high-resolution stereoscopic visual images over large fields of view. Stereoscopic images are often achieved by employing infrared LCD shutter glasses to enable field synchronization (e.g., CAVE display system, Cruz-Neira, Sandin, DeFanti, Kenyon, & Hart, 1992). While the projection display alternative alleviates problems such as excessive helmet weight, issues of comfort, and narrow fields of view, it is important to recognize that the user will not be totally immersed in the VE, that is, aspects of the apparatus, such as cables, mechanical supports, housings, and other apparatus may be part of the user's visual field of regard. Another alternative is retinal display technology (Pryor, Furness, & Viirre, 1998), which may provide a compelling and effective visual medium. However, it is currently an immature technology with numerous technological limitations (e.g., small exit pupils, not robust movement, etc.) that make it inadequate for the hitting scenario.

2.2 Running the Bases

Running the bases is another essential element for simulating the act of hitting, and it too introduces some formidable technological challenges. Ideally, following a hit the player should be able to quickly accelerate down the first base line, deciding to either turn the corner and head toward second base, or simply to run out the single. As described by Durlach and Mavor (1995), the ground surface interface should allow the user to experience the active sensation of locomotion, permitting natural limb movement and providing feedback that matches the spatiotemporal characteristics of the simulated surface. It must also permit the collection of position and orientation data so that appropriate updates can be made to it and the other display interfaces. There are several key challenges for providing an effective ground interface display for running the bases, including, but not limited to, issues involving balance, change in

direction, modeling surface characteristics (e.g., friction, rigidity, etc.), speed, acceleration and deceleration, noise, and capturing, modeling, and translating real leg movements into virtual leg motions.

One approach to providing ground surface interfaces for locomotion is the use of omnidirectional treadmills (see Darken, Cockayne, & Carmein, 1997; Iwata & Yoshida, 1999; and Templeman, Denbrook, & Sibert, 1999, for reviews; also see chap. 11, this volume). For example, the Torus Treadmill, described by Iwata and Yoshida (1999), comprises a set of 12 individual treadmills arranged in a toroidal configuration, affording motion in all directions. However, there are significant limitations in terms of both the speeds and accelerations required for activities such as base running. For example, a fast baserunner can achieve speeds in excess of 9.75 m/sec, whereas the Torus Treadmill has a maximum speed of 1.2 m/sec (Adair, 1994; Iwata & Yoshida, 1999). Clearly, this will not accommodate realistic baserunning, not to mention sliding into home, an activity that is constrained not only by the surface texture but also by the physical size of the device. Furthermore, Iwata and Yoshida (1999) point out that the veridical portrayal of the acceleration cues accompanying changes in direction require an additional layer of apparatus.

Another option for the simulation of locomotion, and hence baserunning, is a gesture-recognition-based input system such as that described by Templeman and his colleagues (1999), which uses leg movements to infer the direction, extent, and timing of the user's traversal of a virtual environment. Because this sensor-based system is not constrained by the physical apparatus associated with a motion platform, it appears that limitations on velocity and acceleration will not be an issue. Furthermore, since the system allows for actual steps as well as gestural steps, realistic baserunning should be attainable given an arbitrary region of sufficient extent. However, it must be noted that most of the technologies described up to this point demand a tethered user and thus do not support motions over large areas. Thus, one has recourse to the gesture-based system, which has its own problems, including underspecification of accelerative forces, necessitating the introduction of a virtual vestibular cue (an admittedly immature technology with its own set of problems; cf. Cress et al., 1996; see chap. 7, this volume), imperfect gesture classification algorithms, and problems generic to all tracking systems (see chaps. 8–9, this volume).

3. OTHER ROLES, OTHER MODALITIES

While the realization of the act of hitting a virtual baseball requires precise and accurate visual, haptic, and tactile displays, it may be that veridical portrayal to other modalities may be neglected without sacrificing fidelity, usability, or presence. This is certainly not true for all of the roles that must be considered in constructing the virtual baseball game. The auditory modality is particularly important for the fielding team, as well as for umpires calling the game (the first base umpire may hear, not see, when the ball reaches the first baseman's glove), while the role of the spectator may require audition (Gilkey and Weisenberger (1995) have suggested that audio-free VEs suffer a diminution of presence), as well as olfaction and potentially gustation (heeding the suggestion that a baseball game without a hot dog is not a baseball game).

Spatial audio displays (see chap. 4, this volume) are one of the more mature technologies required for the generation of multisensory VEs, though even they must be employed with some caution. The generation of veridical spatial audio cues is accomplished by measuring the acoustic waveform at or near the eardrum of a listener, and interpreting the difference between the spectra of the source and the resultant wave as a transfer function characterizing, for a given ear and a given source position, the frequency-dependent modifications of the incident

waveform by the head, torso, and pinna. If this is done for both ears, then it is possible to encode all of the cues necessary for accurate auditory localization using two channels, one for each ear. The transfer functions for each ear, commonly referred to as head-related transfer functions, or HRTFs, can then be represented as digital filters and convolved with an appropriate audio signal to produce the sensation of an externalized sound source whose perceived direction is the same as that of the measured HRTF (Wightman & Kistler, 1989).

While this process may appear trivial, to the extent that it can be completely specified in one or two sentences, there are a number of computational issues that come into play when actually generating a multisource auditory virtual environment. For example, each source requires its own pair of HRTFs, each of which requires a certain amount of memory and digital signal processing. If each spectator in a stadium is equated with a single source, the problem becomes clear. There is also the issue of reflections, which are important when one is not simulating an anechoic environment. Specifically, each reflection requires its own HRTF, and, in a room with four walls, a ceiling, and a floor, each source will have six first-order reflections. In such an extensive environment as the typical baseball stadium, effects such as wind, atmospheric absorption, and Doppler effects might also need to be considered.

Another issue arising in the implementation of spatial audio displays is the fact, recently indicated by Brungart and his colleagues (Brungart, Durlach, & Rabinowitz, 1999; Brungart & Rabinowitz, 1999), that the physical cues subserving auditory localization and distance perception in the near field (i.e., distances less than 1 meter from the listener) are different from those used in the far field, and that listeners are much better at judging distances within this "peripersonal" region than they are at distance judgments in "extrapersonal" space. Thus, in order to faithfully represent auditory events occurring at distances within 1 meter of the listener (such as arguing with the man who just spilled beer on you), multiple sets of HRTFs are required.

One modality that has received little note from the designers of multisensory VEs is that of olfaction. This is surprising, given the recognition that compelling olfactory cues have the potential to enhance the sense of presence in a virtual environment (Barfield & Danas, 1996), invoke emotion (Corbin, 1982), and provide salient spatial cues (von Békésy, 1964). To date, the most comprehensive treatment of the olfactory system in the context of VEs has been provided by Barfield and Danas (1996), who review the physiological and psychological aspects of olfaction, discuss mechanisms for the presentation of odorants, and enumerate a number of olfactory analogs to visual parameters, such as field of smell (field of view), the great variety of smells (color), and spatial resolution. While other researchers have speculated on the utility of olfactory displays for entertainment applications (Cater, 1992, 1994), only recently have commercially available olfactory displays been offered (e.g., SENX Machines, iSmell Digital Scent Technology, Aromajet, etc.). While these and other olfactory displays might serve to enhance the presence of the spectator, Barfield and Danas (1996) suggest a number of caveats. Of particular concern are such stimulus-related issues as the precise control of intensity and duration, both functions of the volatility of the odorant, as well as perceptual issues such as habituation, individual differences, and pathologies in odor perception (as Barfield and Danas point out, approximately two million American adults suffer some form of olfactory dysfunction). Collectively, these challenges continue to limit the use of virtual olfactory displays.

4. CONCLUSIONS

The ambition of this chapter was to discuss technological challenges in the design of multisensory virtual environments. Toward this end, a general classification scheme was introduced

that facilitates meaningful comparisons between current VE display and control technologies and users' perceptual and perceptual-motor requirements. The relatively simple taxonomy, i.e., spatial and temporal resolution, computational complexity, and synchronization, captures the necessary elements for a critical analysis of most, if not all, multisensory virtual environments.

As an example of the complexities and challenges involved in designing a usable multisensory VE, some of the technological issues in providing a multisensory virtual baseball game were considered, focusing primarily on the hitter. Indeed, even the most cursory analysis of this baseball application reveals numerous inadequacies of current multisensory VE technology. Specifically, significant advances in position and orientation tracking technologies (see chaps. 8–9, this volume), tactile and force feedback displays (see chaps. 5–6, this volume), and omnidirectional locomotion displays (see chap. 11, this volume) are needed to afford a compelling simulation of the act of hitting and running the bases. Even in those cases where VE technologies are sufficiently mature (e.g., various visual and auditory displays), the overall effectiveness of the system will be determined by the extent to which spatiotemporal disruptions of critical perceptual information are minimized. This conclusion is not unique to the baseball application, but rather, to any application domain that comprise tasks involving tightly coupled perceptual-motor skills.

It is also interesting to note that the effects of inadequate VE technology are highly task-dependent. For example, while excessive time delay for the hitter and baserunner would likely result in uncoordinated behavior, time delays in the spectator's displays may result in disturbing perceptual illusions (Azuma & Bishop, 1994; see chap. 22, this volume), spatial disorientation (see chap. 24, this volume), and possibly sickness (see chap. 30, this volume). In the case of the spectator, where the goal is to create presence (see chap. 40, this volume) by immersing the user in the sight, sounds, and smells of the virtual ball park, it appears that current multisensory technologies are not sufficiently mature. Consequently, perhaps the most effective means for immersing oneself in the game—other than going to a real ballpark—is to sit down with a radio and spectate within the “enclosed green field of the mind” (Giamatti, 1998).

The current discussion of technological challenges in designing usable multisensory VEs is limited in several ways. First, though not addressed here, it is important to point out that researchers and engineers have developed a wide variety of schemes designed to compensate for some of the technological limitations described herein, including: (1) offsetting time delays in the system via algorithmic prediction of input data; (2) reducing the computational complexity for generating visual scenes (e.g., texture mapping, restricting the resolution outside of the user's field of view, etc.); and (3) exploiting user's ability to adapt to spatial-temporal rearrangements in the virtual environment (see chap. 31, this volume).

As one might expect, each of these strategies is accompanied by a variety of advantages and disadvantages, hence the decision to incorporate these solutions is nontrivial and highly task-dependent. Second, the adequacy of VE technology as a training apparatus for hitting was not addressed. The key question here is whether or not VE technology facilitates positive transfer of training to the real world (i.e., would training in a VE batting cage transfer to batting in a real game?). Of particular concern is the issue of whether constraints imposed by inadequate VE technology, for example, time delay, compel users to develop and adopt control strategies that are specific to the VE, and, if so, whether or not these VE-specific skills negatively impact performance of tasks in the real world. Considerable research has been devoted to the transfer of training question in the area of flight simulation, and it will likely continue to be a relevant question in any application domain in which VE technology is considered for real-world skill acquisition (see chap. 19, this volume). Finally, although the current discussion was largely limited to the act of hitting, it should be realized that there are numerous other roles in baseball that warrant a similar examination.

5. ACKNOWLEDGMENTS

The authors would like to acknowledge Dr. Mark Draper of the Air Force Research Laboratory for his careful review of an earlier draft of this manuscript.

1. INTRODUCTION

Creating embodied autonomous agents for a virtual environment combines research from computer graphics, animation, and artificial intelligence, as well as ideas from psychology, sociology, and cognitive sciences. In this chapter, some concepts that should be considered when designing and creating embodied agents for virtual environments (VEs) are discussed. Some of these concepts have been researched for many years, and some are just now being considered. Likewise, some of the associated research problems have more complete solutions than others. The chapter begins by defining embodied autonomous agents for virtual environments. Then agent appearances are discussed. Next, research on animating the actions of agents is reviewed. This is followed by a discussion of agent communication and mental processes. Finally, an outline of research in action selection is provided, concluding with a discussion of future research directions.

1.1 Definition

The term *agent* has received a lot of use in the past few years, but the definition of an agent is still unclear. In computer graphics an agent might mean any autonomous entity in the virtual environment. For example, any human or even gravity might be viewed as an agent. Agents might be defined in contrast to avatars, which are graphical representations of a user in the environment that are under his or her direct control: An agent would be any autonomous human actor.

Artificial intelligence has struggled even more with their definition of an agent. Although there is still no set definition of what an agent is, Wooldridge and Jennings (1995) have proposed

a weak definition as a computer system with the following properties:

- *Autonomy*: Agents operate without the direct intervention of humans or others, and have some kind of control over their actions and internal state.
- *Social ability*: Agents interact with other agents (and possibly humans) via some kind of agent-communication language.
- *Reactivity*: Agents perceive their environment, and respond in a timely fashion to changes that occur in it.
- *Proactiveness*: Agents do not simply act in response to their environment; they are capable of goal-directed behavior by taking the initiative.

A stronger definition of an agent adds to these properties the idea that the system is described using concepts that are usually applied to humans, such as beliefs, knowledge, and intention.

In this chapter the term *agent* will be used to describe a synthetic or virtual human agent in a VE with some degree of autonomy, social ability, reactivity, and proactiveness. An agent might be a semiautonomous agent, which acts autonomously but can be corrected or redirected by a user. The user may input high-level goals for the agent to achieve, but how the agent achieves these goals is left to the agent. Adding the word embodied further focuses this chapter. All of the agents herein discussed will have a physical (geometric) representation in the environment.

2. APPEARANCE

Autonomous agents can take the form of human beings, faces, animals, or more exotic forms. Their appearance in the virtual world can range from cartoonish to a physiologically accurate model. The proper level of detail and style of the character depends on the application. This discussion concentrates on realistic looking (embodied) human, autonomous agents. A human's appearance can be characterized by its age, aesthetics, gender, body type, ethnicity, hair, skin, bone, and muscle modeling.

Generally, the appearance of a virtual human is designed offline and then displayed during live interactions. Body, face, and muscle models have been created by many groups, including Gourret, Magnenat-Thalmann and Thalmann (1989); Badler, Phillips and Webber (1993); Wilhelms and Van Gelder (1997); Capin, Pandzic, Noser, Thalmann, and Magnenat-Thalmann (1997); Scheepers, Parent, Carlson, and May (1997); and Ting (1998). In general, low-polygon-count models with simple shading are used for interactive applications such as virtual environments. For an overview of modeling realistic virtual humans, see Kalra et al. (1998).

Modeling of hair and skin adds to the realism of an agent's appearance. The complex task of hair modeling has been studied by Anjyo, Usami, and Kurihara (1992); Watanabe and Suenaga (1992); and Sourin, Pasko and Savchenko (1996). In recent years, much attention has also been given to the modeling of skin including wrinkles and textures. There are three basic models used to simulate skin deformations: geometric models; physically based models; and biomechanical models. Geometric models can be further broken down into parametric models (Parke, 1982) and muscle-based models (Magnenat-Thalmann, Primeau, & Thalmann, 1988; Waters, 1987). Ishii, Yasuda, Yokoi, Yoriwaki, and Toriwaki (1993) propose a geometric model of micro wrinkles. For expressing folds and ridge features, their model uses a curved surface on a base polygon. Viaud and Yahia (1992) proposed a hybrid model for expressive wrinkles. The bulges of the wrinkles are modeled as spline segments.

Physically based models of the skin include three layered deformable lattices (Lee, Waters, & Terzopoulos, 1995) and finite element methods (Koch et al., 1996; Larrabee, 1986; Pieper,

1992). Wu, Kalra, and Magnenat-Thalmann (1997) have created a biomechanical model in which a simulated muscle layer causes skin deformations. Several layers of color, bump, and displacement mapping are used to increase the realism of the wrinkles.

An agent's clothing also influences one's perception of an agent. Dressing a virtual human is not a simple task. Not only must one design the clothing shapes, one must also design the simulation of the cloth, handle collisions between the cloth and the body, and simulate folding, wrinkling, and crumpling. Most cloth models are physically based, using elastic deformations and collision response. Early models were based on spring and mass models (Haumann & Parent, 1988; Weil, 1986) and simulated flags or curtains. Terzopoulos, Platt, and Barr (1987) and Terzopoulos and Fleischer (1988) created more general elastic models, which modeled a range of deformable objects. Particle-system-based models, which use fabric deformation data to simulate simple cloth objects, are fast and flexible (Breen, House, & Getto, 1992; Eberhardt, Weber, & Strasser, 1996). Finite element models (Collier, Collier, O'Toole, & Sargand, 1991; Eischen, Deng, & Clapp, 1996; Kang & Yu, 1995) are accurate but slower and more complex.

Volino and Magnenat-Thalmann (1997) propose a cloth model that is robust and suited for interactive design and simulation. Their aim is to create a tool for interactively designing garments and dressing virtual humans in a natural way. They describe a mechanical model that simulates the elastic behavior of cloth, in which the cloth surface is broken into irregular triangle meshes. They build on previous work in an attempt to create a fast, flexible, and accurate cloth modeling system. Baraff and Witkin (1998) have also created a fast-cloth model using physically based constraints and implicit integration.

Although the appearance of agents has been researched for years, and Babski and Thalmann (1999) have made strides in fast skin modeling, there is still a need to make both skin and cloth deformations real time and also a need to show how the characteristics of appearance impact other parts of an agent model. For example, an agent's age may impact its locomotion, and its appearance or ethnicity could have an impact on its behaviors. An agent's appearance will influence how he or she is perceived because it is often an external indicator of status and role.

3. ANIMATING ACTIONS

In order to move agents in VEs one must animate actions such as posture changes, balance adjustments, reaching, pointing, grasping, giving-taking, other arm/hand gestures, locomotion, eye gaze, head gestures, facial expressions, and speech. These animations involve controlling parts at the graphical level via joint transformations (e.g., for limbs) or surface deformations (e.g., for face). There are two tool kits available to aid in the construction of actions for virtual humans: Motion Factory's Motivate and Engineering Animation, Inc.'s, Jack. Standards are also being designed, such as Humanoid Animation Group and MPEG-4. Many other approaches are described in Wilcox (1998). Methods for animating agents for VEs include frame-by-frame animation, key-frame animation, motion capture, kinematics, and dynamics.

3.1 Locomotion

Most methods for generating locomotion can be classified into kinematics (Boulic, Magnenat-Thalmann, & Thalmann, 1990; Bruderlin & Calvert, 1996;), dynamics, which are slower and more complex (Bruderlin & Calvert, 1989; Hodgins, Wooten, Brogan, & O'Brien, 1995; Laszlo, van de Panne, & Fiume, 1996; McKenna & Zelter, 1990), motion editing (Gleicher, 1997; Lee & Shin, 1999; Popovic & Witkin, 1999), and combinations of these methods (Anderson & Pandy, 1999; Girard & Maciejewski, 1985; Ko & Badler, 1996). Sun, Goswami,

Metaxas, and Bruckner (1999) have created a system that combines motion-captured data with a procedural model. Their system can scale the motion across different size figures, alter the motion stylistically, and allow the agent to perform curved-path locomotion on uneven terrain in near real time.

The inclusion of locomotion for agents in VEs brings about issues of path planning or navigation, and collision detection and avoidance (Becket, 1996; Kuffner & Latombe, 1999; Noser, Renault, Thalmann, & Magnenat-Thalmann, 1995; Pandzic, Capin, & Magnenat-Thalmann, 1997; Reich, 1997). For a good survey of research on locomotion see Multon, France, Cani-Gascuel, and Debumne (1999).

3.2 Body Actions

Body motion is crucial to agent behavior and is accordingly well studied. Research has been done on many areas of body actions, including gesture generation (Cassell et al., 1994), grasping (Gourret et al., 1989), reaching, lifting, posture changes, and more (Badler, Phillips, & Webber, 1993). Similar to locomotion, techniques for generating body actions can be classified as kinematic (Calvert, Chapman, & Patla, 1982; Tolani & Badler, 1996) or dynamic (Hodgins, Wooten, Brogan, & O'Brien, 1995; Kokkevis, Metaxas, & Badler, 1996). There is also work being done on editing motions (Wilhelms, 1986), and motion retargeting (Bindiganavale & Badler, 1998; Hodgins & Pollard, 1997; Gleicher, 1998).

Transitioning from one action to another is also very important to natural-looking behaviors (Boulic, Becheiraz, Emeling, & Thalmann, 1997; Granieri, Crabtree, & Badler, 1995; Maiochhi & Pernici, 1990; Rose, Guenter, Bodenheimer, & Cohen, 1996; Wiley & Hahn, 1997). Sengers (1998) talks about action expression, which is the linking together of actions with transition actions to better describe the agent's cognitive state. These types of transition actions may allow human observers of agents' actions to better understand the agents' goals and activities.

In recent years, adding expressivity to human animation has been studied (Koga, Kondo, Kuffner, & Latombe, 1994; Perlin & Goldberg, 1996). In order to have believable agents, their movements should be individualized and based on their current emotional state. EMOTE (Chi, Costa, Zhao, & Badler, 2000) is a real-time, three-dimensional (3-D) character animation that modifies independently defined arm and torso movements through the specification of Effort and Shape parameters (Laban & Lawrence 1974, see Fig. 15.1). The underlying arm and torso movements are defined through key time and pose information, which may be created using key framing or generated synthetically by inverse kinematics, motion capture, or other prestored movement patterns. EMOTE provides an easy way to add emotion and drama to gestures, giving them a more natural appearance.

3.3 Facial Expressions

The face has a great deal of detail in the muscle, bone, and tissue. These structures influence deformations in facial features. There is no facial animation model that represents and simulates the complete, detailed anatomy. Approaches differ in their characterization of surface representation, sources of facial surface data, ability to generate varied geometric models, and animation capability. In addition to the physical structure of the face, there are also attributes of surface colors and textures. There has been significant effort in the development of computational models of the human face.

Parke (1972) proposed the first computer-generated facial model. It uses linear interpolation of a few expressive poses of a face, similar to key frame interpolation. The first physics-based face model was developed by Platt and Badler (1981). It included a simplified model of skin, muscle, and bone structure. The skin was represented by an interconnected elastic mesh, which

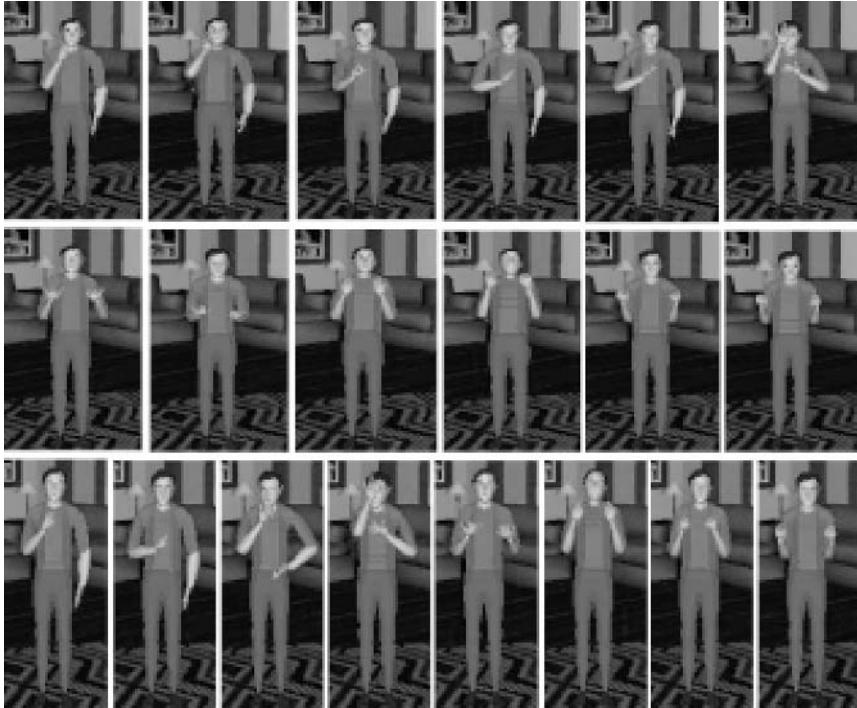

FIG. 15.1. Signing with the EMOTE system.

connected to inflexible bone by muscle arcs. Facial expressions were manipulated by applying forces to the skin mesh through the muscle arcs. The Facial Action Coding System (FACS), proposed by Ekman and Friesen (1977), was used as the notation scheme for the muscle actions. FACS represents facial expressions in terms of 66 action units, which involve one or more muscles and associated activation levels.

Waters (1987) simulated two types of facial muscles, linear muscles that pull and sphincter muscles that squeeze, by using a mass-and-spring model. In these models, the ability to manipulate facial expressions is based on simulating facial muscles.

Lee, Waters, and Terzopoulos (1995) use a physics-based approach for creating a head from laser scanner data. Their biomechanical model is more accurate than previous models, for it allows for the automatic placement of facial muscles and enables the use of a simple control process across different facial models. The physically based point-to-point control technique produces realistic results by offering subtle facial movements. Unfortunately, the equations used tend to be complex and therefore computationally intensive.

Kalra, Mangili, Magnenat-Thalmann, and Thalmann (1992) use a Rational Free Form Deformation (RFFD)-based approach to deform the facial skin surface. An expression editor allows the user to specify expressions at a high level without detailed knowledge of the anatomy of the face (see Fig. 15.2). Regrettably, the digitization process to construct the geometric model of the face is a labor-intensive job, and the approach does not produce realistic facial expressions and subtle facial motions. The interpolation-based animation approach used by this method requires manual creation of all facial expressions.

DeCarlo, Metaxas, and Stone (1998) present an anthropometry-based approach. They use anthropometric statistics to automatically produce varied geometric models of human faces. Compared to manual modeling techniques, this method provides sufficient generality to

FIG. 15.2. An angry facial expression.

describe a large sampling of face geometries, but because a single base shape was used, all of the sample models generated by their system have a similar shape. Blantz and Vetter (1999) describe a system for generating new morphable faces from linear combinations of prototypes. For an overview of facial animation, see Parke and Waters (1996) and Massaro (1998).

4. COMMUNICATION

Even though natural language in the form of spoken utterances is a natural and easy form of communication for humans, it is quite difficult for virtual humans. It involves solving many hard problems that are still being researched, including: dialogue planning, natural language processing, lip-synching, turn taking, and speech synthesis. Interactions between virtual autonomous agents and the human user in a VE go in both directions. Not only will the autonomous agent convey information through speech or body language, the agent will also receive information from the user by observing his or her avatar's facial expressions, body language, and attention.

It is often said that body language reveals as much if not more than verbal communication does. Cassell et al. (1994) and Cassell, Bickmore, Campbell, Vilhjalmsson, and Yan (2000) present a system that automatically generates and animates conversations between multiple agents. A dialogue planner creates the conversation and generates and synchronizes appropriate intonation, facial expressions, eye gaze, head motion, and arm gestures.

Gestural communication and body language have been studied by several groups (e.g., Kurlander, Skelly, & Salesin, 1996; Morawetz & Calvert, 1990). Becheiraz and Thalmann (1996) present a model of nonverbal communication where agents react to one another in a VE based on their postures. The agent's character influences how it reacts to the other agent's postures, and relationships between the agents evolve based on the perceptions of postures. Johnson and Rickel (1997) present an animated pedagogical agent that uses both gestures and attention to aid in the instruction of manual tasks. Andre, Rist, and Muller (1998) describe a presentation agent for use on the World Wide Web. Their interface agents present multimedia material to the user by following directives in a script. Every agent has its own persona and presents the material through moving and pointing. Chi, Costa, Zhao, and Badler's (2000) EMOTE animation system conveys emotional information through gesture.

Facial expressions are also a very important source of communicative information. Facial expressions can indicate what the agent is thinking and feeling. Facial expressions can be explicit or affective. Explicit expressions lack emotional content and include "fluttering of the eyelashes" and "pursing the lips." Affective expressions include "raising eyebrows expectantly" and "indulgent smiles."

Both Brand (1999) and Poggi and Pelachaud (2000) have researched ways of generating facial expressions for speech. Brand generates facial animation from information in an audio track. The facial control model is learned from real facial behavior. His voice puppet

automatically incorporates facial and vocal dynamics, including coarticulation. Poggi and Pelachaud concentrate on the visual display of intentions through facial animation based on semantic data. They model performatives, which are the type of action a sentence performs, such as requesting or informing. They also discuss how degree of certainty, power relationship, type of social encounter, and affective state effect facial animation.

What the agent or user pays attention to is another form of communication. Like facial expressions, attention can be termed explicit or affective. Explicit attentions include “looking at weapons,” “gazing,” “staring,” and “listening.” Affective attentions include “eyeing him warily,” “glaring,” and “giving dirty looks.” Vilhjalmsson and Cassell (1998) created an interface for chat room avatars that allows the user to give conversational cues through attention control. If a user sees an agent that he is talking to begin to look away from his avatar more and more, then this is probably an indication that the agent no longer wants to participate in the conversation. Thorisson (1998) describes an architecture for multimodal, face-to-face communication between a human and an agent.

Agents and users can also interact or communicate through actions and changes to the environment. For example, a user may direct his or her avatar to move a box to a tabletop. An agent may move the same box to the floor. The user may move it back to the table and the agent may move it back to the floor. This exchange of actions indicates each participant’s desired location for the box. Even though this is not a direct interaction, it is an important interaction nonetheless. For more information on virtual agent communication see Cassell, Sullivan, Prevost, and Churchill (2000).

5. MENTAL PROCESSES

Mental processes are an autonomous agent’s decision-making processes and other processes that contribute to, influence, and interfere with the decision-making process.

5.1 Personality

A believable autonomous agent should have a personality. Personality is a pattern of behavioral, temperamental, emotional, and mental traits for an individual, and it describes the long-term tendencies of the agent. Personalities can affect the way an agent perceives, acts, and reacts, and add to the believability of the character (Loyall & Bates, 1997; Perlin, 1995; Rousseau & Hayes-Roth, 1996). Most of the work in personality for virtual humans centers around five basic personality types: dominance, friendliness, conscientiousness, emotional stability, and openness (Tupes & Christal, 1961). For more information on research done on personality and agents, see Trapp and Petta (1997).

5.2 Emotion

Emotions are closely related to personality but have a shorter duration. The creation of emotion for autonomous agents has been studied by several research groups (Amaya, Bruderlin, & Calvert, 1996; Bates, Loyall, & Reilly, 1992; Bates, 1994; King, 1994; Perlin & Goldberg, 1996; Picard, 1997). Most simulations of emotions in autonomous agents are based on the work of Damasio (1994), Frijda (1987), or Ortony, Clore, and Collins (1988). In the Ortony, Clore, and Collins (OCC) model, emotions are generated based on three top-level constructs, namely the consequences of events, the actions of agents, and aspects of objects. There are a limited number of other influences considered under each of these areas including consequences for others and self, and prospects relevant and irrelevant. The model eventually is grounded in

22 different emotions: love, hate, pride, admiration, shame, reproach, joy, distress, happy-for, gloating, resentment, pity, satisfaction, relief, fears-confirmed, disappointment, gratification, gratitude, remorse, hope, fear, and anger. The first and most comprehensive implementation of the OCC model is the Affective Reasoner (Elliot, 1992). Emotions affect not only which actions the agent chooses to perform, but also the manner in which they are performed. For more information on emotions and autonomous agents, see Cassell, Sullivan, Prevost, and Churchill (2000).

5.3 Ethnicity and Culture

Cultural associations condition the way an agent perceives, acts, and reacts. For example, in Japan bowing is the accepted form of greeting, but in Western culture a handshake is preferred. These same norms should hold for autonomous, virtual agents. Culture helps in determining the importance and immediacy of the activities of life. Culture, along with personality and role, determines how emotions are expressed. Furthermore, when two people converse, culture influences more than just the language in which they speak. It is said that cultural information is a minimum prerequisite for human interaction, in the absence of such information communication becomes a trial and error process (Knapp & Hall, 1992). Culture influences how messages are sent, received, and interpreted. Cultural information pertains to a person's native language, myths, societal norms, and prevailing ideology. Different cultures have different distances for interacting; they also have different touching behaviors, gestures, and eye gaze patterns. However, it is interesting to note that there are some things that are similar across cultures (see Fig. 15.3). Studies have shown that the six basic facial expressions (happiness, anger, disgust, sadness, surprise, and fear) can be identified across cultures (Ekman & Friesen, 1971). Also, some behaviors have cross-cultural similarities. Among them are coyness, flirting, embarrassment, open-handed greetings, and a lowered posture for showing submission.

Skin color has been studied by Kalra, Mangili, Magnenat-Thalmann, and Thalmann (1991), but the behavior differences that accrue from ethnicity are just now receiving attention from various research groups.

5.4 Status

People in the theatrical arts have long known that status plays an important role in a scene. If one character has power over another, it will be reflected in what actions he or she performs and the manner in which they are performed. The same should be true of virtual actors. Hayes-Roth, van Gent, and Huber (1996) have explored the use of status with virtual humans in the form of a master-slave relationship. They illustrate how the postures and actions of the characters change as the servant becomes the dominant character in the environment and then returns to

FIG. 15.3. A sad agent.

his submissive role. Poggi and Pelachaud (2000) model status through facial expressions called performatives, which are facial expressions that accompany and add interpersonal relationship information to speech.

5.5 Role

Every character in a VE should have a role that it is playing, whether it is a professor of astrophysics, a tour guide, or just a man walking down the street. Roles involve expectations, both from the individual playing the role and from those interacting with the individual playing the role. One expects certain appearances, personalities, status, capabilities, resources, ages, actions, and goals. These expectations affect the way people interact. In order for a character in a VE to be believable, it must meet the expectations of the role it is playing (unless its personality or emotional state leads to a deviation from the expectation for dramatic effect).

Roles are learned, generalized guidelines for behavior. People play different roles in social contexts. The participants' expectations and perceptions define a role more than what is actually said or done. In fact, there are three types of roles: expected roles, perceived roles, and enacted roles. *Expected roles* are sets of behaviors that members of a group anticipate from an individual in a certain position. *Perceived roles* are sets of behaviors a person in a position believes he or she should exhibit. *Enacted roles* are the sets of behaviors actually performed. Among other things, a role can stem from an individual's occupation, kinship, age, gender, prestige, wealth, or associational grouping. In a situation, one participant normally establishes his or her role and the other participant(s) must either go along or counter with a different role definition. There must be an agreement on the roles to effectively interact, otherwise communication will break down.

Generally, people have multiple roles. They must be flexible and able to switch between their roles with ease. This, however, is not always the case and conflicts can arise. For example, workaholics often have a conflict between their role in professional life and their role in family life. Competent role performance involves experimentation, improvisation, and adjustment. Adopting a role over a long period of time may affect one's personality and identity.

The complex characteristics of roles and their interactions with other mental processes make them difficult to simulate well, but they may simplify the decision-making process of the agent by narrowing the number of action choices. Isbister and Hayes-Roth (1998) have explored roles in relation to intelligent interface agents. They found that making the role of an interface agent clear helps to constrain the actions users will take in their corresponding roles.

5.6 Situation Awareness

People all perceive situations differently and form different mental representations of the environment, people, and actions of a situation. This implies that their actions are predicated on their knowledge and understanding of the situation. To be able to create true individualized autonomous agents, situation awareness needs to be included.

An agent's representation of a situation depends on that agent's level of situation awareness. Situation awareness is a task-related understanding of the dynamic entities in an environment and their possible impact on agent actions. Situation awareness involves extracting useful information from the world while ignoring the overwhelming amounts of useless information. According to Endsley (1998), there are three cognitive levels involved in a person's situational awareness: observation, integration, and projection. A person perceives elements of the situation; then, he or she forms an understanding or mental image of the situation. Finally, he or she projects the status of the elements in the situation into the near future. Baxter and Bass (1998) indicate that there are three types of situations: the real world, the perceived situation, and the desired or expected situation. A key idea is that the situation representation can vary across

agents, especially agents of differing cultures. It is possible that the represented information may even vary by role, gender, personality, and emotions.

Before one can even begin modeling situation awareness, the agents' perception of the environment must be modeled. Currently, many VE systems and computer games fake agent perception by allowing the agent code access to the data structures that hold the world model, making the agents omniscient. Doyle and Hayes-Roth (1998) describe an object annotated Multi-User Domain (MUD)-type world. Kallmann and Thalmann (1999) describe smart objects for virtual environments that provide agents with information about interaction. Both of these models limit an agent's perception of the world to what is annotated into the objects. Noser, Renault, Thalmann, and Magnenat-Thalmann (1995) have studied synthetic vision, which is a truer version of perception. Chopra-Khullar and Badler (1999) have studied attending behaviors. They indicate that attention is directed by volitional, goal-directed aims known as endogenous factors that correspond to the current tasks being performed. Exogenous factors are involuntary attentional capture, such as stimulated by peripheral motion or local feature contrast. Here, attentional behavior is generated automatically based not only on the motor actions the agent is performing, but also involuntary visual functions, such as visual pursuit and spontaneous looking.

Naturally, an individual's perception of the environment is a key element in its behavior. The following are examples of perceptual bases and corresponding reactions. The perception of formality can lead to less relaxed, more hesitant, stylized, and superficial actions. The perception of psychological warmth tends to make individuals be relaxed, comfortable, and linger longer. The perception of privacy also greatly impacts an individual's actions depending on whether the individual is alone or with another person, what his or her perceptions of the other person are, and the individual's other perceptions of the environment. If the environment is unfamiliar, a person will tend to be cautious, deliberate, and conventional. The perception of constraint is important; whether and how easily a person feels he or she can leave will influence his or her decisions and actions. Another important environmental perception is distance. When the setting forces people into close quarters with individuals they do not know, they try to psychologically increase the distance and decrease the feelings of intimacy by lessening eye contact, increasing body tenseness and immobility, becoming silent, laughing nervously, joking about the intimacy, and creating public conversations directed to all present.

People also perceive and act in terms of the label applied to a situation. For example, if a foreman told his workers that they were going to be working around empty steel drums they would react differently than if he told them they would be working around drums filled with radioactive waste.

Although situation awareness is an important feature for agents in virtual environments, it has not been heavily researched by the community. It requires attention, synthetic vision, a representation of the situation, and a way to determine what is important in the situation based on the agent's current goals, emotions, culture, role, personality, expectations, and more. Once the environment has been perceived and the situation represented, the representation can be used in projection or planning and decision making.

6. ACTION SELECTION

6.1 Planning, Decision Making, and Volition

Agents, however, should not merely react to the world they find themselves in. They should actively attempt to satisfy goals, execute instructions, interact with other agents, and otherwise change the environment. Since agents are to act in the world they need a way to create, retrieve,

manage, and execute sets of actions. An autonomous agent must have some goal or goals and some mechanism for choosing actions that will lead to those goals. In choosing which actions to perform, the agent model should consider various properties of the actions. Are the actions fallible or infallible? What is the utility of the actions? What do the actions cost in terms of energy, time, money, and the agent's value system? Also, all of the characteristics outlined in previous sections should have an impact on the decision-making process (as should the agent's capabilities and resources). In addition, since most VEs are dynamic, continuous environments, in order for the agents to be realistic and believable, decisions and reactions must take place in real time.

How an agent behaves can be dictated through scripting, by using rules in a rule-based system, by specifying goals that are input to a planning or reactive system, or combinations of these. Scripting the actions of agents results in agents that can only be used for the scenario that they were scripted for. They lack robustness. Using rule-based systems or planning systems can add to the robustness, autonomy, reactivity, and proactiveness of the agent.

Other than scripting and artificial life methods, there are currently three strategies for building autonomous agents. Agent architectures can be deliberative, reactive, or a hybrid of the two. These architectures can include blackboards, rule-based systems, case-based reasoning, finite-state machines, neural networks, genetic algorithms, and virtually any other tool developed for artificial intelligence applications.

6.1.1 Deliberative Architectures

The deliberative model contains an explicit symbolic representation of the world and the agent's actions. In this model, decisions are made through planning and logical reasoning. While these techniques work well on toy domains, it has been found that they do not scale well to time critical, real-world scenarios (Chapman, 1987).

References to deliberative systems include: GPS system (Newell & Simon, 1961); STRIPS planning (Fikes & Nilsson, 1971); hierarchical planning (Sacerdoti, 1974); nonlinear planning (Sacerdoti, 1975); AI planning (Allen, Hendler, & Tate, 1990); Algernon (Crawford & Kuipers, 1991); O-Plan (Currie & Tate, 1991); interleaving planning (Wood, 1993); regression planning (Kurlander & Ling, 1995); hierarchical decomposition (Russell & Norvig, 1995); and abstract plans (Pfleger & Hayes-Roth, 1998).

6.1.2 Reactive Architectures

In order to avoid the limitations of the deliberative model, some researchers turned to a reactive model. The idea here is to create agents that respond to their environment in time for those responses to be useful. Case-based reasoning is where all the expected situations and responses are characterized in advance. During execution, if an existing case is determined to match the current situation, then that case determines the next actions to be performed.

Rule-based reasoning is more robust than case-based reasoning. Rule-based reasoning uses mappings of complex relationships reduced to if-then parameterized production rules. Actions are the result of firing matched rules. Using rules for control may enable certain types of learning (e.g., from examples and possibly by parameter generalization). This model also has drawbacks. Because agents do not have a representation of their environment, there must be enough local information available from the environment for them to determine their next action. Also, the overall behavior of these agents emerges from its reaction to the environment. While this is a selling point for this model it is also a drawback, because it is difficult to determine the behavior of an agent ahead of time. In other words, it is difficult to engineer these agents to fulfill specific tasks. In addition, it remains difficult to construct agents with

numerous and complex behaviors. Reactive systems are usually constructed with finite state machines or situation-action rules that map percepts to actions.

References to reactive systems include: the PENGI system (Agre & Chapman, 1987); subsumption architecture (Brooks, 1991); competence modules (Maes, 1994); Improv (Perlin & Goldberg, 1996); concurrent reactive agents (Costa & Feijo, 1996); JackMOO (Shi, Smith, Granieri, & Badler, 1999); and the L-system (Noser & Thalmann, 1999).

6.1.3 Hybrid Architectures

In order to lessen the problems associated with both of these models, hybrid systems have been created. In these systems the agent is both data-driven and goal-driven. The agents are able to react to their environment while pursuing their own or externally supplied goals. Such systems have a tendency to be specialized to a certain environment. These architectures are normally layered, hierarchical systems. Each layer in the hierarchy deals with data from the environment at a different level of abstraction. Normally the lowest layer is reactive, the middle level layer is knowledge (Newell, 1982) and makes use of symbolic representations, and the highest layer is social knowledge (Jennings & Campos, 1997). Each layer may produce suggestions about the next action to perform. These suggestions are then mediated to ensure coherent behavior.

References to hybrid systems include: touring machines (Ferguson, 1992); RAP (Firby, 1994); 3T (Bonasso, Kortenkamp, Miller, & Slack, 1996); INTERRAP (Muller, 1997); STEVE (Johnson & Rickel, 1997); YMIR (Thorisson, 1998); CML (Funge, Tu, & Terzopoulos, 1999); and PAR (Bindiganavale et al., 2000).

A subclass of hybrid models is practical reasoning agents, which are also known as belief, desire, intention (BDI) agents. The construction of this type of agent is based on the pragmatic reasoning done by real humans. Beliefs relate to what the agents think about their environment. Desires roughly correspond to goals that the agent could pursue. Intentions are the desires to which the agent has committed resources to accomplishing.

References to practical reasoning agents include: the Procedural Reasoning System (Georgeff & Lansky, 1987); practical reasoning (Bratman, Israel & Pollack, 1988); agent-oriented programming (Shoham, 1993); and BDI (Kumar & Shapiro, 1994).

One way to improve an agent's decision-making performance, regardless of the architecture, is to create a layered architecture where each layer differs in level of detail of the action represented. For example, a planner or rule-based system may just decide that an agent needs to walk from point A to point B. The next layer in the architecture might decide the exact path the agent should take. Yet another layer might take care of obstacle avoidance and decide the placement of each footprint. In this way, each layer can be specialized and independently optimized. For more information on decision making, action selection, and agent architectures, see Russell and Norvig (1995) and Jennings, Sycara, and Wooldridge (1998).

6.2 Reflexes and Background Behaviors

There should also be a notion of reflexes, which bypass any planning or decision-making components and directly map situations to actions. These actions should take place immediately after a stimuli is sensed and include both body actions, such as removing one's hand from a hot stove, and facial expressions, such as a look of shock when seeing a pig fly. There may also be a notion of subconscious behaviors, which are actions that are not planned and the agents may not even be aware that they are doing. Many of these actions can be thought of as background behaviors, such as scratching the head, stretching, yawning, tapping nervously, and twiddling

of hair. These sorts of actions do not overtly achieve a goal, but they greatly add to the realism of the character.

6.3 Goal Generation

Goals must also be generated in some way. Logan (1998) discusses some issues associated with agents and their goals, including: the autonomous generation of goals; achievement versus maintenance goals; single versus multiple goals; commitment to goals; utilities of goals; meta-goals (managing the time and resources used to achieve a goal); consistent beliefs; and certainty of beliefs.

Goals normally are created by the user or the designer of the VE in a programming environment. The Parameterized Action Representation (PAR) system (Bindiganavale et al., 2000) allows users to dynamically input immediate or persistent instructions during the simulation, thereby giving new goals to the agents or constraining the way previously established goals are achieved. The user inputs these instructions as natural-language statements. This allows users to dynamically refine the agents' behaviors in reaction to simulated stimuli without having to undertake a lengthy offline programming session. The input instructions can range from specific instantaneous instructions like "Stand up" to very general standing orders, like "Always drive an abandoned vehicle to the parking lot." The natural-language instructions are translated into PARs and then sent to the appropriate agent for execution. The details of how the actions are performed are left up to the agent, which allows a degree of individuality.

Table 15.1 summarizes many of the characteristics of agents and notes increasing levels of complexity for each characteristic. Table 15.2 compares how the complexity of each of these characteristics varies across current agent applications.

7. CONCLUSION

Creating agents for VEs can be a complex task, but when creating agents one should keep in mind what role each agent is playing and therefore where design efforts should be concentrated. For example, if one is creating an agent that will essentially be an "extra" that never comes close to the camera position, time and effort should not be spent creating a detailed appearance for the agent. Likewise, if the role of an agent is to sit on a bench and read a newspaper, there is

TABLE 15.1
Increasingly Complex Characteristics of Agents

Apearance	2-D drawings > 3-D wireframe > 3-D polyhedra > curved surfaces > free-form deformations > accurate surfaces > muscles and fat > biomechanics > clothing and equipment > physiological effects (perspiration, irritation, injury)
Function	Cartoon > jointed skeleton > joint limits > strength limits > fatigue > hazards > injury > skills > effects of loads and stressors > psychological models > cognitive models > roles > teaming
Time	Offline animation > interactive manipulation > real-time motion playback > parameterized motion synthesis > multiple agents > crowds > coordinated teams (time to create movement at the next frame)
Autonomy	Drawing > scripting > interacting > reacting > decisions making > communicating > intending > initiative taking > leading
Individuality	Generic character > hand-crafted character > cultural distinctions > gender and age > personality > psychological-physiological profiles > specific individual

TABLE 15.2
Comparative Graphical Agents

<i>Application</i>	<i>Appearance</i>	<i>Function</i>	<i>Time</i>	<i>Autonomy</i>	<i>Individuality</i>
Cartoons	high	low	long	low	high
Special effects	high	low	long	low	medium
Medical	high	high	medium	med	medium
Ergonomics	medium	high	medium	med	low
Games	high	low	short	med./high	medium
Military	medium	medium	short	med./high	low
Education	medium	low	short	med./high	medium
Training	medium	low	short	high	medium

no need to create a complex goal or perceptual model for the agent. There are times when the simplest solution is the best solution. Similarly, different applications require different levels of concentration in different dimensions of agent design (see Table 15.2). The success of the agent depends on its purpose in the VE, whether it be to entertain, do job training, participate in team coordination, test manufacturing and maintenance procedures, educate, test emergency drills, or just be an “extra.” When the purpose of the agent is to entertain it is often not necessary for the agent to have extremely complex, consistent behaviors. Human viewers have an imagination and will come up with explanations for the agent’s persona, provided that the agent has at least a minimal amount of believability and coherence in its behavior.

However, when complex models are needed one should try to create autonomous agents with reuse in mind. One approach is to create the autonomous agent with as much modularity and parameterization as possible. This will allow designers to more easily adapt agents for other scenarios. For example, if an autonomous agent is created in which emotions, personality, role, status, culture, and other components are parameterized structures that are each modified by a corresponding process (which may reference the parameters of other components during its processing), the decision-making process can then also reference the parameters of the components when it is choosing the agent’s next actions. This structure allows new autonomous agents to be created simply by changing the setting of the parameters and upgrading or modifying the complexity of an agent component by component. Different decision-making processes could be built with varying complexities and tools (i.e., planners, rule-based systems, neural networks, etc.) and then interchanged to create agents with even more individuality. Creating agents with individualized identities makes the VE more dynamic and interesting for the humans that interact with it.

With some architectures and representations it is also possible to incorporate learning (explanation, abstraction, caching, reinforcement, etc.) into agents. This can add to the robustness and naturalness of agents while providing another form of individualization (different learning rates). In order to include learning, some form of memory must be included. Memories can be declarative (I know something), procedural (I know how to do something), or episodic (I remember the event). For more information on learning and memory, see Russell and Norvig (1995).

As Table 15.3 shows, even though there has been significant research on embodied autonomous agents, there are still a number of unsolved problems in agent design and development.

TABLE 15.3
Some Unsolved Problems in Agent Design and Development

Appearance	Real-time, realistic deformations of muscle and skin Real-time modeling of secondary movement of hair and clothing
Animating actions	Blending of actions and action transitions Actions that will work in any context (especially grasping) Actions that express both the cognitive and affective state of the agent
Communication	Real-time lip-synching Real-time robust dialogue planning Expressive, personalized gesture Proper synchronization of the different channels of communication Natural sounding and personalized speech synthesis
Mental processes	Comprehensive model of perception and attention Creation of individuals More comprehensive and integrated model of the mental processes Modeling of ethnicity and culture Modeling of situation awareness and its links to perception, attention, and decision making
Action selection	Systems that are more robust and always real time Systems that are both reactive and deliberative Systems that are easily portable to new domains (the agents have the necessary functionality) Systems that take into account comprehensive mental processes Systems that take into account physiological effects (e.g., fatigue, hunger) Systems that enable agents to be comprehensively autonomous (in reacting, decision making, communicating, intending, and leading)

1. INTRODUCTION

Hosting virtual worlds on the Internet introduces many problems not inherent in private networks. These include security, reliability, speed, and differing agendas of participants. The purpose of this chapter is to review the history and present status of Internet-based virtual environments (VEs) and to discuss a number of efforts designed to meet perceived future needs.

2. INTERNET PROTOCOLS

2.1 The Basics

This section sets the context for the rest of the chapter. It is by no means a thorough journey into the world of Internet protocols. Those wishing such a presentation are referred to Stevens (1994).

Several conceptually simple properties make the Internet work. Its richness comes from building new protocols and paradigms on top of a well-conceived foundation. First, for a computer (host) to participate as one of the many nodes in the worldwide network known as the Internet, it must be assigned a unique Internet protocol (IP) address. An IP address (old form) is a 32-bit number, usually presented as a “dotted-decimal notation,” which includes the decimal equivalents of the four bytes comprising the address, separated by periods. The great popularity of the World Wide Web has resulted in the need for a richer set of addresses. This is being met by a new standard (IPng) that extends addresses to 128 bits, represented by 8 sixteen-bit segments, separated by colons rather than periods.

The IP addresses are assigned statically to hosts that constantly reside on the Internet, or dynamically, from a collection of locally available addresses, whenever a transient host joins the Internet through some server.

Communication on the Internet occurs between two hosts, using their respective IP addresses. Long messages are broken up into shorter packets, source and destination addresses are appended, and the data is effectively and efficiently routed from source to destination.

Basic IP communication is then extended with a very thin layer to create UDP (the User Datagram Protocol). The only thing that UDP adds is the notion of ports and some minimal error checking. Ports are the logical channels through which peer applications communicate. A port is represented by a 16-bit address, with low-numbered (well-known) ports being reserved for standard kinds of interactions, e.g., file transfer (21), time-of-day (13), or Web services (80). Packets associated with UDP communication include the port numbers of the sender and receiver, in addition to the IP addresses of these participants as required in any IP packet.

UDP is employed for very simple kinds of interactions. For example to inquire about the time of day, a user need only send a message (any data will do) to port 13 of a designated host. The sender must establish a local port through which this communication occurs. The recipient will then send a response back to the sender using the port through which the sender started this interchange. The response is, of course, the time of day at the recipient's site.

UDP is inherently unreliable. There is no acknowledgement of the receipt of a message unless the protocol of the service requires a return message, e.g., as in a time service. Furthermore, messages, even when received, may not be in the order in which they were sent. This latter property is a direct consequence of the fact that IP routing can be dynamic, allowing the system to effectively manage load balancing and adjust for lost links in the network. The low overhead of UDP makes it desirable for cases where speed is paramount and some loss or reordering of data is acceptable. Examples of this are streaming audio or video, and a global clock. In fact, streaming audio or video would be greatly compromised by an obsession with reliable receipt; can you imagine the player producing a great silence while it waits for one missed note?

In support of shared virtual worlds, VEs often use UDP when messages need to be communicated quickly, and the effects of lost data are minimal. Examples of protocols built in this way are often called *self healing*. A standard example of this is in the communication of small movements of a character in a virtual world. Sending the new position of an object every time it changes keeps every one's view up-to-date. Loss of a packet of positional information is easily compensated when later position packets arrive in a timely manner.

The Transmission Control Protocol (TCP), or TCP/IP, as it is usually known, builds on top of UDP. This protocol adds, among other things, a sequence number to each message. The receiver uses the sequence number to determine if packets are missed or received out of order. Its obligation is to acknowledge receipt of messages. The sender must retransmit missed packets. The receiver must reorder out of sequence messages.

TCP also extends UDP by being a connection-based protocol. This means that TCP establishes contact and keeps the connection open until some two-way communication task is completed. In contrast, UDP is used for quick exchanges. Writers often equate UDP to letter sending; you may or may not get a response, but you at least let the receiver know your name (port) and address (IP address). TCP equates to phone conversations; you establish a connection, participate in a dialogue, and then close the connection when one of the parties deems it is time to do so.

TCP is preferred over UDP in virtual worlds when losses of messages can create critical inconsistencies in the views of participants. For instance, if I pick up an object and the message does not get to you, you may get frustrated trying to pick up this same object when it is no longer available.

In summary, the Internet moves information in packets of manageable size using the following tools: IP addresses, message routing, ports, and optional reliability. These features serve as the building blocks to support all communication between participants in Internet-based virtual worlds (VWs).

2.2 HTTP Protocol

The HyperText Transfer Protocol (HTTP) is built on top of TCP. This service, running on port 80 of a host, just listens to see if anyone wants to acquire hypertext files from this particular site. When a request comes in, the message within that request specifies what file is to be sent back. The initiating computer is then responsible to interpret the returned file, for example, by displaying text and/or images in a browser's window and by requesting additional data, as required in the page's hypertext description. This simple protocol is at the heart of the World Wide Web.

Note that HTTP is built on top of TCP, not UDP. This is because reliability is critical here; a document with phrases out of order or missing makes no sense. Many Internet-based VEs use HTTP to help participants find and join currently available virtual worlds. Dynamically created hypertext can provide up-to-date information on existing worlds and include the links needed to connect to these worlds. In addition, the advent of Java applets even makes it possible to dynamically provide participants with the most current programs they need to interact with these worlds. Users need never worry about having outdated VE software cluttering their machines because these virtual world engines will be delivered on demand and destroyed when no longer in use.

2.3 RMI, Tuplespace, and Jini

UDP, TCP, and even HTTP are often too low level for the needs of developers of virtual environments. It's not that one cannot build what is needed with these protocols; all Internet protocols are built on top of UDP. It's that developers are often forced to work at the wrong level of abstraction, reinventing interaction protocols.

Many protocols have been developed over the years to support the kind of distributed collaboration required by shared virtual worlds. This discussion will focus on just a few, all of which are currently Java-based, but not Java-dependent. CORBA, the mother of all such protocols, is not addressed, not because it's irrelevant, but only because it is not used in any of the systems herein discussed.

Remote Method Invocation (RMI) is a modern version of Remote Procedure Calls (RPC). RMI is built on TCP, extending it to allow communication between remote objects (software objects distributed across a network) using the standard object-oriented paradigm of messages being sent to objects that respond in ways appropriate to their class identity. In effect, this carries the object-oriented message-passing paradigm into the world of distributed computing, even supporting the transmission of software objects as raw data, followed by the subsequent reconstitution of these objects at the receiver.

RMI is a natural tool for VE developers. With its availability, VE systems can send messages by reference or by value directly to remote objects without having their designers develop arcane, hard-to-understand message passing schemes that turn out to be homegrown versions of RMI. In other words, VE developers are left to concentrate on issues central to their domains of interest, knowing that the existing infrastructure supports object-oriented message passing, even in the context of distributed objects.

Tuplespace is based on the conceptual framework of a globally shared memory (shared among a very large group of computers, potentially including all computers in the world) conceived in 1985 and refined in Gelernter (1991). His simple idea is to allow cooperating processes to write messages onto a global message board. These messages can then be read or consumed (read and then destroyed) by other processes, based on some pattern that matches the form of the original message. *Tuple* is a mathematical term for messages that are comprised of ordered lists of components. One can think of a tuple as a row in a relational database, except that no preordained schemes need to be used. Matching is then a form of “selection” from among those tuples that would “naturally” be organized into the same relational table. The absence of a matching tuple can block the requestor, thus providing coordination as well as communication.

Tuplespace was a theoretically interesting, but not heavily used concept up until very recently. With the advent of Java and its potential to make ubiquitous computing a reality, Sun and IBM, the two big Java players, were each seeking a vision for how data should reside in the massive network of the Internet. Both came to the conclusion that tuplespace is a very appealing option. IBM has developed an API called TSpaces (Wyckoff, McLaughry, Lehman, & Ford, 1998), whereas Sun has developed JavaSpaces (Freeman, Hupfer, & Arnold, 1999). At present, both of these are layered on top of RMI.

Tuplespace, like RMI, offers many benefits for VE developers. It raises the level of abstraction to allow one to think about communication, not with peers, but rather with a shared blackboard. This shared space can serve to communicate state information and coordinate critical activities, all without participating nodes needing to have any explicit information about the locale or even presence of other participants. Multiple tuplespaces can be used to categorize data, provide redundancy, or even maintain a history of all interactions that ever occurred in a virtual community. Such a history can be an archeological treasure, especially if data is maintained in XML, the extensible markup language in which data is marked with domain-specific tags.

Sun has further enhanced the desirability of JavaSpaces by having made it one of the core technologies in its Jini vision of the network as the computer (Edwards & Joy, 1999). The VE community’s interest in Jini can easily be seen from Sun’s own statement (Roberts & Byous, 1999) that “Jini technology provides simple mechanisms which enable devices to plug together to form an impromptu community—a community put together without any planning, installation, or human intervention. Each device provides services that other devices in the community may use. These devices provide their own interfaces, which ensures reliability and compatibility.” If you replace the word device by citizen in a shared virtual community, the relevance to VEs is immediately apparent.

The goal of Jini is to make network computing painless—the service provider and service requestors take care of their own connectivity without human intervention. The protocols by which services are registered and found are key to the Jini vision. The registering of a service is initiated when a provider broadcasts a message seeking to discover a service broker. Jini objects that act as service brokers recognize these messages and report back their willingness to act as intermediaries between the service provider and its potential customers. After a bit of negotiation, the service provider sends information to one or more brokers describing the kind of service and its special attributes. So, for example, an instantiation of a virtual world might announce its availability, indicating that it is a virtual world with attributes of being “social” and focused on “Celtic music.” Those wishing to participate in a virtual world can broadcast a message intended to find a broker who is acting as the intermediary for some virtual world service. This participant can specify required attributes, like “social.” Any broker who “hears” the request will respond with an indication that it can negotiate on the user’s behalf. A successful negotiation results in access to the service, perhaps employing RMI (the service

provides a handle to a remote object) and/or the local instantiation of software objects on the client's machine.

Clearly, Jini and other systems that support directory services provide one part of the solution to helping users find virtual worlds that meet their needs. The very existence of such brokers highlights the need of VE designers to pay close attention to the kind of audience they intend to serve. Some of those considerations are discussed in more detail in the next section.

3. CHARACTERISTICS OF INTERNET VEs

3.1 Lack of a Dedicated Network

The fact that Internet VEs must operate in the wide-open spaces of the Internet has profound effects on their design, and often on their inherent limitations. Three of the primary factors that the Internet influences are speed, reliability, and security. In fact, these three factors often interact with each other in very negative ways.

Consider speed first. Traffic on the Internet does not just slow down message passing; it introduces unpredictability. Experiments in human factors have shown that variations in delays can often be more disconcerting to users than predictably slow performance. This issue of unpredictability becomes more profound as the number and geographical diversity of participants increases, unless the VE is designed from the outset with scalability in mind. Two systems reviewed here, NetEffects (Das, Singh, Mitchell, Kumar, & McGee, 1997) and Bang (Bjarnason, 1999), address this problem in effective, but radically different ways.

Reliability often directly conflicts with speed. For example, using TCP over UDP improves reliability at a cost in speed. One of the VEs reviewed here, DeepMatrix (Reitmayer, Carroll, Reitemeyer, & Wagner, 1999), originally used UDP where unreliability is tolerable and TCP where reliability is critical.

Virtual environment designers often ignore security, although it is critical to the acceptance of some systems (e.g., when they are employed in schools or business settings). Again, as with reliability, security often runs counter to speed. One particularly easy way to provide security is through the encapsulation mechanism of objects. This implies the use of RMI, or some other remote object passing system, adding another layer with its attendant delays to the network protocol. The use of this mechanism can be seen in VRMINet (Reed, Hughes, & Moshell, 1999).

3.2 Device Heterogeneity

The Internet playground was designed to support diversity among participating computers. This platform independence has many sides to it. Some of the most significant variables are computation power, display capabilities, rendering speed, operating system and media support available in the machine being used.

Independence from specific machine architectures makes the Internet more accessible, but it can create a burden on VE designers. For example, to reduce network traffic designers often place computational burdens on all participating nodes, whether they are high-end workstations or low-end PCs. A simple example of this is in the use of "dead reckoning" within ExploreNet (Hughes & Moshell, 1997) and NetEffects. The idea behind dead reckoning, a concept borrowed from the military shared VE Simnet (Calvin et al., 1993), is that detailed movement of objects does not need to be communicated. Approximate positions can be computed locally, so long as each participating node knows the destination or direction of movement of an object, and the speed and perhaps acceleration at which it is moving. The upside of this is a reduction

in network traffic. The downside is that all nodes interested in this object's movement must now consume computational power, including that needed to avoid unintended object interactions (e.g., a character going through, rather than around, a wall).

In general, there is no easy answer to the dilemma of supporting a wide range of machine architectures, but Java platform independence does provide a seductive middle ground, one that is being adopted by many of the newer systems appearing today. This comes with the usual performance penalties one faces when choosing complete machine independence, although that is less of a consideration with "just-in-time" (JIT) compilers.

Supporting a wide variety of display capabilities can lead designers to target their products for either the lowest common denominator or toward only high-end users. Some systems, like ExploreNet, defer the decision to world builders. In this approach, the size of scene background images determines the amount of resolution needed on the displays of participants. Again, there is no "silver bullet" that solves this problem, although the device independence of Java is certainly a great help.

Device independence, however, does not resolve the issue of the diversity of rendering speeds. In many experiments we have run, the rendering component has turned out to be the bottleneck, more so than computational or network speed. The solution to this is generally out of the hands of VE designers, and more appropriately the concern of device and rendering engine designers. However, VE developers often feel forced into making trade-offs between procedural graphical scene description APIs like Java3D (Sowizral, Rushforth, & Deering, 1997), and declarative description languages like Virtual Reality Modeling Language (VRML; Web3D Consortium, 2000). A compromise is to allow VRML to be used for the external description and Java3D for the internal representation. Bang employs such a strategy.

Operating system issues have led some VE designers to abandon diversity and focus on specific platforms (e.g., Microsoft VWorlds group). Again, Java is viewed by many as the savior, especially with its Java Media Framework, which supports a common protocol for existing and projected media objects, and the performance improvements one gets through its HotSpot technology.

3.3 Community Size and Diversity

The Internet community is both large and diverse. Its size factors are ones of geographic separation as well as sheer numbers of potential participants. NetEffects addresses this problem through the use a three-tiered network system, in which participants are connected to a community server, which is in turn connected to a master server. Load balancing and relevance clustering are then used to keep the system responsive over time.

Diversity is an extremely challenging issue. On one level, this means that VEs should be designed with an international audience in mind. An orthogonal concern is accessibility (e.g., for those without sight or hearing). Apple, IBM, Microsoft and Sun, among others, provide APIs and guidelines to address these issues, but there is little actual employment of these standards within VE systems. Accessibility represents one of the most important research issues in the design of human-computer interfaces (Stephanidis, 1997).

4. STANDALONE SHARED VEs

Virtual environment systems developed before 1997 tended to be all-or-nothing, stand-alone packages. Here, the designers determined what features users would get and how they would be provided. Two representatives of this class of systems are described in detail, ExploreNet and NetEffect.

4.1 ExploreNet

ExploreNet was developed by two of the authors (Hughes and Moshell) at the University of Central Florida in 1994 based on the Virtual Academy model. Major revisions were made in 1996 and 1997 as part of an experiment in the Department of Defense Dependents Schools. The premier world hosted in ExploreNet is called AutoLand. Eighth-grade students at Maitland Middle School in Maitland, Florida, authored this, based on the requirements of third-grade teachers in Würzburg, Germany. The world was then used to help third graders understand social science concepts related to the acquisition, transportation and refinement of mineral resources. The software is available from the project Web site (Hughes & Moshell, 2000) as unsupported freeware. Unlike the other environments discussed here, ExploreNet hosts two-dimensional (2-D) worlds, designed specifically to support the constructionist model of learning. Chapter 45 (this volume) provides more information on how ExploreNet addresses educational issues.

A world in ExploreNet consists of a number of scenes. These scenes are connected through portals, although some characters can have behaviors that allow them to teleport. An avatar is always located in some scene. Props start out in a “home” scene but can be conveyed from place to place as possessions of, or attachments to, other objects. Props can also propagate, producing fully functional clones. Figure 16.1 shows a scene from AutoLand. Here, two avatars, Sandy and John (he’s the truck driver) are in the same scene, Pittsburgh. There are three well-labeled portals to other scenes. A truck is attached to John, and a pickaxe is, in turn, attached to the truck. Sandy possesses a sifter. These props move from scene to scene with the corresponding avatars. Communication is through cartoonlike speech lines. Normal communication is visible to all users whose avatars are in the same scenes. Additionally, an avatar can page a single recipient or yell so all can hear.

The ExploreNet environment was developed in Smalltalk. The choice of Smalltalk led to a clean object-oriented design. Unfortunately, Smalltalk did not provide appropriate network and media interfaces, and so ExploreNet’s developers had to build their own. Consequently, ExploreNet does not provide a rich set of mechanisms to address issues of security, nor does

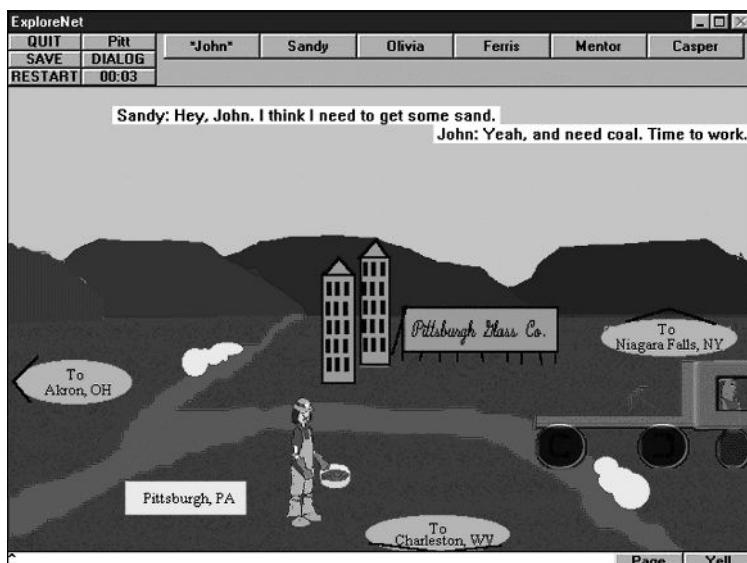

FIG. 16.1. AutoLand: a scene from an ExploreNet world.

it support communication beyond simple textual conversations among participants. Later versions of Smalltalk, like IBM's VisualAge Smalltalk, have addressed these issues, but ExploreNet's future development has been migrated to Java.

Explore Net employs a client–server architecture, but with a twist. The ExploreNet software supports three modes of operation: stand-alone, server, and client. If a user selects stand-alone, no sharing occurs—this case is ignored here. If the user selects server operation, he must then choose a world to offer to potential clients. This user also is a client; in essence, the server spawns a local client who is automatically connected to this world. When a user chooses the client mode, ExploreNet searches the net (using well-known or user selected sites) to find all available world servers. UDP is used here, since the servers need only report back the worlds they are offering. The client then filters the list of offered worlds to include only those for which descriptions are locally available (preinstalled on the client's machine). The worlds that meet these filtering constraints are then offered to the user. When a user selects a world, a TCP/IP connection is made to the associated server. This connection remains open until the user drops out or the server closes the world. The primary features of ExploreNet's protocols discussed below are:

- Affordances
- Ground truth
- Global consistency
- Client dropout
- Historical record

ExploreNet worlds consist of objects and their potential *affordances*. The central objects of a world are its scenes and avatars. Scenes, in turn, possess connecting portals and props. All objects have associated image sets, behavior scripts, and attributes, and can acquire additional images, behaviors, and attributes from their *prototypes*. The prototyping system allows, for instance, a character named Fred to acquire part or all of its behaviors from a prototype called Mentor and another called Human. Fred can, in turn, be a prototype for other characters.

Attributes are specified as names (e.g., `hasChildren`) and associated weights (e.g., 2). Scripts are written in a simple, homegrown, message-based language, with many primitive behaviors from which to build. Each behavior and portal has conditions that must be met in order for it to be active. These conditions can be based on the attributes of any object in the world, and/or the identities of the object, the initiator of the action, or even the relatives (*prototypes*) of any of these characters. The affordances of an object are its presently active behaviors. In addition to selectable behaviors, a world and any of its objects can have automatic behaviors that are triggered any time their conditions are met. These simple mechanisms of conditional and scheduled behavior activation, and conditional portals, along with means to trigger events randomly, make ExploreNet worlds appear to exhibit behaviors that are unpredictable and often interesting.

The evolutionary nature of ExploreNet worlds makes them interesting and useful for problem solving, as well as for quests and social interactions. Unfortunately, the system's primitive support for media, its nonstandard scripting language, and its lack of integration with Web browsers limits ExploreNet's general appeal and usefulness.

Over and above its use of a client–server model, ExploreNet employs several protocols worth discussing. In particular, each client maintains *ground truth* on the avatar(s) it controls. This means that critical decisions about an avatar's state are deferred to the client controlling that avatar, not to the server. However, the server always maintains ground truth on props. This approach is a compromise between the server-centric design seen in typical multiuser domains (MUDs) and the purely distributed approach taken in military distributed simulations.

Messages sent by clients are always to the server who provides *global consistency* to the ordering of events. In fact, clients are unaware of the identity of each other. This approach allows the server to impose an order on the receipt of messages by all clients (recall that TCP/IP is used here). The potential downside of making the server work too hard is alleviated by ExploreNet's protocol, which communicates a complex behavior as a simple message, not as a series of individual primitive actions. It is further alleviated by the fact that navigation is communicated as a destination, with the receiving clients responsible for path planning and actual articulated movement.

A world server expects regular communication from all its clients, and can use the lack of such communication to detect *client dropout*. The clients are correspondingly expected to send brief "I'm alive" messages even when they are otherwise passive. If a server observes that a client has been quiet for too long, the client is sent a "wake-up" message. Whenever a client fails to respond to three consecutive wake-up messages, the client's connection is closed and its avatars are made available to new clients. Similarly, a client expects regular communication from its server. If this fails to happen, the client can recast itself as a server, offering the world, in its current state, to other clients. Of course, that can lead to a world's replication if a server goes down and more than one client chooses to continue the world.

As a world evolves, each client, including the server's attached client, keeps an *historical record* of all messages that have been received. Clients are also free to take snapshots of this history at any time. The complete history, or any snapshot, can be used for retrospective analysis or to restart the world at any point in its evolution. In fact, retrospective analysis can be done from the perspective of any avatar, even with the ability to change the viewpoint from one avatar to another in mid story. Histories also allow late arrivers to a world to see how the world evolved to its current state.

4.2 NetEffects

NetEffects was developed by researchers at the National University of Singapore. The premier world hosted on NetEffects is called HistoryCity (Kent Ridge Digital Labs [KSDL], 1999). This world provides a shared community for 7- to 11-year-old children in Singapore to learn about the history and culture of their city-state. HistoryCity is a virtual Singapore of 1870, consisting of 24 communities complete with historical buildings, costumes, and objects. The software is presently available for download at the Kent Ridge Digital Labs at KSDL, 1999.

A world in NetEffect consists of a collection of communities. These communities have a hierarchy of venues, typically consisting of an outdoor area (e.g., a town square) and a number of buildings. The buildings, in turn, contain rooms. Avatars can move within a venue and from venue to venue based on geographical relationships. Visibility among objects is limited to those in the same venue. Movement can also occur between communities, but there are some limitations on this movement, as discussed below. Text communication is within a venue. Speech communication is a private conversation between any two avatars, whether or not they reside in the same venue or even the same community. Agents are objects in a venue that can provide content, for instance, in the form of stories, jokes, or sound effects, or services like acting as brokers for the exchange of possessions. Figure 16.2 is a snapshot of the Commercial Square venue in HistoryCity, inhabited by citizens and containing many buildings into which these citizens can move.

According to its authors, NetEffect is implemented largely in Java, communicating via TCP/IP. NetEffect employs a client/peer-server/master-server architecture. When a user enters a NetEffect world, she does so through a master server. Based on prior history (e.g., where this user was when she last left the world), the master server selects a peer server that is handling communication for this community, passing its address back to the user's client machine. The

FIG. 16.2. HistoryCity: a scene from a NetEffect world.

client then connects to the community through the assigned peer server. The peer server provides the client with a community description, from which it constructs the three-dimensional (3-D) world. Users can navigate and interact within this community, or move into other communities through visible portals. The primary features of NetEffect's protocols discussed below are:

- Three-tiered networking
- Need-to-know updating
- Group dead-reckoning
- Dynamic load balancing

As noted above, NetEffect employs a three-tiered networking strategy. The center of the network is a single main server. As part of its start-up, the main server starts a number of peer server nodes, usually one per community. It then passes each of these peer servers a community allocation table so that each knows its responsibility. Having all servers aware of the location of every community also enables intercommunity communication.

The master server is also responsible for maintaining the personal databases of all the world's citizens. Since users always start at the master server, this provides a simple mechanism by which these users can resume wherever they left off in the world.

The periphery of the network consists of the client nodes on which users reside. Generally, a client node only talks to the peer node that supports the user's current community. When a user moves from one community to another, the client stops communicating with one peer server and starts communicating with another, unless of course both communities reside on the same peer server. The mechanism's operation is somewhat analogous to the way cellular telephone systems work.

The master server accepts TCP/IP connections on two ports, one for peer servers and the other for clients. A peer server keeps its connections open to the master service for as long as it is online, whereas a client drops its connection once it learns the identity (IP address, port number) of its peer server. Each peer server also accepts connections on two ports, one for other peer servers and the other for clients. Connections made by peer servers are persistent so long as the other server is online. Connections made by clients are broken when the client

leaves or migrates to a community served by another peer. To migrate to another peer server, the client gets the IP address and port number of the new peer server from its current server. This is possible since every peer server knows about all the others. In fact, migration is only possible if the new peer reports that it can handle the additional load.

While this three-tiered network approach is an effective means of supporting NetEffect's goal to scale up to many users, congestion in a single community, and thus on a single peer server, is still possible. One might expect a situation in which all updates must be broadcast to all residents of a community. To alleviate this problem, NetEffect employs *need-to-know updating*. For instance, a user inside a room does not need to hear conversations or see movements anywhere but within this room. When the user leaves the room, information can quickly be passed that reflects the state of objects in the corridor into which the user just moved.

NetEffect also employs a technique called *group dead reckoning*. The idea here is to prevent a continuous flow of positional messages as a user moves throughout a community. ExploreNet uses a destination-based scheme to avoid this, whereas NetEffect uses an interval-based scheme. Users in NetEffect send their positions to their server every C seconds, but only if they have moved. The peer server then accumulates this positional data from each user and broadcasts a composite packet to all group members every P seconds. C and P are parameters with which an administrator can experiment. In the case of HistoryCity, they are set to 1 and 1.5 seconds, respectively. The notion of a group is also flexible. The group could be all users in a community or all users in a venue (e.g., room). HistoryCity uses the former, but NetEffect supports both protocols.

The final technique used to support NetEffect's scalability goal is *dynamic load balancing*. The scheme is rather simple, but effective. The master server periodically checks to see if the world load is balanced across the peer servers. A number of strategies can be employed here, from detailed traffic analysis to just counting the number of attached clients per server. When the master server recognizes an imbalance, it devises a new community allocation across peer servers and initiates the process of reassignment. During this time, all interactions by clients are stopped, so one hopes that this event is infrequent.

5. SHARED VRML WORLDS

Starting in 1997, VE developers switched from creating stand-alone monolithic systems to ones based on plug-ins and Java-enabled browsers. Much of the motivation for this change came from the emergence of the 3-D interactive Web standard VRML97 and its External Authoring Interface (EAI) specifications, which allow 3-D objects to be manipulated by external applications that are not written in the VRML language (Web3D Consortium, 2000).

VRML is based on the mature and powerful scene graph architecture defined in the Silicon Graphics Performer and Inventor technologies. VRML's shortcomings for large virtual worlds are its relatively low performance and the lack of a large body of ongoing development in substrate tools such as rendering engines, browsers, optimizers, and utility libraries. Low performance manifests itself in numerous ways, such as simplistic lighting models, unreliable texture handling, and rapid performance degradation as the world's polygon count increases. Performance degradation occurs because there is no effective continuous level-of-detail or load module control mechanism.

Despite VRML's drawbacks, its provision of an Open API rendering layer and its easy access to Java's rich networking capabilities afforded independent developers the tools needed to implement distributed virtual world systems. Further development of the Living Worlds specification (Web3D Consortium, 2000) provided guidance to anyone who wished to create

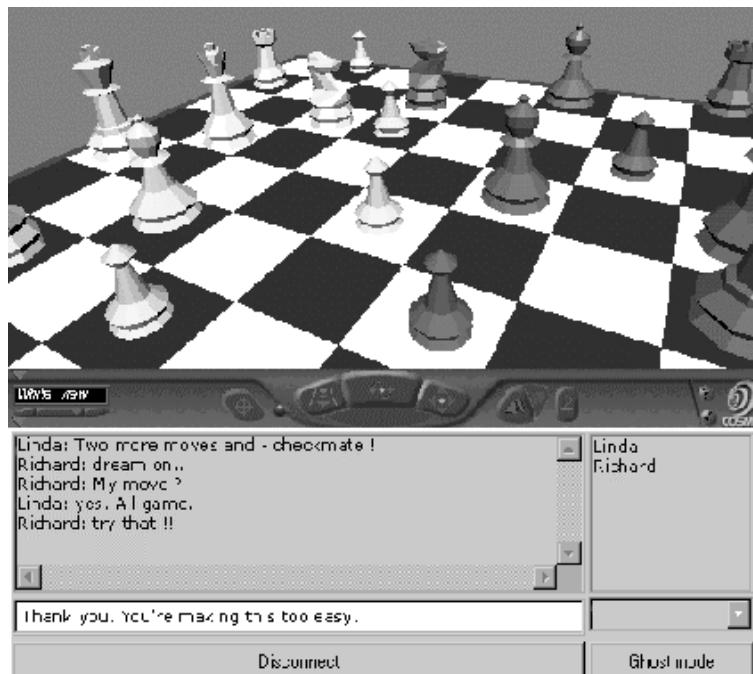

FIG. 16.3. Chess Board: a scene from a DeepMatrix world.

shared VRML worlds. Detailed descriptions are presented of two such systems, DeepMatrix and VRMINet.

5.1 DeepMatrix

DeepMatrix was developed in 1998 by a collaborative team from Vienna University of Technology, Geometrek in Nyon, Switzerland, and Arizona State University (Reitmayer et al., 1999). This system focuses on scalability and is optimized for low-bandwidth environments. It has no particular premier world, so Fig. 16.3 presents an image of a representative shared world in which participants can compete in chess.

DeepMatrix is written in Java, runs as an applet within a Java-enabled browser, employs a client-server model, and follows but does not completely implement the Living Worlds specification. All code is “semiopen” (Geometrek, 2000), with much of it having been previously implemented in VNet, the first publicly available implementation of the Living Worlds specification (White, 1997). The VRML plug-in provides basic navigation and display of the 3-D world. The chat window, list of participants, and the “Ghost mode” and “Disconnect” buttons complete the user interface. Each of these widgets is a standard visual component available in the Java Abstract Windowing Toolkit (AWT). With its simple textual chatting area, this system provides support for games like chess and many other forms of social interaction. The primary features of DeepMatrix’s protocols discussed below are:

- Loading, rendering, navigation
- Room objects
- Real-time communication

DeepMatrix does not handle the loading, rendering, or navigation of a world’s visual components. Rather, VRML code that defines the visual aspects of DeepMatrix worlds is transported

using the HTTP protocol. DeepMatrix just passes information about the location of VRML code for its rooms and client objects by transmitting URLs pointing to VRML files. The VRML plug-in uses HTTP to acquire the files, creates a scene graph from the VRML description, and manages all rendering and navigation. DeepMatrix only requires that some simple changes be made to the VRML file so it can learn about gates (portals to other worlds), objects, and their behaviors, and so there is a “center” point in the world relative to which it can sense and communicate avatar movement to other clients. This requirement to sense movement is a consequence of the fact that DeepMatrix does not provide its own navigator. DeepMatrix also supports two optional fields, *inMotionBehaviour* and *notInMotionBehaviour*, in avatar prototypes. These specify behaviors that are triggered automatically when an avatar is moving or standing still. Their use facilitates articulated motion when the avatar is moving and fidgeting behaviors when it is at rest.

Scalability is addressed on a DeepMatrix system’s server by defining *room objects*. A “room” defines a partition of the entire world, and clients receive messages only from the room that they are in. This partitioning of a single, large VE or several interconnected VEs dramatically reduces the overall messages that a client machine will receive. Partitioning in this manner can also reduce server load since separate machines can be responsible for different rooms.

The transport layer of DeepMatrix was originally a combination of the UDP and TCP/IP protocols. In these earlier versions, the streamlined UDP protocol was used for real-time communications (e.g., state updates of the avatars). Since reporting avatar state changes is the largest single source of network traffic, DeepMatrix’s original use of UDP increased response time and used less bandwidth than a pure TCP/IP session. A TCP stream connection was implemented for control messages (e.g., logging in and logging out), managing of Avatar objects, and passing of chat messages.

DeepMatrix 1.1 incorporates a major change to the transport layer in that it no longer uses UDP, relying instead on a single TCP stream. Gerhardt Reitmayr, one of the authors of DeepMatrix, states that this change was necessitated by differences in Java implementations within different browsers (personal communication, May 12, 2000). Message filtering now removes “stale” messages (ones whose values are superceded by newer updates), in contrast to the UDP approach, which can sometimes flood a network with very small incremental updates.

5.2 VRMINet

VRMINet is a system developed in 1999 at the University of Central Florida (Reed et al., 1999). The name “VRMINet” is based on VRML + RMI (Remote Method Invocation) and also reminds one of the occasional use of “vrmin” as a humorous and somewhat pejorative term for geeks who have access to no professionally supported graphics systems. However, the choice of VRML in VRMINet was not driven by lack of alternatives, but by a desire to adhere to a component-based technology, wherein the descriptive language of VRML can be retained while the rendering component might later be replaced.

The premier world hosted in VRMINet is “Caracol Time Travel.” This world was authored by an interdisciplinary group of 18 undergraduate students. The team spent two semesters designing and constructing an interactive drama-based educational role-playing game. The game is fashioned after an actual Central American archaeology project being carried out in Belize under the supervision of Diane and Arlen Chase (Caracol, 1999). The game was designed to teach basic concepts of archaeology and facts about the life of the ancient Maya, to a target audience of middle school students.

A world in VRMINet is a shareable VRML world with Java implemented behaviors. Figure 16.4 shows a scene in the Caracol world with three avatars (Ana, Pedro, and Dr. Smith). Participants are in a cave found at the site, studying a 3-D map of the ancient city. In addition

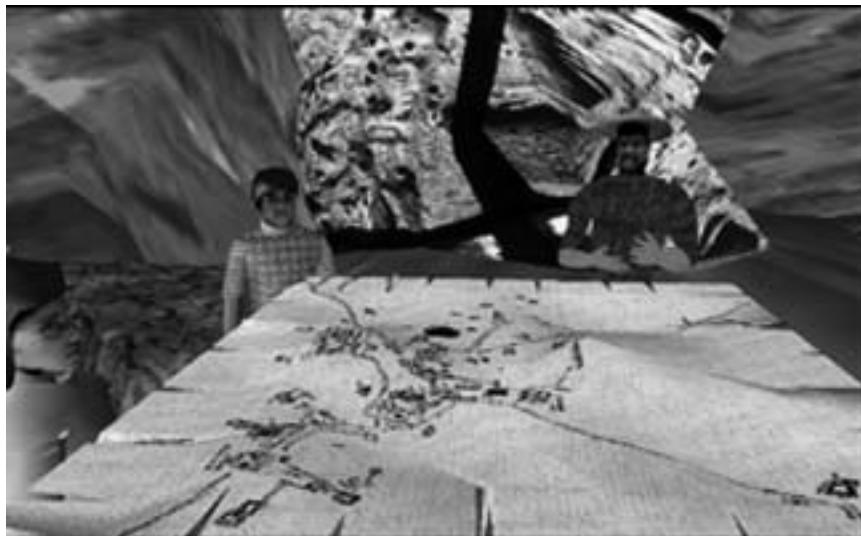

FIG. 16.4. Caana in the modern-day city of Caracol: a scene from a VRMINet world.

to the avatars, this scene is populated with many artifacts that have autonomic behaviors triggered by actions and/or states of the participants. One of the most complex behaviors in the Caracol world involves a flight by a Toucan, with all the avatars being dragged along for the ride from modern times at the archaeological dig into classic Maya times.

VRMINet is written entirely in Java. Software is available for educational use at Reed et al. (1999). The server is a Java application, whereas each participant merely references an html page that contains the client applet. Thus, the standard HTTP Web protocol is used to find a world. A user logs in, selecting a role to play in the world. When log-in is successful, the VRML scene and a Java applet dashboard are displayed. This dashboard allows many forms of interaction, but is not needed for basic navigation and thus can be minimized at any time.

Initially, the user is controlling the position of the avatar that was selected and seeing the world through its eyes. If the “out of body” button is clicked, this stations’ viewpoint is detached from its avatar and can be pulled back to get an over-the-shoulder view, or maneuvered in such a way as to frame any desired view of the scene. The same button toggles the viewpoint back into the avatar.

An “online users” window provides the user with a list of the other humans in the world. The available sound menus contain, respectively, sound effects (or utterances such as “Hey!”), and short canned speeches (if desired). An “available gestures” menu selects behaviors a participant’s avatar knows how to carry out. A “free bodies” window lets participants take into their possession any available objects in the scene. The primary features of VRMINet’s protocols discussed below are:

- Behavior authoring
- Client–server architecture
- Distributed leases
- Remote method invocation
- Performance

Selecting a free object (which is not an avatar) in the scene either triggers an automatic default behavior or opens a menu, listing the optional behaviors one can specify for this object. This control is very similar to that provided by ExploreNet. However, *behavior authoring* in

VRMINet is very flexible, allowing any combination of VRML routes, VRML Script nodes, and Java methods to define behaviors. The component nature of this system even allows other scripting languages to be employed. In fact, JPython (a Java friendly variant of Python) has been successfully (actually effortlessly) used in several experimental worlds.

VRMINet employs strict client–server architecture. While this is necessitated by Java’s security model, it also provides the message-ordering benefits discussed while describing ExploreNet. Thus, all clients receive messages in the order that the server handles them, and all clients have the opportunity to process these messages in the same order.

Ground truth in VRMINet is implemented through the concept of *distributed leases*. Java 2 (JDK 1.2) introduced the idea of leased resources in a Java network environment. The notion is similar to a landlord and tenant lease agreement. The landlord (server) grants the tenant (client) a lease on his property (behavior) if it is available. At some point in the future, the lease expires and the tenant and landlord must renegotiate the lease or the property (behavior) is no longer in the hands of the client. The client must vacate the property (stop executing the behavior) and regain the lease before taking possession of the property again. There are no guarantees that the lease will be renewed once it has expired, so the tenant should be ready to give up ownership of the property at any time.

Most IP-based shared virtual world systems are optimized for scalability and network performance only. These systems implement TCP/IP and/or UDP network communication with socket bases and a rigid protocol. The result is a highly scalable but inflexible system that requires protocol extension on client and server components anytime new features are added.

The Caracol project (the driving force behind VRMINet) required extensibility and flexibility, was operating in an environment supporting high network speed, and was willing to sacrifice scalability for the sake of the educational experiment. RMI was chosen as the transport layer due to its acceptable response time and flexibility. RMI’s primary attractiveness came from the fact that it distributes objects among connected computers without the need for protocol extensions or explicit serialization. Serialization is the flattening of an object that makes it easy to transport across a network and then reconstruct at the receiving node.

Much concern over the network performance of VRMINet was raised during the initial trials with the Caracol project. Player avatars seemed to suffer from network delay when a large load was placed on the system. Observation later showed that delay in the system is largely related to rendering speed on the machine hosting a given client, and to the ways the networking architecture and browser generate motion events that have to be rendered.

Allocating more CPU time to the rendering thread and running the VRML browser under optimal display speed conditions gained some minor performance boost. Further improvement was realized by decreasing the granularity of message passing for movements. On fast machines, the VRML browser produces a large number of movement events for trivial moves. It was observed that for a move of 1 meter, some fast machines could produce over 50 messages that in turn must be sent across the network, executed by the receiving object and then rendered on the video display card. By reducing the granularity of motion, VRMINet decreases the total number of messages passed on the network and thus reduces the number of rendering calls to the receivers’ browsers.

Major degradations in performance were noticed in worlds that were built using extremely complex structures or overabundant simpler structures. The VRML browser uses a great deal of resources when complex models are displayed, which leaves very few resources for the Java Virtual Machine (JVM) to execute. Continuous garbage collection can cause undesirable performance from the JVM, and hence the VRMINet system. Fortunately, Sun’s HotSpot continuous garbage collection technology has made this a nonissue. Nonetheless, best results were obtained from worlds that were optimized by polygon count, model count, and

texture complexity. Optimizing on these criteria resulted in performance boosts for the overall system.

6. THE FUTURE-COMPONENT-BASED VEs

Modern VEs have broken away from the monolithic, all-or-nothing closed systems described earlier in this chapter and have moved toward a component-based architecture. VRML, and its ability to plug-in to Web browsers, started this evolution. Strangely, this model (which provides no economic incentive for the construction of efficient plug-ins) may lead to VRML's own demise, or at least its relegation to a role as a scene description language, but not a renderer or navigator.

Properly designed VEs can and should allow different rendering systems to be “swapped” for the default system. For example, a system could support external scene description in pure VRML, but internal representation in Java3D. This design requires that the underlying state objects, which represent the 3-D on-screen objects, be loosely coupled with the rendering layer. Another requirement is that the 3-D content be specified in file formats that all available rendering layers understand.

Just as with the rendering layer, the network transport layer can be treated as a pluggable component. This means that raw UDP and TCP/IP might be used in some circumstances, and remote method invocation or even tuplespace in others. The choice will depend upon the requirements of the world and the characteristics of the network environment.

Two systems will be briefly discussed that are representative of component-based VEs, VRMINet (a second visit) and Bang.

6.1 VRMINet Revisited

VRMINet is an example of a VE that supports shared VRML worlds. That categorization, while correct, understates the component nature of this system. VRMINet really has no dependence on standard VRML rendering—its rendering component could easily be replaced. However, from another perspective, the renderer doesn't care about the network transport layer; it just wants to know about transformations and changes of viewpoint that occur. In fact, the system doesn't even depend on its current authoring tools; it was previously pointed out the ease with which JPython was incorporated as a scripting language.

6.2 Bang

Bang (Bjarnason, 1999) is a Java-implemented VE that can read VRML descriptions but maintains complete independence from VRML plug-ins. In fact, its internal scene graph representation is in Java3D, allowing content to be provided in either VRML or serialized Java3D. Bang is also one of the first VEs to use Sun's Jini to support the discovering and sharing of worlds. The persistent state of each world is maintained in a tuplespace, using Sun's JavaSpaces implementation. Basic communication is still done using open source from the DeepMatrix and VNet Living Worlds specification implementations.

Bang's use of JavaSpaces provides both persistency (world objects stay around after their creating processes leave) and scalability. The essence of Bang's approach to scalability is to divide the world into $100m \times 100m \times 100m$ -sized sectors that are used for loading and unloading objects and geometry. As a user moves from sector to sector, his client registers its presence in the new sector and unregisters its presence from the old one. Notifications of changes in geometry are only sent to those clients registered in the sector in which the change

occurred. This approach is in sharp and obvious contrast to other VEs that manage large spaces through logical scenes or communities and portals, rather than physical regions. Bang also allows users great flexibility in their choice of sound and speech engines. It merely requires that chosen components implement the appropriate services defined in Java's Media Framework.

7. A FEW MORE SYSTEMS OF NOTE

Any page-limited review of IP-based VEs is destined to leave out many systems worthy of detailed study. We are clearly guilty of this crime of omission. The following are just a few of these systems. Readers are encouraged to pursue further study (and recreation) by following the leads provided below.

7.1 Noncommercial Systems

All but one (NetEffects) of the VEs previously discussed are free, noncommercial systems. Such software typically comes from universities or small groups of diehard developers. Free software, of course, comes with its risks. Over the last decade, most of the giveaways have died away, leaving their users feeling deserted. The recent trend of open software, in which users have access to the source code, as well as executables, is breathing new life into these systems. For instance, VNet, a student project at the University of Waterloo, has not been updated for several years, yet its code is still alive within DeepMatrix, VRMINet, and Bang. Among the many other systems that now provide open source, two are highlighted below, Bamboo and Virtual Worlds Platform.

7.1.1 *Bamboo*

Bamboo was developed at the Naval Postgraduate School, based on its many years of experience in the development and deployment of VEs (Singhal & Zyda, 1999). The goal of this system is to serve as an extensible environment using a generalization of the plug-in metaphor, whereby each plug-in can declare its interdependencies, triggering the loading of required cohorts. Bamboo is in effect a host for new VE technology and a VE system, in that it provides default components built on top of a very lightweight kernel. The ADAPTIVE Communication Environment (ACE), an open-source framework that implements design patterns for concurrent communication software, provides the networking infrastructure for Bamboo. The communication software tasks provided by ACE include event handling, signal handling, interprocess communication, shared memory management, message routing, dynamic (re)configuration of distributed services, concurrent execution, and synchronization. Using ACE, Bamboo can employ unicast, multicast, and broadcast message passing to build complex protocols, including HLA, the military "high-level architecture" for distributed interactive simulation. In this regard, Bamboo is the only one that addresses the needs of virtual worlds that must be physically correct.

7.1.2 *Microsoft VWorlds*

As in other areas of Internet computing, Microsoft has a major presence with both VE products and active research. The heart of this research is Microsoft's Virtual Worlds Group, which has developed a number of engaging virtual environments, ranging from the playful ComicChat to the experimental VWorlds system (Vellon, Marple, Mitchell, & Drucker, 1999). The latter VE integrates seamlessly with Internet Explorer and includes a suite of wizards for avatar and world creation. It also employs a novel event handler that automatically propagates

event notifications to an object's contents (e.g., the passengers in a car), container (e.g., a scene), and peers (e.g., other objects in the scene). Source code, executable binaries, and sample worlds are available at the organization's Web site (Virtual Worlds Group, 2000).

7.2 Commercial Systems

The commercial world of VEs is a brutal one, where a typical system has a very short life span, occasionally followed by a reincarnation as a very specialized product. Some go on forever in a state of limbo, in the sense that they have a Web page but no content. Two of the survivors in this commercial arena are Active Worlds and Blaxxun.

7.2.1 *Active Worlds*

Active Worlds provides a free browser, with additional privileges afforded to those who register for a nominal fee. Its server technology requires payment based on intended usage (personal or commercial) and intended size in inhabitants and virtual land. The main Active Worlds server hosts over 600 well-traveled virtual worlds, including a shopping mall. The granddaddy of these is AlphaWorld, with over 700,000 users and almost 50 million objects (sizes mentioned here are current as of February 2000). The AlphaWorld territory is slightly larger than the area of the state of California, and growing (Activeworlds, 2000).

7.2.2 *Blaxxun*

Blaxxun also provides a free viewer, which is in fact a shared VRML browser that can be used as your primary VRML plug-in. Server and software development technology can be purchased. The primary world hosted by Blaxxun is called Cybertown. As with AlphaWorlds, there is a large virtual space for users to colonize. The metaphor to a real community is strong, in that citizens can develop unique identities, own homes and other possessions, organize activities, and, in general, go about the business of virtual life (Blaxxun, 2000).

8. CONCLUSIONS

This chapter has reviewed a number of shared VEs designed to interoperate using standard Internet protocols. We have not attempted to be complete, but rather to cover a number of contrasting systems, highlighting features that make them interesting objects of study.

Those wishing more detail are encouraged to visit the Web sites referred to herein. Of course, as with all things ephemeral, we cannot guarantee that these sites will still be alive and up-to-date if you try to access them years (or even months) from now. So, enjoy yourself, but come with a sense of humor and patience.

1. INTRODUCTION

1.1 Background

Little systematic attention has been paid to the way in which virtual environments (VEs) should be designed. This may be because most early VEs were “proof of concept” demonstrations (with fairly crude object representations), entertainment games, or usability test prototypes. The first category, demonstrations, were produced at great speed, often by trial and error, to sell the idea of VEs to potential user organizations. Little time or thought was given to defining the development process. Often the VEs and development processes used were commercially or militarily confidential, and therefore publication was not an option. Second, VE games were often based on other computer games, and in any case their developers had no scientific reason to publish anything on their design and development process and had good commercial reasons not to. No published accounts therefore exist (although see the note on games development in the next paragraph). The third category of early VEs, simple usability test prototypes, allow ergonomists and psychologists to experiment with various aspects of the virtual experience and with factors of VE usability. Again, there would be little need for, or thought given to, the VE design process.

There is now some research under way that should lead to useful guidance on the whole VE development process; accounts exist which cover some of the development cycle (e.g., Grinstein & Southard, 1995; Green & Sun, 1995; Loftin, Bartasis, & Johnston, in press). Guidance on design for VE usability has been published, for instance from groups at City University in London (e.g., Kaur, 1998; Kaur Deol, Sutcliffe, & Maiden, 1999), at Virginia Polytechnic (e.g., Gabbard, Hix, & Swan, 1999; Hix et al., 1999; chap. 34, this volume) and chap. 46, this volume, at University of Nottingham (e.g., Neale, 2001; Tromp, 2001; Tromp & Fraser, 1998; Tromp et al., 1998a). Notwithstanding the somewhat anarchic nature of the PC

games software industry, and especially the unstructured nature of their development alluded to above, there are moves to better understand best practice in games development. *Game Developer Magazine*, and especially its online archive at www.gamasutra.com, is a useful source of contributions. These are mostly at the level of general principles but do have content of relevance to VE development, to do with overall style, characters, levels of environment, menus and other interface elements, use of sound, animation, and the artwork.

Even recognizing the contributions identified above, much work of VE specification, building, and testing is characterized still by a lack of guidance across the whole process. Systematic guidance for VE development would reap dividends in terms of a more efficient design process and more functional and usable virtual environments. The allocation of limited processing resources, the nonintuitive nature of (most of) the physical interfaces, and the limits that must be applied in deciding what aspects of the real world to model are all issues that must be addressed within a structured VE development framework.

To some extent, VEs could be developed following design process guidance for any human-machine system or human-computer interaction (HCI), of which there are vast numbers (e.g., Newman & Lamming, 1995; Sanders & McCormick, 1993; Sutcliffe, 1995; Wickens, Gordan, & Liu, 1998). However, the effort required to model objects and actions of the real world and the nature of the cognitive interface (the participant being "within" the database) mean that VE development also requires guidance specific to its own special characteristics and needs. In any case, guidelines and models within the human factors and "conventional" HCI communities are notorious for not always being useful or usable by designers, engineers, or even ergonomists. Acceptable and useful guidelines to design for usability are not easy to produce in ergonomics generally. Designers might, of course, draw upon any similar development guidance in simulation design, but VE design has sufficiently different attributes and purpose for its own structured development framework and associated guidelines to be needed.

This chapter starts by describing such a framework—VEDS (the Virtual Environment Development Structure)—and subsequently expands in some detail upon its major stages of analysis, specification and storyboarding, building VEs, enhancing user performance, presence and interactivity, usability, and evaluation. Within the chapter the focus is on the third type of design as defined by Bolas (1994), namely design *of* VEs, in contrast to design *with* VEs (e.g., solving design problems) or design *for* VEs (VE system improvements); "design of virtual environments is perhaps the most exciting and challenging VR design task" (Bolas, 1994, p. 53).

The chapter is largely focused on VEs that model and give experience of interacting with a device, or that allow exploration of a space such as a factory or dwelling. Therefore the sorts of VE used for stress analysis or as a virtual wind tunnel, for instance, are not covered in terms of the engineering models on which they build. Nor are very large geographical representations addressed, for instance, as used in landscaping projects, harbor navigation, or city planning. Furthermore, support of groups of participants in collaborative virtual environments (CVEs) is not explicitly addressed. Many of these issues are taken up elsewhere throughout this volume (see chaps. 12, 14, 25, 34, and 41).

1.2 Barriers to VE Applications

In a United Kingdom (U.K.) research council–funded program of work from 1994 to 1995, examining potential industrial application for VEs, we collaborated directly with about a dozen U.K. companies and surveyed, in varying degrees of depth, over 250 more. Despite considerable enthusiasm for the potential of the technology (in planning, design, training, and layouts), internal "marketing" demonstrations, and exemplar VEs built by outside research or consultant teams, were the only industrial VE applications found (Wilson et al., 1996). This picture is confirmed by the authors in repeat exercises carried out from 1997 to 2000, and,

despite some optimism from the German motor industry, in other sources (e.g. DTI, 1996; Financial Times, 1994; SUSECA, 1998). Across the world, there are few if any working applications of VEs built that have replaced another technology or are doing something new.

From work with potential users, four barriers have been identified from the state of VE technology, which meant that most companies were not then (1994–95) expecting take-up of the technology for at least another three to five years. The barriers were defined as: “technical” (particularly integration with other technologies and the implicit technical trade-offs in data processing); “usability” (the nonintuitive nature of the interfaces, both hardware and software, see chap. 34, this volume, and concerns about possible side and aftereffects, particularly with head-mounted displays [HMDs], see chaps. 30–32, this volume); “applications” (the paucity of serious applications working for real, and available for inspection); and “evaluation” (the poor evidence of added value from VE application; for some notable exceptions see chaps. 42–55, this volume).

Although the barriers were, and still are, real ones, they are not insurmountable, given likely VE technical developments over the next few years and assuming careful selection of appropriate applications. Potential industrial users raise the difficulty of effective data input and output and systems integration more frequently than any other, so this may be the key to mass industrial use. It is currently the focus of urgent development. The paucity of salient working demonstrations of VEs and poor evidence of added value from good quality evaluations was summed up by one manufacturing engineer attending one of a number of hands-on demonstration workshops we have run for industrialists (see Wilson, Cobb, D’Cruz, & Eastgate, 1996, p. 119): “I can’t even begin to discuss use of VR sensibly with them [company engineers and decision makers] unless they sit with it, try it, use some worlds they can relate to.” The needs for evaluated demonstrations of applications are related to the need for a structured methodology to guide application identification, building, and evaluation against operational criteria. Some means of assessing the usability of VE technology is required, embracing utility, usability, likeability, and cost, and addressing system integratability (with other technologies and company functions) or organizational usability. The last criterion, organizational usability, relates to the integration of VE with other technologies and to how VE changes existing company strategies and groupings.

To the four original limitations or barriers one can add a fifth, resulting from and leading to some of the others: the lack of a structured methodology by which organizations might establish a potential need for a VE solution, and then specify, develop, employ, and evaluate VEs in real applications. All five barriers are being addressed in the current large European Union Funded research project, “Virtual and Interactive Environments for Workplaces of the Future” (VIEW-project no IST-2000-26089).

2. VEDS—VIRTUAL ENVIRONMENT DEVELOPMENT STRUCTURE

Development of any product or system, including setting appropriate requirements and specifications, will be aided by guidance from a clear, flexible framework that defines what issues are relevant, what data and information are needed, what decisions must be made at what stages, and how these stages interconnect, including feedback loops and iterations. The human factors/ergonomics community is clear on the need for a process or framework to be established. Only in this way can early design decisions be taken to improve the usability, likeability, and general acceptability of a product or system in enough detail in order to influence the final outcomes. Virtual environments are no different than any other product, system, or human-computer interface, in that their development needs clear goal setting and constraints,

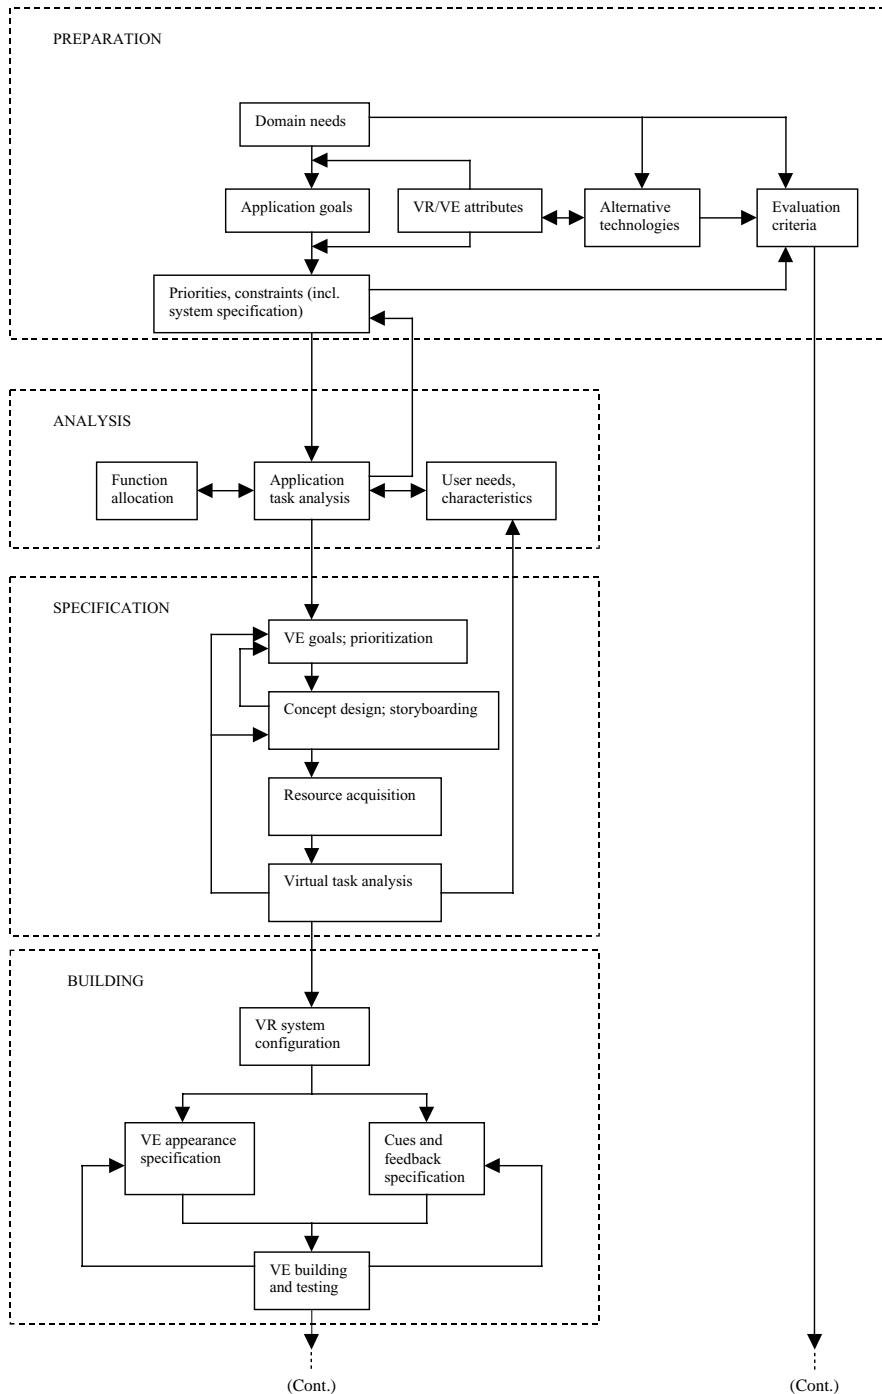

FIG. 17.1. VEDS: Virtual Environments Development Structure (adapted from Wilson et al., 1996, and Wilson, 1997). Note: Only major feedback loops are shown, for clarity; in fact, the whole process is an iterative one.

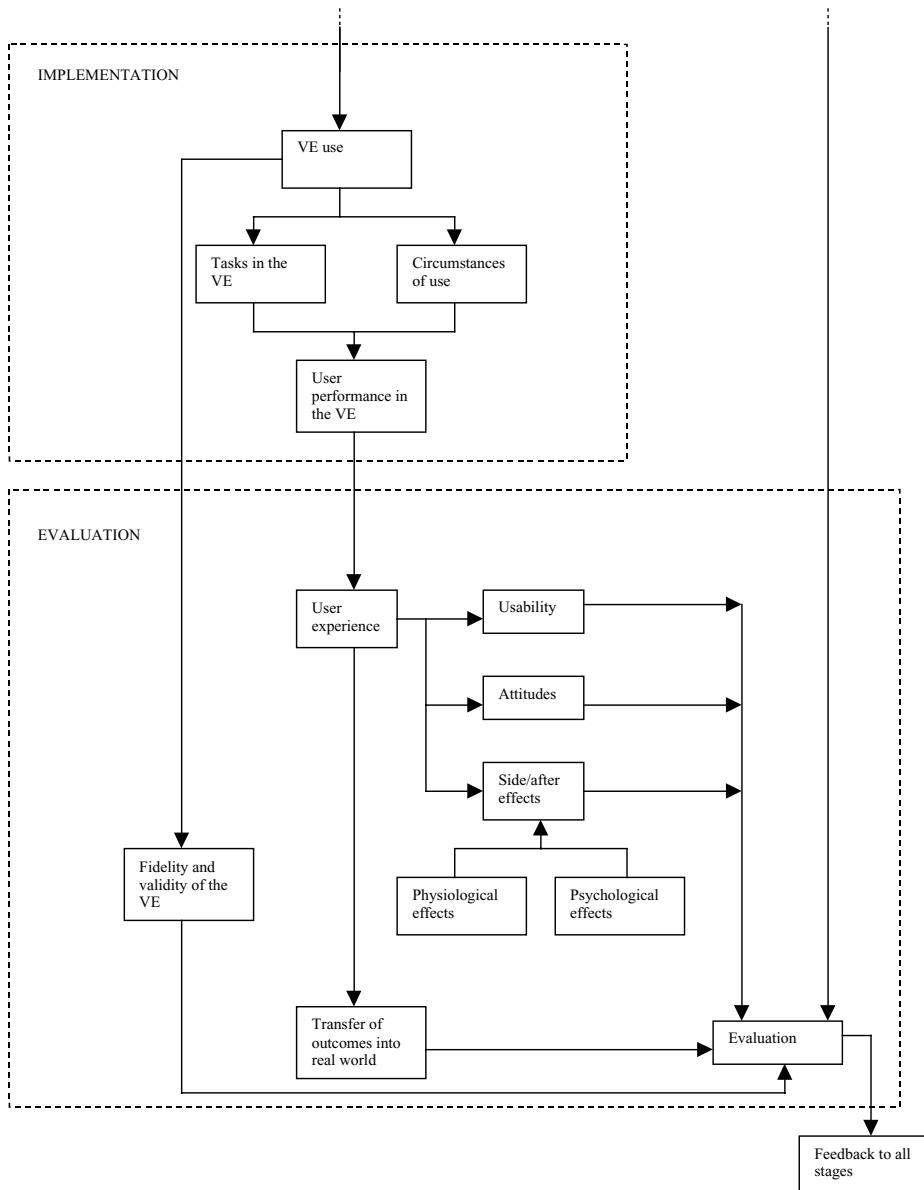

FIG. 17.1. (Continued)

requirements analysis, task and user analyses or models, appropriate interface guidelines, predictions of task performance, an iterative design/test cycle, and a clear evaluation process.

Over a number of years we have worked with potential users of virtual environments in industry, medicine, and education to produce a structured framework to guide VE development—the Virtual Environment Development Structure (VEDS). Various generations of this framework can be found in Wilson et al. (1996), Wilson (1997), and Wilson (1999). The current version is shown in Fig. 17.1. Before discussing VEDS, two points should be made. First, as drawn it appears as if only a top-down approach is suggested. Although a structured development process is perhaps best suited to top-down working, it is recognized that certain aspects of development will need to take place bottom-up. Bryson (1995) terms these as *design for the task*

and interface metaphor (top-down) and design for performance (bottom-up). Second, only the main feedback loops are shown, but this is for clarity in the diagram. The whole process is iterative, embracing formative and summative evaluation and a design morphology as the VE (and test methods) becomes more sophisticated through design cycles within the process.

The key stages of VEDS are described in the rest of this chapter, but the whole process is summarized here. At the outset, a clear view of the attributes of VR/VE (what they are ready for and what not) and knowledge of the domain are needed to obtain agreement on goals for the application and to identify likely priorities and constraints. Considerable effort in task and user analysis and in function allocation (for instance, when it is preferable for the VE or intelligent agents within it to control a participant's options or actions) will pay off later in improved concept, prototype, and final design. Technical and systems limitations can be reduced in their effects on the application by appropriate choice of technology in the light of a task analysis, and by goal-oriented- and user-need-based world building. Concept design must be rational, realistic, and parsimonious, rejecting any elements not important to the core application goals and to support user performance. World building will involve choices of whether to provide the participant with extra functionality or higher levels of complexity and appearance of the environment. The number of objects modeled, and their level of detail and degree of associated intelligence, must also be considered carefully before including them within the virtual environment. As with any product or system, the participants' performance within the VE will be determined by the environment itself, personal characteristics, tasks to be performed in or with the VE, and the circumstances under which those tasks are carried out (for instance, without training, under time pressures, or with incentives). A virtual task analysis, which may build on the real-world task analysis carried out earlier, can support decisions within VE building. In addition to participants' performance within the VE and behavior with the VE system interface, subsequent outcomes might be manifest in the transfer of the participants' effects upon the real world (for instance, measured as design process effectiveness, better product designs, or training program efficiency), their reported and observable experiences, and any health-and-safety-related side effects. At the outset, when defining the application and activities, alternative solutions that do not employ VEs should be identified, and evaluation methods, measures, and criteria set. Although the evaluation may be somewhat crude at times, it must be carried out to assess the success of the VE in meeting its goals, examining both individual and organizational effects against the evaluation criteria.

In the rest of this chapter the different stages of VEDS are discussed, with particular emphasis on structured analysis, specification and building.

3. TASK AND USER ANALYSIS

The early process of VE development to meet the needs of users should differ little from that normally followed in ergonomics, namely to: (1) assess what tasks must be completed in the VE and in the real world subsequently; (2) determine what the user characteristics and needs are; and (3) produce a task analysis (or often synthesis, because these frequently will be new endeavors). Such a process should allow the client and the developer of the virtual world, together with the ergonomist or psychologist, to specify the goals to be achieved by the virtual environment. Preferably these goals should be prioritized, because only rarely can all be attained.

The classic starting point for application of ergonomics in systems design, following specification of goals and constraints, is the task and user analysis (Kirwan & Ainsworth, 1992). In developing VEs, if the intention really is to enable cognitive (if not always physical) replication of interaction with the real world, then the task analysis will be carried out twice, once for the

actual tasks being modeled—the *application task analysis*—and secondly for the tasks to be carried out within the VE—the *virtual task analysis*. The first of these is axiomatic for human–machine systems development to understand what tasks must be carried out within the domain where the system will be used and the requirements or constraints this will impose upon the people involved. Such early task and user analysis will then enable decisions to be made about:

- Whether VE technology even has a role for the particular application and what alternative technologies there are
- Which functions within the application will be supported by using VE technology (in many applications a mixed setup, comprising virtual and hard elements, may be appropriate)
- How VE technology will be integrated with other technologies if there is a mixed environment
- How eventual use of the VE will be evaluated in terms of direct and indirect outcomes and effects
- Which VE system (hardware and software) is most appropriate for the tasks, task environment, and user group
- What elements of the real world and tasks should be included in early specification of the VE design

Some of the development decisions that might emanate from the task and user analysis are shown in Fig. 17.2 (see also Gabbard & Hix, 1997; chap. 34, this volume). Some of the decisions implied in Fig. 17.2 may not be possible at this early stage and their resolution may depend upon the virtual task analysis that is carried out later.

There are two distinct fundamental approaches to account for the user in VE development that relate to the philosophy of VE itself. These are “*VE as an alternative real world*” and

Degree of ‘reality’ desirable: real world replication, highly abstract
Type of presence: egocentric, egocentric
Participants: one, few, many
Temporal collaboration: none, synchronous, asynchronous
View of scale: close-up, arm’s length, room sized, far horizon
Vision: monocular, bi-ocular, stereoscopic
Manipulation: none, one-hand, either hand, both hands, whole body
Virtual tool provision: none, separate palette, within the VE
Resolution: coarse, fine
Mobility: stationary, ground anchored, flying
Control: passive, active presentation of scene
World state: transient, persistent
Sensory cues: visual, auditory, haptic, olfactory

FIG. 17.2. Development decisions made on the basis of application task analysis and virtual task analysis.

“VE as computer interface.” Virtual environments can be treated as alternative representations of “real worlds,” and existing knowledge, models, criteria, and methods can be applied as appropriate. There are a number of problems with this approach. First, there is little agreement about the meaning of such concepts as spatial awareness and perception in the real world (e.g., Flach & Holden, 1998), let alone in a virtual one. Second, even if the software could provide a strong representation of equivalent perceptions in the real world, the peripherals that people need to experience the VE currently interfere with this parallel. Third, there is still considerable confusion about the underlying psychological mechanisms and processes involved in the use of virtual environments, and whether and how these might be similar to those in the real world. For instance, what is a sense of presence (see chap. 40, this volume), and is it equivalent to or related to attention (Zahorik & Jenison, 1998)?

The other approach is to treat the VE as simply another, if potentially richer, computer interface and apply existing HCI knowledge, models, criteria and methods. Again, there are a number of problems with this approach. The state of knowledge and coherence of the HCI field itself is open to criticism, and it is arguable that HCI as a discipline has already struggled to redefine itself, first with the almost universal move from command line to graphical user interfaces and then with the growth of various multimedia interfaces. Is HCI knowledge ready to be applied to virtual environments, especially those where a participant is navigating across the interface and within the VE itself? There are a large number of technical variables which are specific to VEs and not relevant to work elsewhere in HCI, including the impact of temporal lags or problems with the optics and field of view of HMDs (see chap. 3, this volume) and which leave developers with trade-offs between potential attributes of complexity, pictorial realism, and speed of update. Therefore, although VE developers and researchers might build on the 30 or more years research in HCI, any such models, criteria, or knowledge must be used with care. Their applicability needs testing by careful research.

The task analysis phase of development provides information, ideas, and a set of requirements on which to base conceptual design and VE specification and is covered in the next section.

4. SPECIFICATION: CONCEPT DESIGN, STORYBOARDING AND VIRTUAL TASK ANALYSIS

4.1 Basic Concept Design

The analysis phase will leave the development team in a position to prioritize the goals for the VE implied by the application goals. Some basic choices as to the structure and functionality of the VE might be made, in the light of the computer processing limitations for candidate VE systems and on the basis of the application task analysis and the virtual task analysis. (Note: Virtual task analysis is defined in Fig. 17.1 as occurring at the end of the VE specification phase. In fact, it can occur at any time during specification or even during the building phase, much as application task analysis can take place at any time in the early phase of development.) For instance, VE builders and their clients might choose to look for added value from interaction via “manipulation” of objects or via “exploration” around the virtual environment. Development of a concept design and then VE building will need to be robust enough to deal with both VEs built to provide the participant with the ability to manipulate (e.g., switch on, switch off, open, turn, etc.) elements or objects in the VE, and also those to walk through or around a large, rich, complex, but essentially unchanging virtual environment (see Fig. 17.3).

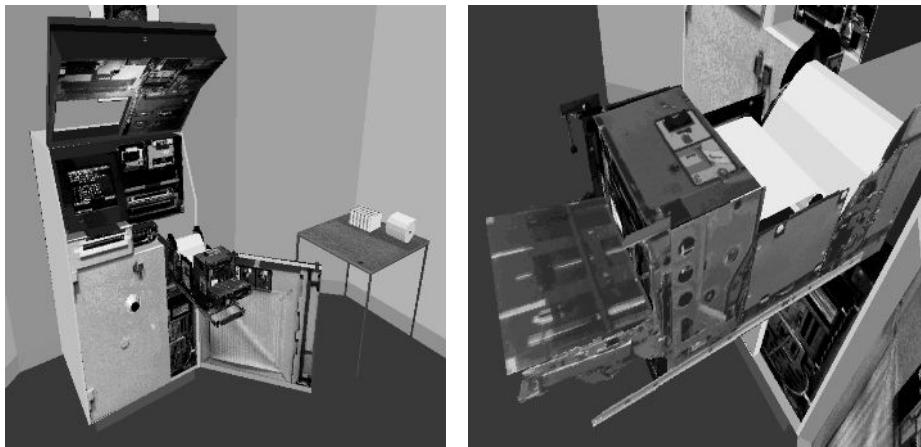

FIG. 17.3. An example of a VE that gives the participant the ability to manipulate elements within the VE as well as navigate through them. This shows a virtual ATM, or cash point, that can be “racked out” to practice day-to-day replenishment procedures by selecting buttons, catches and switches.

Out of the analyses, the target VE will be specified in terms of its goals, the expected user tasks, complexity, and the balance between interactivity and exploration afforded. This specification must then be agreed by the VE development team and client, the most common means being storyboard development.

4.2 Storyboarding

A storyboard is a set of frames, each using pictures and words to describe a stage in the experience offered by a virtual environment. It can differ from a storyboard for a film in that a VE may not be a straightforward narrative sequence, so the links and relationships between frames may be more complex. On the other hand, it may not be necessary to show the links between the frames if, for example, the sequence of events does not affect the outcome. In that case the frames will contain descriptions of interactive elements within that part of the virtual environment.

Virtual environments are often designed by more than one person, frequently by a group whose members work for different organizations and come from different backgrounds. Some of these people will have a good understanding of the possibilities offered by a virtual environment. Others will be experts in their own field and have a good idea of what they want the VE to do, but little idea of what is feasible. A storyboard is a method by which the different parties involved can describe, design, outline, and agree on the form the VE should take. The developer can use the storyboarding process to work out how to match the requirements of the client to the limiting factors of the VE system. The storyboard can then be used by the developer to build the VE, ensuring during the process that the design closely matches the requirements of the client.

It is important to get all stakeholders involved at the storyboarding stage. Experience has shown that if this is not done, a VE may be developed which does not meet the requirements of the one person who was not consulted, resulting in expensive and time-consuming re-development. Generally, the stakeholders in the storyboarding process are: the project manager (to oversee the process and keep it within budget); the VE developer(s) (to establish exactly what the client wants and to explain what is technically feasible and how long it will take); the

client (the person or people who specified the VE to make sure the VE will fulfill the specified requirements); representatives of the user population or participants (to make sure the VE will be suited to their characteristics and needs); and a usability or HCI expert—who is possibly one of the developers (to guide discussion from a user perspective, instantiate this into the design, and incorporate best practice in interface design). It is often the case that one person may fill more than one of these roles, in which case the size of the storyboarding group will be reduced. Typically between two and five people can develop a storyboard. A storyboard can be graphical or textual (see Figs. 17.4 and 17.5), and its content will depend on the type of VE and size of project. A set of potential contents is shown in Fig. 17.6.

Once developers start building the VE they will be confronted with many unexpected and previously unforeseen problems at every stage. It may not be possible for developers to make some decisions, and they will have to be referred back to the relevant person in the storyboarding group, which can delay the development process. It is therefore important to establish as much detail as possible at the group storyboarding stage and to use the conceptualization that storyboarding allows to obtain consensus. Developers have to drive this process by asking questions about the design of the virtual environments.

4.3 Acquisition of Resources

Information must be acquired about objects to be modeled and their setting. As well as taking notes and making sketches, many developments will require object attributes that can be included from resources in the form of photographs, video, and sound recordings. At an early stage it may not be possible to determine exactly the way in which any particular object is going to be modeled, for instance, if it will be texture- or geometry-based. It is therefore important to have some guidelines to follow that will ensure that, regardless of the method employed, the data will be available. Table 17.1 shows how the nature of the geometry, color, and sounds of an object can indicate what data should be collected in order to model that object. Shortcuts can be taken in resource acquisition. One obvious source is computer-aided design (CAD) and other solid model (three-dimensional [3-D]) data. Translators may be required here and some precision in geometry may be lost, but this can allow much more rapid development. Other sources may be image and mapping agencies or the Internet for models or animations.

TABLE 17.1
Types of Information to Be Collected

	<i>Simple</i>	<i>Complex</i>	<i>Dynamic</i>
Geometry	Measure dimensions (e.g., cube)	Measure dimensions and take photos (e.g., tree)	Measure dimensions, photograph and video (e.g., bicycle)
Color	Note color (e.g., painted wall)	Photograph orthogonally* (e.g., brick walls)	Video or photograph sequence (e.g., TV screen)
Sound	Record sound	Record sounds	Record sound and video or make notes on relationship between sound and object behavior (e.g., car accelerating)

*If orthogonal photos cannot be obtained (e.g., due to obstructions or limited access), take the photos as square on to the surface as possible and then use a graphics package to “straighten” the image.

Screen layout	
VE window	Resolution 1024 x 768
Icons	How big? 800 x 600 Where? Top (center?)
Help boxes	Temporary over VE window (possibly only visible whilst right mouse button is held down?)
Instructions	Automated walkthrough (in the form of an AVI?) shows users what to do
Initial scenario	
Room layout	
Doors	Door to XXX room
Furniture	
Shelf	
Mat for HG testing	
Panel for WB testing	
Pictures on walls (XXXX, no smoking, ESD signs etc)	
Clothing / equipment	
Wrist band (WB)	
On shelf	
Heel grounder (HG)	
On shelf	
Overalls	
Actions	
No entry to XXX room without tested HGs and WBs and wearing overalls	
If attempt is made without them message tells user how to get them	
Click on HGs and WBs to select	
Feedback? Icon changes from bare wrist to wrist with WB	
XXX room scenario	
On entering the room a message appears;	
There are ten ESD hazards in this room. Use the ESD meter to find them. Click on the ESD meter with the left mouse button to pick it up. Use the left mouse button to click on items that you think are an ESD hazard.

Likely ESD voltage level (for ESD meter) ?	
Jacket on back of chair	
Likely ESD voltage level?	

FIG. 17.4. Extract from a text-based storyboard.

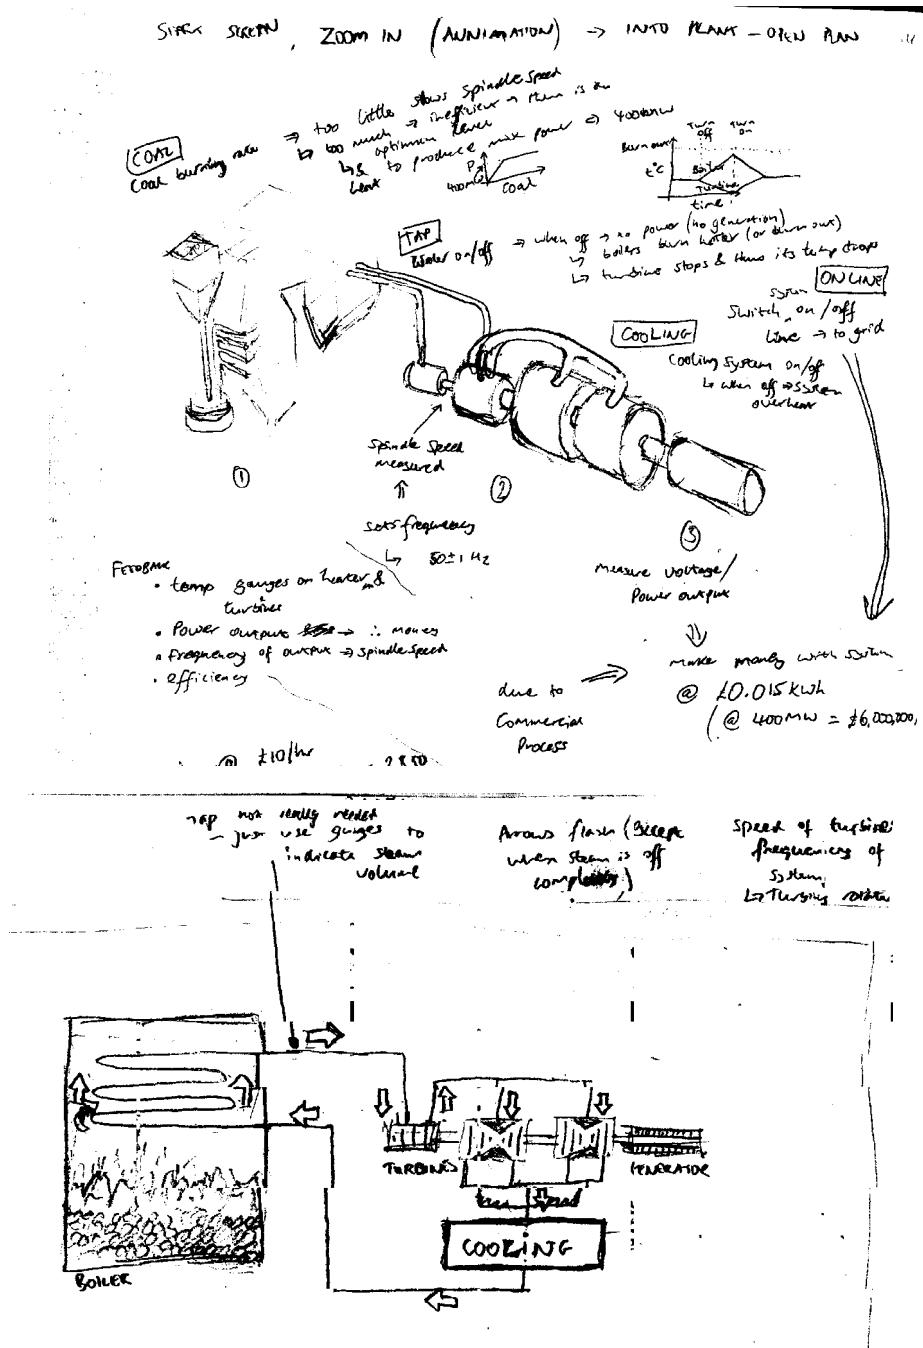

FIG. 17.5. An example of a picture-based storyboard (for an electricity generating plant demonstration).

4.4 Virtual Task Analysis

During or after specification of the VE there is the second application of task analysis: the analysis of the tasks to be performed by the participant within the virtual environment. This is a critical component of the VE development process for several reasons. First, there are trade-offs across the technical capabilities of the systems. For any particular level of system

A wire-frame model or skeleton of the structure of the VE.
The initial scene presented when the participant first enters the environment.
The expected layout of the scene at subsequent points.
Any narration or instructions within the VE, whether aural or textual.
Any implicit or explicit signs or cues given to the participant.
Images to describe the activities in which the participant is expected to take part.
The broad class of control and input devices by which participants perform activities.
Images to show the consequences of various actions (both correct and incorrect).
The approximate sequence of events given an ‘ideal’ use (e.g. for training); where there is no sequence required (i.e. the user can perform the tasks in any order) this should be stated.
Any links with other software (e.g. multimedia clips).
A “formal end” to the virtual experience if this is needed (for instance when a VE lesson has been completed or a full escape route navigated).

FIG. 17.6. Potential elements in a storyboard.

sophistication and cost, there must be prioritization among the variables of: VE complexity—and thus sensory richness; update rate—related to sense of presence and any disturbing effects; and interactivity—numbers of objects that can be “manipulated” in real time and how this is to be done. Analysis of the tasks that the participant must perform within the VE and any consequences and support needs can assist this prioritization. Second, a critical part of VE specification, assisted by the task analysis, is to define the minimum set of objects capable of interactivity and how cues to this interactivity might be provided (Eastgate et al., 1997, and later in this chapter). Third, by extension, there is the production (through prediction and observation) of task analyses for collaboration and task performance within collaborative virtual environments (Tromp et al., 1998a, p. 61). Finally, task analysis of what must be done within the VE to achieve set goals can be used to define behaviors which are expected (or not) to underpin successful use of the VE—for instance, in achieving learning objectives (e.g., Neale et al., 1999)—and so give a basis to evaluation of participation within a virtual environment.

Many of the decisions, which could have been made on the basis of the application task analysis (see Fig. 17.2) may, in fact, be made after the virtual task analysis or be revisited at this stage in the process. Some assistance for the process of virtual task analysis may be obtained by use of taxonomies (e.g. Gabbard & Hix, 1997) or else cognitive models. An example of the latter is the Resources Model reported by Smith, Duke, & Wrigth (1999). Kaur et al.’s (1999) model of interaction might also help with virtual task analysis.

5. APPROACHES TO BUILDING VIRTUAL ENVIRONMENTS

There are a number of factors that influence the way a VE is developed and, consequently, how it eventually performs. Some of these factors have a stronger influence than others, but all are interlinked in some way. These factors include: the purpose of the application; the

target user population; the developer's ability and experience; the involvement (or not) of end users; the client–developer relationship; the VE system (hardware/software) available; the time available for development; and financing available. Also influential will be the extent of the developer's understanding of human factors and human performance in VEs and of how to enhance usability, which requires much better fundamental knowledge and practical guidance than is available at present. The understanding of performance in VEs will be addressed in the next main section. First, the act of building VEs will be examined in terms of strategies and techniques available to developers.

5.1 Basic Choices

After VE specification is complete, construction of the VE involves a series of hard choices over what can be done to meet the user and application needs. A fundamental choice facing the world developer is where to concentrate building effort (in time and creativity) and computer processing resources. Crudely, VEs may be designed to maximize the participant's ability to interact with them through exploration (i.e., visualization and walk-throughs), their interaction through manipulation (i.e., alterations in the state of objects), or to compromise by trying to meet needs for both. Technical limitations of VE technology, present in differing degrees in all systems from the simplest desktop to a Cave Automatic Virtual Environment (CAVE), usually result in the world builder having to make a number of trade-offs. The aim is to render recognizable 3-D representations in real time, updating synchronously with a participant's control inputs or movements in the virtual environment. The trade-offs will often involve choosing between providing the user with functionality, including a high degree and speed of interactivity, or producing a higher specification for the complexity and appearance of the environment itself. The total number of objects to be modeled and the level of detail and degree of associated intelligence for each must be considered carefully before including any within the virtual environment (see Eastgate & Wilson, 1994; Richard et al., 1996; Smets & Overbeeke, 1995). The application and virtual task analyses and prioritization exercises will be used for this. Some decisions over what to model, and how, can be made through modeling tools, for instance, extraction of geometry from photographs and drawings.

5.2 Programming Interactivity

One vital aspect of building VEs, and a major component of usability, is interactivity. Virtual environments have, of course, been typically defined in terms of possessing presence, autonomy, and interactivity (Zeltzer, 1992). Of these, interactivity is arguably the most critical attribute, as it clearly defines the difference between VE and other 3-D modeling systems. Here, the term *interactivity* is used broadly to mean any action on the part of the participant that results in a change in the virtual environment. An obvious case is selecting one object to initiate change in another object or in the scene, but interactivity can also include navigation where a user moves through a VE while it updates and changes according to one's movements and position. There are many computer applications that offer varying amounts of interactivity, but it is reasonable to suppose that VE technology can offer more representations of the types of interactivity commonly encountered in real life.

As with all facets of VE development, the technical limitations of any particular system and user interface mean that there will be limits on the amount and quality of interactivity available. In an ideal world the participant would feel that they are interacting directly with the virtual objects in the VE even while they are actually interacting with peripherals in the interface. However, due to the limitations of current VE technology, the user interface is more likely to form a barrier between the user and the VE, whatever the nature of the sensors and

effectors and whichever of the user's senses are engaged. One of the jobs of the VE developer is to make this barrier seem minimal within the constraints of the application.

There are two extremes in VE interactivity. The first is to aim to accurately model as many of the characteristics of the real application as possible. The second approach is to deliberately create an approximation of reality, where the result is a crude representation of salient characteristics rather than an accurate simulation. The first approach may end up with a VE that is too complex for the processor to update as fast as required for exploration and manipulation interactivity, whereas the second approach may result in an impoverished or very simple VE, insufficient for the requirements of the application user. Therefore, a compromise between the two extremes of modeling interactivity will generally be used to achieve the best solution for any given application. The model will be built to mimic the behavior of the real world, behaving "correctly" in a variety of circumstances. Object-oriented design, maximizing object autonomy, will make the VE easier to adapt or expand in the future if the need arises. Where accurate models of the structure or dynamics of an object or process cannot be justified on the grounds of programming time or processing overhead, they can be replaced by, for example, a texture, an animation, or a model based on a simplified algorithm.

5.3 Choices Over Object "Intelligence"

One way in which VEs may not match the real world, at least in their underlying construction, is in the selection of which objects have the capability to be "intelligent," to change configuration or else determine the form of the total virtual environment. For example, materials or objects being worked on or manipulated during a manufacturing process are generally "dumb" in that they have no influence over the process. It is the manufacturing machines or systems that can influence the position, orientation, deformation, and joining of the materials or objects. Although veridical representation means we should attach code to give intelligence to the machines, it is sometimes simpler to attach intelligence to the objects being manipulated without affecting the visual representation of the process. In this way, the real world can be represented in the most efficient way possible, rather than exactly simulating it. For example, where a robot has to move components from a conveyor onto an assembly, in principle it is one "intelligent" object working with an unknown number of "dumb" objects of known type. It is often simpler to create one component which has a program associated with it, such that it can react correctly to the robot, and then to duplicate that component (and associated program) as necessary, than it is to program the robot to cope correctly with an unknown number of components. This effectively takes the "intelligence" from the robot and assigns it to the component.

This approach, however, has disadvantages. If an object has been programmed to sense when a robot is picking it up and to behave accordingly, it may be given code only to be able to recognize one robot or type of robot. Also the robot will be incapable of manipulating other objects for which the user would expect it to be suitable but which do not have the required program associated with them.

5.4 Implementation of Physical Properties

Virtual environment software usually gives developers limited ability to assign some physical properties to virtual objects, particularly dynamic characteristics approximating those expected in the real world. One factor limiting the "realism" from doing this is a lack of temporal consistency in some 3-D visualization systems. Any factor that decreases the rendering speed, such as visual complexity, can result in a slowing down of the dynamic properties of moving objects. To get around this, it is usually possible to link the dynamic properties to the processor's

real-time clock. However, it is not possible to increase the rendering speed using this method; instead, the step size of the movement of the objects is altered, so if the rendering speed becomes very slow a fast-moving object may appear to jump across the screen. This can become particularly pronounced in collaborative virtual environments, where the collaboration is taking place over a network with its inherent potential for lag. Local activity will render smoothly, but remote activity will jump about as packets of information arrive over the network. Thus, to achieve smooth but temporally accurate dynamics, the developer has to be aware of the potential bottlenecks in the processing and rendering of the virtual world on particular VE systems.

Some VE development systems provide facilities to give objects physical properties, for example, gravity, coefficient of friction, coefficient of restitution, and velocity, both linear and angular. These are not generally designed to simulate the laws of physics, but rather to give VE developers shortcuts to making objects appear to obey the laws of physics. Coefficients of friction and restitution are determined by the properties of both of the materials which are coming into contact and cannot be allocated to an object in isolation. One physical property which is not generally available is center of gravity. Without this property is not possible to make an object topple realistically.

Dynamic characteristics not provided by a VE development system can sometimes be programmed by developers using a relevant programming or scripting language. By assigning a piece of program code, any virtual object can be programmed to behave in a particular way independent of other virtual objects in the same environment. Alternatively, objects can have their separate codes linked (e.g., via common variables) such that one object's behavior depends upon another's.

Any use of simplified physical constraints can make an interaction more realistic without sacrificing real-time updating and can provide a more intuitive interface (Papper & Gigante, 1993).

5.5 Overcoming Limiting Factors in VE Development

The combination of VE complexity and finite system processing power will limit the rendering speed of a VE presentation. It is important that rendering speeds are sufficient to avoid causing usability, likeability, and utility problems. When faced with restrictions, there are various possibilities available to the developer. More than one of these techniques would normally be used in combination. The facilities offered by the VE system software, and the developer's ability and preferences are most likely to influence the choice (see Grinstein & Southard, 1995).

5.5.1 *Texturing*

A large amount of 3-D detail can be replaced by a bitmap texture pasted onto a single facet in a virtual environment. Depending on the subject matter textures can increase rendering speeds and will generally be quicker to create than 3-D geometry. Whereas textures are a good way of adding realism to a VE, they can only be used in certain circumstances. A new development, which offers a compromise between the increased speed from textures and the interactivity available with modeled objects, are algorithms that automatically replace textures with modeled objects according to the participant's apparent distance away from an object (e.g., Rosenblum, Burdea, & Tachi, 1998).

5.5.2 *Level-of-Detail Management*

Level-of-detail (LOD) management, or distancing, is a widely used technique, whereby if a virtual object is more than a specified distance from the viewpoint of the participant it is replaced by a simpler model or else disappears altogether, thus reducing the amount of

processing time required to render that object. Extensions of this technique can be found in layered depth images, and, for one specific problem, use of portal culling and portal textures (e.g., Rafferty, Aliaga, Popescu, & Lastra, 1998).

5.5.3 Reducing the Screen Resolution

Reducing the resolution of a display is an indiscriminate solution that results in a reduction in the amount of detail visible to the participant. This will make some tasks in the VE more difficult (e.g., perceiving details) and will also reduce the photorealism of the VE, possibly making the experience less meaningful and enjoyable. It is possible to reduce the screen resolution selectively around the periphery of the screen while maintaining a high resolution in the center (Watson, Walker, & Hodges, 1995).

5.5.4 Selectively Including Objects

Reducing the number of objects in an environment will increase rendering speed and decrease development time. The decisions as to which objects to include should be based on the task analyses and rational thought about which objects are really needed, but tend also to be made on the basis of the size of objects, ease of programming, and individual programmers' preferences. In the worst case such decisions are made arbitrarily, with little understanding of how the choice will affect participants.

A technique that can both decrease development time and increase rendering speeds is to selectively include objects. It is applicable across all hardware and software platforms and will be compatible with future VE systems. The resulting VE should not be significantly inferior (at achieving its specified purpose) to a hypothetical one in which all objects are modeled. Indeed, it may be found that omitting some objects may increase the effectiveness of a virtual environment. A parallel is the use of a stylized graphic drawing in a book of instructions rather than a photograph, to avoid confusion through unnecessary detail. What is required is a set of guidelines to help developers through the process of deciding which objects to include and which to omit. This guidance will have to be developed with reference to the specified purpose of a VE and user behavior within the virtual environment.

6. UNDERSTANDING HUMAN PERFORMANCE IN VEs

The goal of VE world developers is to create effective, safe, usable virtual environments that enable participants to achieve goals in a better, more motivational, and cost-effective fashion than by using alternative technologies or by using the real situation. Producing VEs should thus ideally be based on an understanding of how people will behave and carry out tasks within the virtual environments. Developers need general guidance on human performance within VEs and specific guidance on enhancing VE usability (see chap. 34, this volume). Clarity about what determines usability of VEs will be enhanced with better understanding of participant performance.

Task and user analyses will allow some identification and categorization of participants' requirements, and storyboarding will outline how the VE should be specified and designed to meet those requirements. A more detailed examination should be made of how participants will respond to different elements of the VE, utilize all its functionality, and be able to comprehend and use interface elements to meet application goals. As part of this, developers need to know how to encourage participants to explore the VE and enable them to understand which elements can be interacted with, identify how this interaction might be achieved, and minimize dysfunctional participant behavior and serious errors. In other words, an improved understanding

of human behavior and performance within a VE is needed, but such understanding is in its infancy.

There are a number of candidate theories and approaches that might help. For instance, behavior of groups of workers in complex technical and organizational environments can be interpreted within a framework of distributed cognition (e.g., Hutchins, 1995). In such a view, the handling of information and decision making that characterize work in transport control, for instance, is distributed in time and space across teams of people and various computer and telecommunication systems. An ethnographic approach may then be taken to study and interpret work behavior and skills. This may be a framework within which to study performance in networked VEs or CVEs.

Another possibility is to build understanding of participation in VEs, and thus guidance for their design, around the notion of situated action (Suchman, 1987). In this view, work cannot be understood merely in terms of individual skills and institutional norms, but is the product of continually changing people, technology, information and space. Further, people do not approach tasks with a clear set of plans in mind, but build and modify their plans in the course of situated action.

A third possibility for understanding performance in VEs is to utilize the notion of situation awareness. People perceive cues from their environment and use them to make sense of the current state of the world and to project this understanding into the future (Endsley, 1995). Various measurement methods are available to assess situation awareness that might have value in understanding and measuring performance in virtual environments. Also, there is a strong connection between the role played by situation awareness and the participant's mental model. Guidance on design usability then, would concentrate on those VE elements expected to help build a strong and "correct" mental model for the participant or to match their existing ones, and to contribute to high levels of situation awareness.

Finally, developers could borrow from a large variety of models and frameworks used to understand, predict, and reduce human error, generally in safety critical systems. A particular possibility here is Rasmussen's (1986) well-known SRK model of skill-, rule-, and knowledge-based behavior. If the types of tasks in the VE can be defined as to whether they are skill-, rule-, or knowledge-based, one might be able to distinguish between the types of design guidance offered for each. More usefully, characterization of real-world tasks as skill-, rule-, or knowledge-based, and particular variants of these, could allow association of different ways to deliver their representations in the virtual environment. The SRK model is often used in conjunction with Reason's (1990) typology of human error—slips, mistakes, and violations—and the underlying psychological error mechanisms involved. Again, adaptation of these to the VE domain could allow a better understanding of the types of behavior exhibited by VE participants and, subsequently, lead to production of useful development guidance.

7. USABILITY OF VEs

The notion of usability of VEs and usability engineering is explored in depth elsewhere in this volume (see chap. 34). Included here are only the major issues of usability that must be addressed in the development process.

A NASA-sponsored workshop on VE research requirements started with a brief that the most important issues to discuss were aftereffects and sense of presence. Twenty-five specialists, from Germany, the United States, and United Kingdom, prioritized problems and research needs and established interconnections between issues. Many concerns were with systems design, for instance, display design, latency, and real-time interaction. Beyond these, the workshop participants agreed with the importance of minimizing aftereffects, the need

for better understanding of participants' sense of presence, and on the need for a substantial human-factors research agenda to address VE usability concerns (Stanney et al., 1998).

Defining usability of any product is not easy, particularly if this definition must be translated into appropriate design parameters and evaluation metrics. Also, most accepted definitions of usability refer to it as being related to "specified users" with "defined goals" in a "specified context of use," rather than as a generic context-free attribute. Furthermore, in HCI for instance, attributes of usability—leading to measurement methods, measures, and criteria—might include effectiveness, efficiency, usefulness, learnability, long-term performance, memorizability, flexibility, feature usage, acceptability, likeability, and satisfaction, meaning that usability is a multidimensional concept. An understanding of how people operate in VEs, and of what concepts such as presence (see chap. 40, this volume) or navigation (see chap. 24, this volume) actually mean in a synthetic environment is not yet advanced enough to operationally define such usability attributes in order to generate metrics and explicit design guidelines. Some exceptions in part include contributions from Gabbard and Hix (1997), Nichols, Haldane, and Wilson (2000), Pausch, Proffitt, and Williams (1997), Singer and Witmer (1999), Vinson (1999), Watson, Walker, Ribarsley, and Spaulding (1998) and Welch (1999), from all of which some metrics and some guidelines might be extracted. Our knowledge at this time would also allow some usability heuristics and structures for cognitive walk-through assessments to be established and run, which in turn might be translated into a first set of guidelines.

One of the barriers to the proliferation of VE technology identified earlier was widespread concern over the usability of both the VE equipment and of the VE itself. The equipment concerns will limit the freedom of systems developers. They manifest themselves in terms of the design (see chap. 25, this volume), comfort and fit of HMDs and handheld devices (see chap. 41, this volume), temporal and spatial resolution limitations, field of view restrictions (see chap. 3, this volume), and generally the limitations implicit in communication using visual and auditory information only. Some of these systems concerns translate into potential problems of usability within the VE itself. Others might be minimized by careful design of the virtual environment.

There are a large number of usability issues related to successful implementation and use of VE technology (see Barfield & Furness, 1995; Draper, Kaber, & Usher, 1998; Wann & MonWilliams, 1996; Wilson, 1997, 1999). Few have been satisfactorily addressed as yet, although the work of Gabbard and Hix (see chap. 34, this volume), Kaur (1998), and Tromp (2000) is helping to redress this. For each usability issue one must ask: Is it a significant issue for VE development and for its safe and effective use? Are the usability issues unique? Can we utilize data and criteria from other domains and from knowledge of performance of related tasks? Broad usability issues to be considered during VE development include:

- Forms of representation of the participant within the VE: none, limbs, full block, full lifelike
- Modeling of avatars and mannequins: sizes, shapes, appearance, movements, facial expressions (see chap. 15, this volume)
- Supporting navigation and orientation within VEs: interface tools and other aids, shortcuts, familiarization routines, optimum world sizes (see chap. 24, this volume)
- Understanding and enhancing presence and involvement in VEs: balancing pictorial realism, size and complexity of the VE, update rules; use of sound and shadowing; enhancing interest (see chap. 40, this volume)
- Requirements for cues and feedback to assist the participant (see later discussion)
- Minimizing any side and aftereffects: sickness, performance decrement, and physiological change (see chaps. 29–32, this volume)
- Providing interface support and tools for interactivity: mixed-reality design, metaphors, interface elements, tool kits, and so forth

8. CUES AND FEEDBACK

One particular aspect of usability that is intimately linked to design choices made by developers, and to the notion of interactivity addressed earlier, is the provision of cues and feedback to the participant. When participants enter a VE it is important that they soon perform some activities that affect the VE to motivate them in further exploration. In order that they can successfully perform these activities, the VE should offer some cues that tell participants what types of activity are afforded. In this sense, VEs are no different to human-computer interfaces or to consumer products generally, in terms of the concept and importance of affordances (e.g., Norman, 1988). Cues to assist the participant could be in the form of navigational signs to aid their movement through the VE and to help them recognize their current location. Alternatively, cues could suggest that a certain type of control action would afford a particular response. The participant will benefit from knowing which objects afford interaction, whether they are available for interaction at that moment, what method of interaction is appropriate, and what effect interaction with that object might have on the virtual environment. Then, having interacted with a chosen object, they will want to know whether that interaction was successful. Tables 17.2 to 17.4 illustrate simple “look up table” guidance being produced by our group at VIRART to support world developers in improving the interactivity and feedback in their virtual environments. Many of the potential problems can exist also when interacting with objects in the real world, but some, especially those relating to explicit, formal (or “designed in”) feedback may be exacerbated in a badly designed virtual environment.

The design choice outlined earlier—of whether to design to model realism or some abstraction of this, or even to model a deliberate distortion of reality—is as valid for interactivity as for visual appearance. The points of interaction, the cues for these and the feedback given might all interfere with, or detract from, any visual fidelity in the scene and objects. Points of interaction may be of a size, shape, and color very different from their real-world counterparts; feedback and cues may need to be explicit in the form of text or audio prompts and messages. Such elements may strongly influence any usability/presence trade-off in the virtual environment.

TABLE 17.2
Possible Combinations of Cue for, and Potential for, Interaction

	<i>No Interaction Possible</i>	<i>Expected Interaction Not Available at This Time</i>	<i>Affords Expected Interaction</i>
Little or no cue	User assumes correctly that the object is noninteractive.	User may not attempt interaction, however, if interaction is attempted, and with appropriate feedback, the user will realize the potential for interaction.	User may not attempt interaction.
Inappropriate cue	User may try in vain to interact with the object.		Unsuccessful interaction is likely.
Appropriate cue	User will correctly not try to interact with the object.		Successful interaction is likely.

TABLE 17.3
Possible Combinations of Potential for Interaction and Resulting Feedback

	<i>No Interaction Possible</i>	<i>Expected Interaction Not Available at This Time</i>	<i>Affords Interaction</i>
No immediate feedback	User assumes correctly that the object is noninteractive.	User may not realize that interaction with this object can, but currently does not, have the desired effect.	User assumes wrongly that the object is noninteractive.
Inappropriate feedback	Not applicable.		User does not know what they have done.
Appropriate feedback	Not applicable.	User realizes that this action can, but currently does not, have the desired effect.	User knows what they have done.

An example of the use of decision tables within a real VE development project, provided as part of VE development guidance for models of an automatic teller machine, is shown in Table 17.5.

9. EVALUATION

For all VE applications, evaluations should be made of both the environments themselves and also their use and usefulness. Such evaluations can be divided into examinations of validity, outcomes, user experience, and process (see also Tromp, Istance, Hand, Steed, & Kaur, 1998b).

Developers should seek to address the validity of VEs in every project, at the very least by “walking through” them with the client or other experts. The potential usefulness of VEs

TABLE 17.4
Possible Combinations of Cue for, and Feedback from, Interaction

	<i>No Immediate Feedback</i>	<i>Inappropriate Feedback</i>	<i>Appropriate Feedback</i>
Little or no cue	User assumes that the object is noninteractive.	User may not attempt interaction.	User may not attempt interaction.
Inappropriate cue	User may try to interact with object, but will not know whether that interaction was successful.	Unsuccessful interaction is likely.	Initially unsuccessful interaction is likely.
Appropriate cue		Successful interaction may be aborted.	Successful interaction is likely.

TABLE 17.5
Decision Table for Interaction Points—The Case of a Virtual ATM

<i>Point of Interaction</i>	<i>Cue to Possible Interaction</i>	<i>Method of Interaction</i>	<i>Effect of Interaction</i>	<i>Main Feedback</i>	<i>Availability of Interaction When Object Is Visible</i>	<i>Feedback If Interaction Is Currently Unavailable</i>
All room doors	Implicit	Collision	Door opens	Visual	Always	N/A
Lock	Hidden	Mouse	Console becomes unlocked	Audible click	Sometimes	None
Console	Obscure	Mouse	Console opens if closed, closes if open	Visual	Sometimes	Textual prompt
Mode panel	Color coded	Mouse	Slides out if in, in if out	Visual	Always	N/A
Mode switch	Implicit	Mouse	Toggles display screen between normal and supervisor mode	Visual	Always	N/A
Outer door catch	Color coded	Mouse	Outer door opens	Visual	Sometimes	None
Outer door	Implicit	Mouse	Outer door closes	Visual	Sometimes	Textual prompt
Receipt printer release catch	Color coded	Mouse	Allows receipt printer module to be racked out	Small visual	Sometimes	None
Receipt printer handle	Color coded	Mouse	Racks out or replaces receipt printer module	Visual	Sometimes	Textual prompt
Receipt paper feed switch	Implicit	Mouse	Feeds paper through	Visual	Sometimes	None
Receipt paper spool spindle	Color coded	Mouse	Multiple effects depend on current state of system	Visual	Sometimes	Textual prompt
Receipt paper	Obscure	Mouse	Multiple effects depend on current state of system	Visual	Sometimes	Textual prompt
Safe door	Implicit	Mouse	Unlocks safe door	None	Sometimes	None
Combination lock						
Safe door handle	Implicit	Mouse	Opens safe door	Visual	Sometimes	None
Safe door	Implicit	Mouse	Closes safe door	Visual	Sometimes	Textual prompt
Currency cassette release catch	Color coded	Mouse	Allows currency cassette to be removed	None	Sometimes	None
Currency cassette handle	Color coded	Mouse	Removes or replaces currency cassette	Visual	Sometimes	Textual prompt
Currency cassette lid release catch	Color coded	Mouse	Opens or close currency cassette	Visual	Sometimes	Textual prompt
Currency holder	Color coded	Mouse	Fills or empties currency cassette	Visual	Always	N/A

has been somewhat harder to evaluate sensibly since few, if any, are sufficiently developed in a form whereby potential users can directly see how they might be applied and carry out test applications. Most structured evaluation work has been of the immediate outcomes of use of a virtual environment, and not surprisingly—given the better developed nature of measures in this area—work has concentrated on education or training applications (e.g., Crosier, Cobb, and Wilson 2000; D'Cruz, 1999; Darken & Bunker, 1998; Hall, Stiles, & Horwitz, 1998). The user experience can be evaluated in terms of performance measures within the VE (reaction times, navigation or selection tasks such as in the VEPAB from Lampton et al., 1994; chap. 35, this volume), side and aftereffects (e.g., Cobb et al., 1999; Nichols, Cobb, & Wilson, 1997; Nichols et al., 2000, as well as chaps. 29–32 and 36–39, this volume), and participant attitudes and usability of the interface and virtual environment (see chap. 34, this volume). Finally, there is evaluation of the process of both building and using virtual environments. One example of this is evaluation of how potential users will help specify, build and evaluate VEs within a participatory design process (Neale, Brown, Cobb, & Wilson, 1999); another is the evaluation of the process whereby VEs are used in participatory work redesign in control rooms (Wilson, 1999).

10. CONCLUSIONS

This chapter has argued for VEs to be developed in a systematic and structured fashion. It describes one framework to support development in this way, VEDS (Virtual Environment Development Structure). This framework has been used to support development of VEs in industrial use (e.g., Wilson, Cobb, D'Cruz, & Eastgate, 1996), industrial training (D'Cruz, 1999) and education (see chaps. 45–46, this volume). By careful, but flexible, use of such a framework, the consequences of some of the barriers to VE application can be minimized. Technical limitations can be circumvented or their effects reduced by appropriate choice of technology and careful specification of the minimum VE size and least complexity required to meet user goals. Trade-offs, such as choices between visual fidelity and interactivity, can more easily be resolved. Usability will be enhanced through selection of appropriate hardware and development of cognitive interface tools and aids, all on the basis of the task and user analysis and storyboarding. Real working applications will only be achieved through selection of those domains to be modeled that make the most of the attributes of VE, using a thorough understanding of what constraints will apply and of how to overcome them in specifying and building the virtual environment. Finally, these applications will best show added value if a rational evaluation process is established at the outset on the basis of realistic and achievable targets for use of VEs and for their incorporation into industrial and commercial practice, education curricula, or training programs.

11. ACKNOWLEDGMENTS

The work reported in this chapter has been carried out over the years with a number of collaborators, most notably Sue Cobb, Helen Neale and Sarah Nichols. Jolanda Tromp, Jerry Isdale, and anonymous reviewers commented on an earlier version and we are grateful for their help. The research on which the chapter is based has been funded over time by the EPSRC, the ESRC and various industrial clients, and most recently under European Commission grant IST-2000-26089.

1. INTRODUCTION

In this chapter a discussion of how individual differences and features of virtual environment (VE) technology affect VE application design is provided. This discussion is motivated by the fact that differences among individual users often account for more variability in performance than system design factors. Individual differences overshadowing system design features in terms of their influence on human–machine system performance is particularly troubling with respect to achieving the primary objective of human factors research, that is, to determine the aggregate effect of a particular system variable on human performance and behavior for the purposes of formulating future system design guidelines to optimize safety, performance, reliability, comfort, ease-of-use, and so forth. Individual differences can severely inhibit a designer’s ability to design for a “typical” effect of a particular design factor. With this in mind, addressing user characteristics through VE design may produce substantial improvements in, for example, virtual task performance and the effectiveness of VE trainers. Specifically, user issues that have been hypothesized to be important to collaborative virtual environment (CVE) design are considered, including the number of virtual participants (i.e., whether the environment is to be shared or structured for individual use), and the location of users. The

impact of both these issues on virtual task performance is evaluated. With respect to the latter, the implications of remote versus proximate access to a VE and the application design are examined.

Educated speculation on the role of user characteristics that have been found to be critical in human-computer interaction (HCI) is offered, including experience, age, and disabilities in the design of VE applications. Projections are made on user performance given different experience levels, and other criteria. Because few, if any, experiments have specifically investigated the effect of individual differences on VE system configuration and VE design, this chapter develops VE application design guidelines to address individual differences based on results of recent VE research amalgamated with inferences based on seminal HCI research into psychological and somatic factors. It is important to consider with caution any inferences on research and to be careful in construing opinions on design as definitive policies.

Given the maturity and flexibility of VE technology and the substantial impact that individual differences may have on system performance, methods for identifying the causes of individual differences in VE use need to be formulated, and knowledge of common user issues should be reflected in VE system design. Addressing these needs will make it possible to develop virtual task performance standards and to ensure acceptable levels of functioning in the use of VEs by broad populations. To this end, this chapter provides general VE design recommendations (at the close of various subsections), on the basis of literature review, to account for individual differences.

Very preliminary research has been conducted to identify the underlying somatic and psychological factors that may affect human behavior in VE applications. This research has primarily focused on VE system development for individual use. It has concentrated on properties of immersion, which have been hypothesized to be linked to performance in VE applications. These properties include the degree of matching between user behavior in the real world and their behavior in a VE, the form of self-representation provided to the user in experiencing a VE, and the extent to which VEs appear to be "worlds" in, and of, themselves (i.e., independent of anything real). Using one set of terminology or another, these elements of immersion have been discussed at length and extant speculation has been offered as to how they may be influential in the design of individual immersive VEs (see Durlach & Slater (1998) for coining of the term *individual* in this context). Convincing anecdotal evidence of their apparent importance in individual VEs has also been offered.

However important these factors may actually be, as in reality, each individual may experience a VE differently because of their background, interests, and other factors. Therefore, individual differences may serve to moderate the effects of the properties of immersion and other VE system design factors on user performance and experiences in virtual environments. Specific psychological or psychophysical factors have also been considered as to their potential impact on user performance in stand-alone VE applications. These factors include user susceptibility to presence experiences, as dictated by imagination, concentration and attention, and self-control (Psotka & Davison, 1993), and user familiarity with the real environments or systems modeled in VEs (Held & Durlach, 1992). Psychophysical factors identified as being potentially influential in performance in VEs have included user age and disabilities (Stanney et al., 1998).

It seems reasonable to assume that many of the individual differences that have been found to be important in HCI may be relevant to human–virtual environment interaction (HVEI). It also seems possible that the properties of immersion that have been established as being important in the design of individual or stand-alone VE systems for enhancing user performance may be applicable to CVE systems. For example, VE application design factors identified as being relevant to user experiences of presence in individual VEs, such as display field-of-view,

simulation update rate, and others may be relevant to CVE design for encouraging shared presence among users. Such contentions are assessed analytically in this chapter. Additionally, hypotheses are formulated on the effects of user experience, age, and abilities in CVE performance. Finally, theoretical guidelines for collaborative immersive VE design are developed considering both user differences and properties of immersion. Some examples are offered to support guideline formulation for effective VE application design.

As a point of clarification of terminology, throughout the chapter, “individual differences” is used to refer to individual variation within user characteristics. For example, human users predominately have two eyes (a user characteristic), but the interpupillary distance may be greater for some users than others (an individual difference). Addressing user characteristic effects on VE application performance seems to have little utility for design purposes. For example, because humans have two eyes, a design guideline that it is necessary to present images to both eyes in display design seems obvious. This is not to say that identifying user characteristics that play a critical role in designing VEs is not an important aspect of the design process. However, in a handbook chapter this work is ultimately encompassed in addressing individual difference issues. This is because in a design context identifying user characteristics is, in fact, a description of the subset of individual differences one expects to affect the application design process. Or, the effect a particular user characteristic has on application performance may ultimately be attributed to the individual differences within the characteristic that produce the effect. Finally, a quick perusal of the HCI literature (e.g., Egan, 1988) on individual difference effects in conventional computer application design reveals the terminology *individual differences* and *user characteristics* to be used interchangeably. Certainly, this does not justify the use of this terminology in the same manner in the VE literature, in general; however, HCI research is supportive of the approach used herein.

As an additional note prior to discussing the effects of specific individual factors on VE application effectiveness, in general, the impact of individual differences on virtual task performance and measures of human cognition in many experimental studies has appeared to be similar to individual difference effects on real-world task performance. Specifically, in studies of human performance in complex tasks, such as human control of teleoperators, simulated air traffic management, and simulated aircraft piloting, whether participants have direct control over a system through real interfaces, interact with virtual models of a real system, or use a VE as an interface to a real system, significant effects of individual differences within experimental groups have been observed. Similar individual difference effects on task performance across reality and synthetic environments have been observed even when dealing with participant samples from similar populations (e.g., undergraduate students, graduate students, highly trained remote robotic system operators at Oak Ridge National Laboratory). These observations seem sensible in that the experience of reality is different for everyone, and if VEs are truly unique environments functioning (for the most part) independently of reality, then why should VE experiences not vary significantly from one person to the next? Unfortunately, these observations do not make the jobs of VE researchers and practitioners easier.

2. INDIVIDUAL DIFFERENCES INFLUENCING VE PERFORMANCE

Individual differences may affect the experience and outcomes of using a virtual environment. To the degree that these effects are important to VE users, user characteristics must be identified so VE system developers can effectively address them. As examples, the sense of presence is affected by user characteristics (Barfield & Weghorst, 1993), as is cybersickness (Parker

& Harm, 1992). Several individual differences that may affect experiences or outcomes are reviewed in this section.

2.1 User Experience

Experience with VE systems can enhance user knowledge of task- and system-relevant information and user skills and abilities that may affect performance. In HCI, it can be “the most powerful predictor of human performance” (Egan, 1988, p. 553). Experience has also been shown to affect performance during teleoperation (Draper, Omori, Harville, Wrisberg, & Handel, 1987a). It seems likely that experience with VE systems will influence exploration strategies (see chap. 24, this volume) and interaction skills (see chap. 13, this volume), perhaps, for example, through development of mental models of how one generally interacts with a virtual environment. In addition, experience within a specific VE system will likely influence task-specific information acquisition and decision making, for example, through development of a mental model of the specific virtual environment.

Virtual environment research has explored, to a very limited extent, the impact of user mental models of virtual tasks on performance in VE applications and the effects of user experience and aptitudes on virtual task performance. What research has been conducted suggests that experience may be an important individual difference in users’ perception that a VE is realistic and, consequently, the sensation that they are present within the virtual environment as well as the effectiveness of the VE application. Egan (1988) summarized several HCI studies that describe experience effects on simple computer task performance. Most importantly, these studies demonstrate that small individual differences in practice or experience produce large differences in human-computer performance. It is possible that this may be the case for VE task performance as well. Further, experience in computer use has been found to play a significant role in user development of mental representations and understanding of systems and tasks (Egan, 1988). Experience in VEs may play a critical role in VE user perceptions of cognitive task load and development of situation awareness (SA) of virtual tasks and processes. Finally, user experience in HCI has been demonstrated to significantly interact with other user characteristics, including age and aptitudes, to affect performance (particularly in the case of novices; Egan, 1988). In VE use, the effect of age and aptitude on user ability to perform virtual tasks may be modulated by VE experience.

The level of experience users achieve in functioning in real environments that serve as subject matter for VE application development may have a significant effect on user performance in the virtual environment. More simply, it may have an effect on user acceptance of VE applications as surrogates to real tasks. This is particularly critical to VE training applications in which a sense of matching to the real-world target task may ensure skill transfer. According to Norman (1986), users form their mental models of tasks or systems based on the task images and information presented to them. In VEs for training, user mental conceptualizations of a task are predictably formed based on their familiarization with the real task. Individual differences in such conceptualizations may affect performance in virtual tasks to the extent that it is influenced by user expectations of consistency between the real and virtual forms of the task (e.g., the degree of matching expected by an expert versus a novice). Consistency is dependent on many factors, including level of VE detail, interactivity, user self-representations, and virtual task loads (i.e., comparison of virtual and real experiences). The latter factors are particularly important in shared VEs in which complex human interactions may need to be modeled.

Here, matching is discussed, including the physical fidelity of a VE, the functional fidelity of a user’s activities, and the fidelity of virtual task loads placed on users, based on their mental representations of virtual tasks developed through real experiences. Matching can be formally defined as the degree to which a VE mimics reality not only in form, but also in terms of

function and the behaviors the VE elicits from users. Physical fidelity refers to the extent to which the structure of a VE is matched to reality. In a reciprocal sense, the influence of VE structure and design on naive user development of concepts of real tasks and environments based on exposure to virtual surrogates are also discussed.

Virtual environment literature (Romano, Brna, & Self, 1998a) has identified individual and collaborative VEs to have the capability to reproduce high-risk, dynamic environments involving team communication, specifically for training purposes. Virtual tasks can also be designed to mimic the degree of cognitive load experienced by users. The realism of the VE and the fidelity of user interactions dictate this form of matching. Matching VEs to reality in terms of cognitive task loading can be critical for two reasons. First, the degree of virtual task difficulty may predict user involvement in, and concentration on, the VE. In fact, virtual task difficulty has been identified as a predictor of the level of presence experienced in a VE (Draper, Kaber, & Usher, 1998). For example, if virtual tasks are boring and mundane, it is likely that users may not attend to them and be readily distracted from performance by activities in the real world. Conversely, if virtual forms of real tasks are too difficult (e.g., using VE for above real-time training [ARTT]) users may give up in attempting to achieve virtual goals. The second important aspect of matching the cognitive load imposed on users in virtual tasks to their real-world counterparts is that loadings must be accurate to ensure skill transfer. Research on the use of VEs for ARTT (Miller, Stanney, Guckenberger, & Guckenberger, 1997) has found that pilots actually perceive flight simulations running at 1.5 to 1.75 times faster than real time to be more realistic than simulations running in real time. Furthermore, the authors state that ARTT improves transfer of training to real domains. Interestingly, through this research one can see that matching of VEs to reality is critically dependent upon users' perceptions and experience and may not always be the best design solution. In the above example, pilots found faster than real-time simulation speeds to be more representative of real flight than real-time simulation. This is apparently a case in which strict matching is undesirable. In designing VE applications it appears to be important not only to match cognitive loading to reality but also to consider user perceptions and experience as well.

Aside from predicting user perceptions of task loadings across virtual and real environments, the physical fidelity of VEs and user interactions in CVEs may also drive a user's ability to develop SA (i.e., to perceive information in the VE needed for virtual task performance and relate it to their virtual task goals). For example, if user information requirements for virtual task performance are not met as they are in the same task in reality (that users may be familiar with) negative transfer of real task performance behavior and skills may result. Furthermore, if specific task-relevant information is not available in VE surrogates to real scenarios, experienced users most likely will not be able to develop the same level of SA in virtual reality (VR) as in reality. Such a lack of matching between VEs and reality could be absolutely critical to the effectiveness of VEs for training applications, such as fighter pilot training in which developing and maintaining SA skills is fundamental to mission success. With this in mind, matching of SA requirements in VEs to reality may also be necessary in VE application design, specifically in VE trainer development for experienced users in order to ensure virtual skill transfer to reality.

The benefit of VEs appears dependent on individual user perceptions and behavioral issues. That is, some users may not perceive CVEs to be realistic because of interface design features, VE rendering capabilities of VE systems (e.g., low simulation update rates, low display pixel density) and their abilities to imagine being in a real environment. For example, Kaber, Riley, Zhou, & Draper (2000) conducted a study of the effects of the design of a VE interface for control of a real telerobot and lag between user actions at the interfaces and the response of the VE or real robot on system performance and user perceptions of presence. They compared a 3-D graphical model of the robot in a simulated task environment with an interface presenting

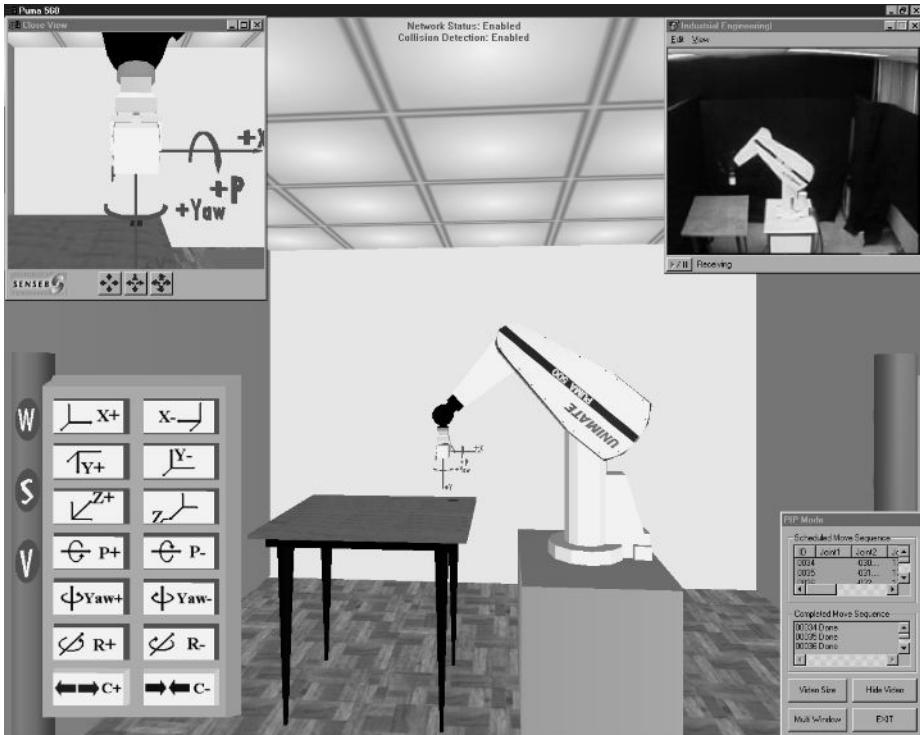

FIG. 18.1. A VE-based graphical preview control interface for a telerobot.

the same models along with live video feedback on the real robot being controlled through the VE (see Fig. 18.1). Control lags in using either interface ranged from 0 to 4 seconds. Both task performance and user presence were significantly influenced by individual differences among a sample of 30 participants; however, perceived realism of the task was found to be significantly greater with the interface integrating VE and video and system performance was best under the minimal lag condition. Along this line of thought, individual differences in perception and behavior may also be underlying predictors of cognitive load experience in VEs and SA acquisition. Consequently, individual differences may limit the capability of individual and CVEs to, for example, accurately replicate for all users realistic cognitive loadings in complex task training or the development of accurate SA in training simulations.

Related to this, much human factors research has demonstrated significant individual differences in perceptions of cognitive workload and the ability to develop good SA in complex task performance (Wickens, 1992; Endsley, 1995). More specifically, significant individual difference effects have been observed in subjective ratings of workload in a virtual task. Riley and Kaber (1999b) observed individual differences in cognitive load perceptions within subject groups in VE experiments using a traditional subjective workload measure (NASA—Task Load Index; Hart & Staveland, 1988) to be so significant that differences among interface technologies in terms of their effect on virtual task workload were not discernable. With respect to SA, Endsley (1995) has observed that often participant ratings of confidence in their own SA differs significantly from the level of SA they have actually developed in complex task performance (e.g., simulated fighter aircraft piloting, automobile navigation with intelligent vehicle highway systems).

It appears that individual differences in experiencing cognitive workload and developing SA may dictate the effectiveness of both individual and collaborative VE applications for

training. That is, inaccurate perceptions of cognitive load in VEs may limit transferability of skills developed in virtual tasks to real-world tasks. Beyond this, Ellis (1993, see Romano et al., 1998a, for reference to Ellis' work) offered that internal (cognitive) processes (such as SA) might actually dictate human perception of sensory information in a VE and, consequently, one's sense of it being a physical reality. Therefore, differences in higher levels of individual cognition, which develop with task experience, may drive perceptual activity in VEs and, consequently, the effectiveness of an application.

2.1.1 Relevance of Experience to CVE Design

To this point the focus has largely been on the role of user experience and cognition in VE application design to individual virtual environments. Of course there are aspects of user experience that are particularly relevant to performance in CVEs and teaming in virtual tasks.

2.1.1.1 Team Experience. On the basis of research in team decision making (Orasanu & Salas, 1993), VE researchers (Romano, Brna, & Self, 1998b) have inferred that experience in team performance may be highly relevant to the success of CVE applications. Specifically, individuals who are accustomed to working in teams and, more specifically, working with a particular group of individuals may better collaborate in virtual groups as a result of being able to easily predict the actions of fellow team members. Novices to real-world teamwork and decision making may, for example, not engage in virtual group behavior in CVEs as readily as experienced team players and, consequently, virtual team interaction may be fragmented and interrupted.

2.1.1.2 Virtual Environment Experience. The impact of experience in VEs on user performance needs to be considered. For example, how effective can a person be in a virtual task if they have experience in using VE systems in general or if they have experience in the specific VE in which a task is to be presented? Observation of people using VE systems (or teleoperators) reveals differences in users' abilities to interact with such systems. Some people find interaction with a VE a simple task, whereas others find it a difficult one. There is a parallel phenomenon in teleoperation: although there are no systematic data, one of us with long experience with teleoperation (Draper) has observed that some people never become capable of performing teleoperation well, whereas some are good at it from their first experience. It is difficult to predict whether these differences will be ameliorated or compounded by greater immersion (i.e., introduction of a fuller range of sensory modalities and enhanced motor interaction in VE systems). It is therefore important to further develop an understanding of how a broad range of aptitudes, including motor and verbal abilities affect human–VE interaction.

Romano et al. (1998a) have argued that individual differences in user adjustment and adaptation to VEs is linked to their experiences of presence and virtual task performance in those environments. Kalawsky's (1993) and Lombard and Ditton's (1997) works are also supportive of this argument. Lombard and Ditton (1997) speculated that the intensity of experiences of presence in VEs is associated with duration and frequency of exposure to virtual environments. Therefore, individual differences in experience level with VEs may dictate user presence.

With this research in mind, CVE design for distributed user teamwork in virtual tasks should consider user experiences in real-world teamwork for forming effective virtual teams. For example, system administrators may need to ensure that users immersed in a CVE participating in a virtual group have a similar level of teamwork experience to promote collaborative virtual task performance. Similarly, CVE application designers should also consider the level of adaptation of users to specific VEs for the same reason.

2.2 Technical Aptitudes

Human-computer interaction research has demonstrated that different technical aptitudes (e.g., spatial, reasoning, verbal ability) are predictive of performance in certain types of computer-based tasks (see Egan, 1988). These studies seem to suggest that persons with low spatial aptitudes may struggle with system navigation issues, like becoming disoriented within hierarchical menu systems (Sellen & Nicol, 1990). This may be particularly relevant for VE systems that require navigation through a world. In teleoperation, McGovern (1993) found that remote vehicle operators can become lost within the remote world, even when provided with maps and landmarks, and remote manipulator operators can become confused in terms of display/control orientation if they are not provided with a view of the entire remote manipulator (a “worldview”). The former result might be expected given that knowledge acquisition from maps is associated with visual/spatial ability (Throndyke & Stasz, 1980). In general, spatial memory appears to dictate user ability to find objects on a display. It seems reasonable to assume that specific aptitudes such as spatial memory, visualization, and orientation may be predictive of human performance in VEs as well, particularly given that an additional spatial dimension describes virtual task spaces in comparison to most conventional computer applications.

Stanney and Salvendy (1994) found that even though persons with poor spatial abilities were unable to internalize the structure of complex systems, they could recognize the structure of systems when they were well organized and when structure acquisition was made salient. This suggests an opportunity for VE system designers; the system can be tailored to accommodate differences among users, but even more powerfully to compensate for the weaknesses of a particular user. It also suggests an approach to training for VE use; persons with low spatial abilities could have their initial experiences constructed to emphasize spatial relationships within the virtual environment. These persons could be restrained from proceeding to tasks until they demonstrated some criterion knowledge of VE structure.

2.2.1 *Spatial Aptitude*

Virtual environment research (e.g., Greenhalgh & Benford, 1995) has relied on the notion that a user's position and orientation in a VE, as in a real environment, will largely affect their perceptions of the VE, other users in a CVE, and their performance in virtual tasks and collaboration. Interestingly, individual interests and projections about events based on environmental information dictate a user's spatial position in any environment. On a deeper level, the background and experience differences among individual users may dictate their spatial abilities to satisfy perceptual interests in a VE and, consequently, their performance.

Obvious differences have been observed between novice and experienced VE users in moving about virtual worlds. Novices appear to have greater difficulty, or encounter problems more frequently, in navigating close virtual spaces (e.g., passing through doors) to see objects of interest (Greenhalgh & Benford, 1995). Therefore, novices may not always be able to perceive VEs as designers intended. Experienced user perceptual interests may be better satisfied and their perceptions of a VE may be more accurate.

As users develop more experience in using sophisticated immersive displays as part of VE systems for perceiving visual stimuli from a VE and they become more accustomed to using hand-controller interfaces to move in VEs that do not use natural human motion control mechanisms as metaphors, their abilities to accurately perceive VEs and to interact with other users in CVEs improves (cf. Hix et al., 1999). With this in mind, VE application designers must look to create more natural control interfaces to promote novice user spatial positioning performance or to take into account user experience in assigning virtual tasks or provide training in virtual motion (Kaber & Riley, in press).

2.2.2 Reasoning Aptitude

Like spatial abilities, reasoning (based on mathematics and science knowledge) has been found to be an important aptitude for computer task performance. Results of HCI research have shown that users who are able to develop their own strategies for computer tasks through experience-based reasoning skills are faster than nontechnical users in error-free performance (Egan, 1988). It is likely that reasoning aptitudes (deductive, inductive, etc.) are important to HVEI as well, particularly in user understanding of the plot, or dynamic of a VE, and how to respond to independent behavior of virtual objects. In a VE that a user has not been exposed to before, the concept of a plot has been identified as being potentially important to providing a sense of involvement in the virtual environment (Allen, Bolton, Ehrlich, & McDonald, 1999). Consequently, reasoning aptitude may affect user perceptions of virtual task involvement.

Unfortunately, there is paucity of VE research relating specific technical aptitudes and user knowledge to experiences of presence in individual and collaborative VEs, or to user performance in virtual tasks. However, on the basis of the HCI literature, it can be hypothesized that different types of reasoning skills may be critical to user development of strategies for virtual task performance. The technical aptitude of computer users has been found to be critical to computer task performance. For example, scientists and engineers have been found to perform better at computer-based information search tasks than persons of a social science background (see Egan, 1998). User technical aptitude and experience may also be important in HVEI, specifically science and engineering learning may be more suited to logic-oriented virtual tasks, whereas other learning may be more appropriate for creative tasks, such as virtual art. With this in mind, it may be critical for VE application designers to consider user aptitudes in virtual task design or to consider the aptitudes of multiple users involved in collaborative virtual tasks to ensure specific aptitudes and experience are represented for error-free performance. It is worth noting that the designers of VEs are generally people with high technical aptitudes, whereas users may not be (depending on the specific application). This mismatch may result in the development of a VE that is not optimal for the target user population. This is a classic human factors problem in system design.

2.3 Age-related Considerations

Age has been identified as a predictor of the difficulty of learning to use computers (Egan, 1988). However, the impact of age seems to operate only across widely varying ages and when experience-related factors are controlled. Furthermore, the studies reviewed by Egan (1988) examined learning to use complex computer systems. In VE systems, although the systems may be more complex *per se* as computerized systems, learning to interact with them may often be simpler. That is, walking through a virtual forest may require a more complex computer hardware and software system than text editing, but the VE task (walking through a forest) may be more similar to mundane experiences than text editing. Therefore it is not clear how well HCI results apply to interaction with VE systems in regard to age-related considerations. The ways in which age affects human interaction with computers and VE systems is not yet fully understood and may involve a cultural bias. At the time of this writing, very few persons have as much as two decades of experience with computers, no matter what their age. The population that matriculated after about 1983 will have much greater experience with computers than the population prior to that time. It remains to be seen how (or if) greater lifelong exposure to HCI will moderate the relationship between age and learning for computers and VE systems.

However, there are physical changes that may occur with age, especially in terms of reductions in perceptual and cognitive capabilities that may influence VE system interaction (Birren

& Livingston, 1985; Fisk & Rogers, 1991; Hertzog, 1989; Salthouse, 1992). These changes may result in difficulty in sensing, perceiving, and understanding VE scenes commensurate with difficulties experienced in real-world scenes. Age-related degradations in visual acuity, hearing, memory, and range of motion are well documented and well-known colloquially. Helping users to cope with these phenomena is one of the potentially important capabilities of VE systems and at the same time a challenge for developing human–VE interfaces.

Many unique applications of VEs for elderly and disabled person use have been identified. These applications include using VE for continuing education and skill training of older persons remote from real educational facilities (Odegard & Oygard, 1997), providing disabled persons with access to virtual replicas of real environments, like clean-laboratory facilities, that would not otherwise be accessible to them (Nemire, Burke, & Jacoby, 1994), and VE training of the elderly and disabled in navigating replicas of foreign environments in advance of actually experiencing their real counterparts (cf. Cripps, 1995). These types of virtual experiences can be extremely valuable to the employability of these populations and the sustenance of a nation as the majority of its population ages.

Beyond these applications, networked VEs and CVEs can be used to provide elderly and disabled populations with access to commercial goods and services in a manner far exceeding that achievable through the Internet and World Wide Web, and that might not be possible in reality because of a person's physical limitations. For example, simple applications such as a virtual grocery store could significantly enrich a physically disabled person's life by allowing them to buy food for themselves and to have a multisensory experience of an everyday activity like an average person (e.g., enjoying the sights and smells of a bakery or delicatessen). This essentially means that networking capabilities for supporting CVEs must provide for near real-time application responsiveness and system synchronization.

Such practical applications of VE motivate the formulation of application design considerations of user age and physical abilities. Unfortunately, as with other user characteristics and individual differences identified in this chapter as being critical to VE application design, little structured, formal empirical research has been conducted into accommodating age and disabilities in VE application design.

User age may be important in VE application design based on learning abilities and difficulty experienced in understanding VEs (Egan, 1988; Stanney et al., 1998). Middle-aged persons and youngsters have been found to be similar in the stages of learning they exhibit in CVE experiences, including developing knowledge on motion and orientation in an environment, and then how to collaborate on interaction with virtual objects and tasks (Odegard & Oygard, 1997). However, developing knowledge on complex VEs may be more difficult for aged persons because of degenerative effects on physiology, particularly the senses (e.g., vision and hearing). This is potentially critical to VE design involving multimodal stimuli, including 3-D imagery and spatialized audio, or tactile feedback through force-reflecting control devices.

Virtual environment application design efforts need to be focused on age-related individual differences in vision and hearing. They may, however, be structured in an identical manner for all age groups according to the stages of user learning. For example, in acquainting both children and older adults with CVE applications, VE research (Odegard & Oygard, 1997) suggests presenting displays and interfaces that allow them to develop an understanding of spatial positioning and navigation in VEs in advance of presenting them with virtual task objects and showing them the representations of other users in the CVE.

The impact of age-related effects is, of course, not limited to the perceptual system, but higher level cognitive processes may also be affected. Human–computer interaction research has demonstrated that with age, user ability to allocate attentional resources to stimuli and divide attention across multiple sources of information degrades (Egan, 1988). User ability to generate complex computer commands and effectively search for information also becomes

significantly worse with age. Differences have been informally observed in how youngsters and middle-aged persons approach virtual tasks. According to Odegard and Oygard (1997), older persons are much more analytical in their approach to the tasks they need to perform, yet they are less clever in formulating strategies to accomplish the tasks in comparison to young children experiencing the same virtual worlds. Youngsters appear to respond spontaneously to stimuli in VEs and are explorative in their approach to solving problems.

These effects of age on human information processing need to be considered in designing VE applications for user performance. Beyond considering attention allocation capabilities, creativity and long-term memory storage in application design, geriatric effects on spatial orientation and memory, as well as technical aptitudes for reasoning should be considered. These user characteristics have been discussed previously, and it has been suggested that they may interact with experience and affect user sensations of presence in VEs and virtual task performance.

2.4 Accommodating Disabilities

Although much speculation could be offered on how user disabilities might affect performance in VE, there is a paucity of research evidence to support specific VE application design guidelines. With this in mind, without attempting to reflect different user deficits in VE design, such applications may not realize their full potential. Like the degenerative effects of aging, deficits in physical and information processing capabilities should be considered to accommodate users in VE design for presence and performance. How specific deficits should be handled needs to be empirically researched.

Virtual environments provide unique capabilities for addressing physical disabilities of users, including hand-control navigation techniques and voice driven input. They also offer methods for dealing with perceptual-cognitive limitations, including multimodal representations of stimuli (e.g., visualizing sound for the hearing impaired). With these capabilities, VE system designers should be able to structure, for example, visual, auditory and tactile interfaces to allow all persons to interact effectively with virtual environments. In addition, displays should be structured to ensure user perception of stimuli from VEs for virtual task performance.

2.5 Personality Traits

Other user characteristics, such as personality, may affect performance in VEs (Stanney et al., 1998). Unfortunately, little empirical data has been developed that supports personality as being critical to HVEI. With this in mind, inferences on the potential effects of personality traits in VE task performance have been made on the basis of recent VE literature and results of HCI research. Specific traits related to computer task performance, in general, which may play a role in VE user performance, include self-concept and self-representation. Self-representation, such as via an avatar, could be critical in CVEs where interpersonal communication must be facilitated among participants. It may also be important to ensure consistent or recognizable representation of users in shared virtual environments.

Other influential personality traits may include user dedication to virtual tasks, the sense of being a part of a group of virtual collaborators and the willingness to collaborate. Human-computer interaction research has demonstrated that user passion for playing computer games is dependent on interface design and gender (Egan, 1988). System design factors and individual differences may also dictate user concentration on VE tasks. With respect to oneness with a group in CVEs, Slater and Wilbur (1997) offered that performance in shared VEs, unlike individual VEs, not only depends on whether the user feels part of the VE, but whether they also feel a part of a group of virtual actors. If users are compelled to a group experience, they may

be more willing to collaborate, which has been found to be critical to performance in shared virtual environments. Romano et al. (1998b) stated that noncollaboration in CVEs degrades performance due to other users simply being distractors to individual task performance.

As a note, when we undertook the development of this chapter we speculated that the majority of theoretical research into individual difference effects on VE application effectiveness would be focused on the study of characteristics other than personality traits (or social skills) and their relevance to VE design. However, subsequent to reviewing the literature on CVEs, we found that many contemporary theoretical writings exist on this topic and some informal empirical investigations have been conducted with intriguing results.

2.5.1 Self-representation in CVEs and Matching VE Interfaces to Human Interfaces to Reality

Virtual environment experiments (Fraser & Glover, 1998) have revealed that differences in interfaces to CVEs, in terms of system displays and hand controllers, as well as how users are virtually represented in a VE, significantly affect individual sensations of realism about the VE and the continuity of user interactions. For example, desktop VR has been compared with immersive VEs, facilitated through projection displays or Computer Automatic Virtual Environments, demonstrating that the transparency of the interface (i.e., the degree to which the user perceives virtual stimuli to be natural or unfiltered by visual display interfaces?) dictates whether task interruptions may occur and how fragmented interaction is among CVE participants (Fraser & Glover, 1998). Low transparency, common with desktop displays with which users feel as if they are looking through a window into the virtual world (Cruz-Neira, 1998), tends to promote interaction breakdown and poor task performance.

With respect to self-representation, recent research (Crampton & Hilton, 1999) has been conducted to develop human body scanning systems for developing virtual embodiments of users participating in CVEs. This work suggests that accurate representation of a user's physical form in VE may be important to participants in CVEs. Further, some VE research (Tromp, Bullock, Steed, Sadagic, Slater, & Frecon, 1998) has offered that CVE users may become embarrassed through their self-representation as a result of specific user-user interactions in CVEs.

Breakdowns in user interactions in CVEs also appear to result from disparities in the functional fidelity of VE from reality causing users to make incorrect assumptions on collaborative activities. Fraser and Glover (1998) found that user perceptions of the behavior of their self-representations in VEs must match, for example, the control interfaces they use to move their virtual embodiment. That is, if a user is provided with a realistic human representation in VE, the interfaces he or she uses to cause behavior of the virtual representation must resemble natural human interfaces to reality (i.e., hands, arms, etc.).

These findings are not particularly surprising, as physical and functional fidelity of VEs have been examined frequently in the literature as to their role in user presence in VE applications and their performance. However, the findings are important to this chapter in that individual differences may largely moderate user perceptions of interface transparency and consistency of virtual representation in a CVE with real interfaces to the virtual environment. For example, different users may perceive desktop VE systems to be more or less transparent depending on their immersive tendencies, including the ability to imagine oneself in another world and to concentrate on the presentation of that world to the extent that they ignore stimuli from reality (Witmer & Singer, 1994). Further, crude virtual block-humanoid self-representations may be acceptable to some participants in CVEs, whereas others may require high-resolution body scans be used to represent them, and that their virtual embodiments be clothed and in a manner representative of their professional or social position. Also, for some CVE users, a wand controller, for example, may be acceptable for facilitating virtual locomotion; however,

others may require tracking of their actual body motions to direct the movements of their virtual embodiments. Therefore, appropriate user self-representation in VE applications may be in the eye of the beholder, as are beauty and fluidity of motion in reality. Unfortunately, to our knowledge there is no empirical evidence available at this point in time that maps individual sensitivities to interface quality and the form and function of self-representations in CVEs to the success of the collaboration measured in any terms (based on Fraser and Glover [1998]).

3. RELATIONSHIP OF PRESENCE TO VIRTUAL COLLABORATION AND TASK PERFORMANCE AND THE RELEVANCE OF USER COGNITION TO SHARED PRESENCE

In the VE literature, individual differences in personality traits seem to be discussed primarily because of a suspected influence on presence experiences in virtual environments. Many facets of human personality and aspects of cognition have been theoretically implicated in user presence experiences in individual VEs, and to a greater extent in CVEs because of the role of personality in human interpersonal communication. Durlach and Slater (1998) have suggested that user experiences of shared presence in CVEs are based mainly on two factors pervasive across users, including a sense of physical presence in a common virtual place and the ability to communicate with other participants. Therefore, the experience of personal presence may be a prerequisite to shared presence, and to achieve shared presence in CVEs user-user interaction must be possible. As a first thought, these seem to be relatively simplistic conditions for shared presence in CVEs as compared to the conditions speculated about in the literature (cf. Slater & Wilbur, 1997) for presence in stand-alone virtual environments. However, Durlach and Slater (1998) suggest that their achievement is critically dependent upon individual differences including a user's background, interests, viewpoints, and sensitivities, which play a role in virtual collaboration and individual presence as well as VE application effectiveness. Differences in perception and cognition may critically influence the effectiveness of CVE applications, or the use of common VEs, by limiting users' experiences of presence and their abilities to concentrate on virtual tasks. Of course, this issue is also relevant to individual VE effectiveness. Also, factors influencing acceptance of individual VEs for work, and presence experiences in stand-alone VEs, may be relevant to CVEs. In fact, recent research (Tromp et al., 1998) has demonstrated that individual presence and sensations of shared presence in CVEs are positively correlated. The potential factors underlying shared presence, and the conditions of its occurrence, seem equally complex as those associated with presence, if not more so.

One might ask at this point, why should we care about presence experiences in stand-alone VEs and shared presence in CVEs, and, furthermore, the role of user psychology in presence experiences in VEs? Romano et al. (1998b) offered that virtual task performance in individual or collaborative VEs is dependent on user ability to develop a sense of presence or shared presence, including the perception of being in an environment with others and engaging in group behavior. Shared presence in CVEs has also been linked to user collaboration. Specifically, it has been speculated that individual ability to achieve presence and sensations of presence in VEs may dictate whether collaboration occurs among users in the same VE (Romano et al., 1998a). Vice versa, empirical study (Romano et al., 1998b) of CVE gaming has shown that when users collaborated effectively, they shared a strong sense of presence in the CVE and performance was superior. However, whether presence produces collaboration and performance or whether collaboration promotes performance and presence still remains a circular argument.

Consequently, the success of a VE application may be indirectly dependent on individual differences in psychology and cognitive abilities including, for example, immersive tendencies, sociability, concentration, and imagination. Furthermore, Romano et al. (1998b) linked the

enjoyment of virtual experiences to presence experiences; therefore, deriving pleasure from VEs, such as in using an entertainment application may also be dependent on individual differences. Finally, since CVEs can be used for unique applications involving human–human interaction and shared presence has been linked to the success of collaboration in VEs, VE researchers have speculated that it may be important to look at human factors in interpersonal communication that are apparent in reality, such as personality, as well as their role in presence experiences for ensuring application effectiveness.

3.1 Immersive Tendencies

Like individual subjective presence, the factors that influence a user's sense of shared presence with other participants in a common virtual place may be affected by individual immersive tendencies. Empirical studies of presence have demonstrated a significant correlation among subjective ratings of presence in VEs and user predisposition or susceptibility to immersion (Kaber et al., 2000; Riley & Kaber, 1999a; Witmer & Singer, 1994, 1998). These tendencies are thought to be dependent on aspects of human cognition and behavior, including concentration, imagination, and self-control (Psotka & Davison, 1993). Individual differences in immersive tendencies, particularly the capabilities of one's "imaginoscope," may dictate the degree to which a CVE seems real to a user and, consequently, the degree of association users perceive with a VE and the shared behavioral presence they exhibit (i.e., acting as if they were present in a real environment). For example, Witmer's and Singer's (1994) work suggests that daydreaming and becoming lost in science fiction novels, among other activities, may predict immersive tendencies and presence experiences in virtual environments. They have also considered abilities, such as remaining focused on television programs and performing mundane tasks, to be predictive of immersive tendencies. These seem to reflect psychological factors that may be indirectly related to VE application effectiveness.

3.2 Attention and Concentration

Recent research into the role of user cognition in performance in CVE tasks has also revealed that user abilities to allocate attention and to concentrate on stimuli from a VE may dictate their degree of presence (Draper et al., 1998), participation in virtual groups and, to some extent, the success of an application. Different degrees of presence among users of CVEs have been informally observed, including an extreme lack of presence. Greenhalgh and Benford (1995) noticed that some users of a collaborative virtual teleconferencing system became easily distracted with activities external to the CVE to the extent that the virtual representations of these users in the CVE did not respond to, or ignored, direct communication from other participants. This is an example of individual differences in attention allocation and concentration abilities playing a role in the effectiveness of a VE for collaborative activity.

The possible psychological factors in presence discussed here most likely represent a fraction of user characteristics that potentially moderate presence experiences in VEs and the effectiveness of applications, particularly VE trainers. However, the role of attention as a factor underlying the impact of a cluster of user characteristics on presence is a research topic that is, at the present time, both insufficiently pursued and potentially very important.

4. PERSONALITY TRAITS AND COLLABORATION IN VEs

The properties of immersion in VEs and individual psychology may not only indirectly affect CVE effectiveness through user presence experiences in virtual worlds, but they may affect it through virtual collaboration, and group behavior or teaming as well. This effect may occur

directly through the roles users assume or do not assume as participants in CVEs on the basis of personality and social skills. Certainly, noncollaboration in CVEs is an option for users, and some may be inclined to function independently based on social disposition (e.g., antisocial) or personality type (e.g., dominant, reclusive). Others may be apt to collaborate in VEs through different roles.

Roles people adopt in VEs have been empirically observed (see Romano et al., 1998a) including "teacher," "pupil," "team player," and "dominator." As in reality, individual differences in personality traits may drive the adoption of these roles. People who are accustomed to doing most of the talking and guiding others may assume the role of "teacher." Persons who normally derive more confidence in their activities through reliance on others may tend to act as "pupils" in CVEs. Collaborative virtual environment participants that share resources and are comfortable with the process of reaching decisions by consensus usually play "team player" roles. "Dominators" are essentially nonteam players that tend to ignore the suggestions of others and attempt to keep physical and mental distance between themselves and other people. "Dominators" are, for the most part, noncollaborators.

Subjective evidence of these roles has been provided by Romano et al. (1998a), who showed that some participants in a CVE game felt that they could do better without a partner and that others felt their performance was enhanced when they could perceive a partner. Unfortunately, specific personality traits of the participants were not recorded and linked to the roles they assumed in virtual gaming.

With respect to the properties of immersion impacting VE effectiveness through virtual group behavior, VE research has shown that the roles persons adopt in CVEs may be dependent on the VE system interfaces they use in addition to user personality traits. Tromp et al. (1998) conducted experiments on small group behavior in CVEs revealing that the computational resources available to a user and the degree of user immersion in the CVE predicted the group leader in collaborative virtual tasks. Interestingly, persons who emerged as leaders in the VE applications did not adopt the same role in reality. This suggests that interfaces to VEs and the structures of VEs in comparison to real environments may be directly associated with user roles. It also suggests that interfaces and structures of CVEs interact with user characteristics to determine emergent roles in a way not predicted by observation of individual behavior in real-world groups.

Other factors beyond individual differences in personality and the capabilities of VE interfaces have been shown to be influential in the roles users adopt in CVEs and their social behavior. Tromp et al. (1998), in their CVE investigations, demonstrated that male users tended to adopt leadership roles in collaborative virtual tasks; however, at a similar frequency, male participants appeared to impose on themselves traditional social barriers observed in reality and did not engage in group behavior. Whether such findings are useful for VE application design purposes has yet to be seen. However, evidence of individual differences in role playing in VEs based on user psychology and gender, for example, can be considered as a testament to the unique capabilities of VEs to replicate real situations, or at least convey to some human users the sense of being in a real environment with others.

While user personality traits could affect VE application effectiveness through user role assumption, it seems important to identify exactly how this may occur. In team decision making, the decision-making power that team members have may be equal, or power may be limited to only a few participants or to the team leader. This is critical because the roles people adopt in groups have been related to the overall effectiveness of the group. Therefore, depending upon how decision-making power is allocated and the roles assumed by users in a CVE, user collaboration may or may not be successful. For example, if decision-making power is allocated to a virtual team leader and a person who is accustomed to a real leadership role adopts the same role in the CVE, the capability of that individual to exhibit autocratic behavior will largely predict the team's effectiveness.

5. ACCOMMODATING INDIVIDUAL DIFFERENCES IN DESIGNING VE APPLICATIONS FOR PRESENCE

Given the plethora of VE properties that may dictate presence and that may play a role in individual and collaborative VE presence, as well as the significant psychological individual differences possibly moderating presence experiences, it is important to identify VE application design methods to optimize presence. Unfortunately, at this time empirical VE research is in its infancy in terms of mapping relationships between VE system characteristics, human factors, and virtual task dimensions to user presence experiences in individual virtual environments. Furthermore, there is a paucity of research into shared presence experiences in CVEs and VE system and user factors underlying shared presence. Of course, VE application design guidelines for encouraging presence experiences are only important if presence plays a role in, for example, VE training effectiveness and performance with VE interfaces to real systems for real task performance. Also, a relationship between presence and performance in VEs has yet to be empirically established through objective measurement of presence and modeling of virtual task performance.

Even in light of all this, VEs have unique capabilities that could be exploited to resolve some of the effects of individual differences in perceptions of virtual worlds including, for example, the ability to provide a single user with multiple viewpoints of an environment, such as the viewpoint of a fellow collaborator. With this in mind, the capabilities of VEs may also be exploited to ensure shared user perspectives on virtual tasks and to encourage a sense of understanding and belonging among users, and shared presence in an application (Greenhalgh & Benford, 1995). These effects may be moderated based on user access, either remote or proximate.

6. REMOTE VERSUS PROXIMATE ACCESS EFFECTS

A VE allows human sensory, motor, and cognitive abilities to span distances and to enter where people may not physically intrude. This requires application of three critical subsystems: the remote portion, including sensors and actuators; the local portion, primarily a human-machine interface; and the communication subsystem, which transmits information back and forth between the user and the computer-mediated area. This section will explore some effects of the latter subsystem on performance within VEs and on how they interact with user characteristics.

For VEs, remote may mean a physical separation, as when a user in Raleigh, North Carolina, operates a VE in Oak Ridge, Tennessee; or it may mean a metaphorical separation, as when a user explores a VE that resides on files stored on her computer. However, physical separation *per se* is not the fundamental issue. Physical separation exercises its impact through the effects of distance on communication bandwidth, latency, and noise. Bandwidth tends to be reduced and latency and noise increased by distance. These critical features of a VE communication system are important whatever the physical separation between user and computer-mediated world. Remote versus proximate is best understood as the metaphorical separation between a user and a VE, a separation of sensorimotor capabilities within the VE from normal human capabilities. From this perspective, the degree of remoteness is the degree of perturbation of information flowing to and from the virtual environment.

6.1 Behavioral Cybernetics

The behavioral cybernetics (or psycho-cybernetic) model described by Smith and colleagues (Smith, 1972; Smith, Henning, & Smith, 1995a; Smith, Keran, Koehler, & Mathison, 1995b; Smith & Smith, 1962; Smith & Smith, 1987; Smith & Smith, 1988; and Smith & Smith,

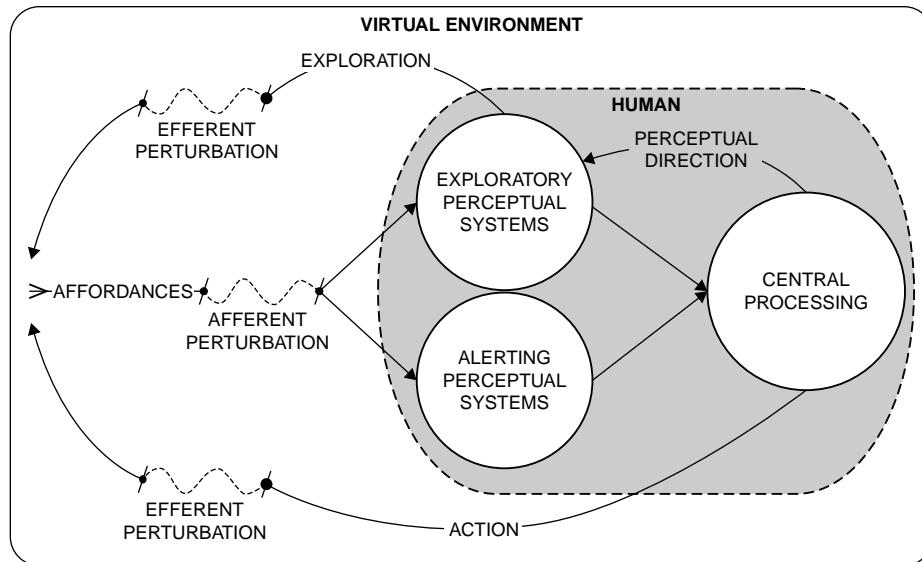

FIG. 18.2. Simple model illustrating perturbations of information flow in the human–VE interface.

1989) provides a perspective for examining the impact of proximate versus distal access. At the heart of this model is the notion that humans respond to information present in an environment (feedback) by manipulating that environment. This changes the feedback and elicits another controlled response. Therefore, humans manage the system with the aim of controlling feedback in a continuous or continuously sampled process that persists until reaching some feedback goal. Perturbations occur when the expected relationship between the feedback and the controlled response is altered as, for example, when their timing is different than expected.

During use of a synthetic environment, perturbations occur in three ways. First, temporal perturbations affect the timing of the feedback and control response. Time delay in signal transmission is an example. Second, spatial perturbations affect the spatial relationships between feedback and control, as when the viewpoint of a representation of one's hands is offset to one side or another in the synthetic environment. Finally, perturbation by filtering occurs when the amount of information in the feedback signal is in some way different than expected. An example is when users view a scene by television: because a television presents images as mosaics with a finite number of elements, the amount of information afforded is less than during direct viewing. In effect, the television is a low-pass filter on visual information. Figure 18.2 presents a simple model of perturbations in information flow in HVEI.

From the perspective of the behavioral cybernetic model, the goal of human factors in synthetic environment development is to identify perturbations, quantify their effects, and analyze the trade-offs of potential solutions. The aim of the process is to optimize the machine for its mission by reducing perturbations as far as is economically appropriate and providing the means for overcoming the effects of perturbations when it is not practical to remove them.

6.2 Common Sources of Perturbations

The issues critical to effective VE application design that depend on user location are predominantly technological in nature. The central issue is communication bandwidth or capacity,

which brings with it the subissues of application resolution, update rate or latency, and level of environment detail, among others. These factors dictate whether, for example, a 3-D user interface can be provided or spatialized sound can be used.

6.2.1 Communication Bandwidth

Bandwidth serves as a low-pass filter on the information from the remote world presented to the user. Certain displays have inherently limited bandwidth: Television, for example, reduces visual information presentation to a 525-line, raster-scanned mosaic image. In many cases, the tools used to transmit information sensed in a remote world to local displays also filter information, typically as low-pass filters.

6.2.2 Latency

Latency is the temporal perturbation that occurs when events in the remote world occur later than expected. There are two common sources: Latency often occurs when the computer system cannot update a virtual world quickly enough, and communication delays can be present between the remote world and the local controls and displays (the latter is commonly called lag).

Latency causes serious difficulties with VE use. For example, low update rates (below 12 Hz) can induce illusory perception of motion and simulator sickness, but images presented at higher rates seem smoother and support better depth perception (Durlach & Mavor, 1995, p. 117; Piantanida, Boman & Gille, 1993; chaps. 29–32, this volume). Time delays during teleoperation trigger adoption of a move-and-wait strategy, in effect shifting users out of real-time control, whether produced by communication delay (Ferrell, 1965, 1966) or poor timing between controller inputs and remote manipulator actions (Draper et al., 1987b).

6.2.3 Noise

Noise may be present in the remote world or produced during signal transmission. For example, suspended particles in seawater and marine growth may be considered noise during subsea teleoperation, and the additional bandwidth provided by stereoscopic television can help users see through the noise to view tasks (Smith, Cole, Merritt, & Pepper, 1979). Noise may be introduced into signals by interference, as when radio signals transmitted from earth surface to low earth orbit are affected by atmospheric conditions.

6.3 Remote Versus Proximate Access Effects on VE Application Design

From the preceding, it is more fruitful to examine remote versus proximate access in a metaphorical sense than in a literal sense. It makes no difference to the user if the “remote” world exists within the computer on her desktop or on the surface of the moon, as long as the literal distance does not affect bandwidth, latency, or noise. The literal distance is important only in terms of its effect on metaphorical distance, that is, if it creates perturbations.

But what is the impact of perturbations on requirements for VE design? Telerobotics is a cousin of VEs, differing mainly in that the remote world is a physical world for telerobotics, whereas it is a computer-generated one for VEs (Durlach & Mavor, 1995). Experience in telerobotics provides illustrative examples.

First, function allocation is affected. The recent success of the NASA Mars rover demonstrates how time delay affects function allocation. Without time delay, it is possible to control telerobotic vehicles in real time. However, with time delay, it is necessary to allocate

functions differently, with the robot responsible for controlling its actions and the human adopting a more supervisory role. In VEs, one might expect a similar effect. Systems with time lags should probably be designed for interaction that is more symbolic and oriented toward strategies.

Second, the nature of displays and controls is affected. Relatively noisy, low-resolution displays may be enhanced by stereoscopic presentations, as was the case for subsea teleoperation (Smith, Cole, Merritt, & Pepper 1979). High-resolution visual images providing crisp edges and texture rendering may not be much enhanced by stereoscopic presentation (depending on the nature of the task and user characteristics). Avatars that have good responsiveness, where responsiveness is how well the VE “reproduces user . . . trajectories and impedance in time and space” (Draper, 1995, p. 71), are probably most appropriately controlled using position-position tracking schemes. Avatars with poor responsiveness may be controlled better using rate control joysticks.

7. SUMMARY AND CONCLUSIONS

The study of individual differences runs somewhat against the common grain of science, which more routinely observes individual cases and induces, from the aggregate, the general. The corollary of this in design is identification of shared characteristics, or a shared range on some characteristic, like stature, and designing toward the common. In science, the unusual is sometimes referred to as an outlier and removed from a data set; in systems operation the unusual must accommodate themselves to the design or create their own modifications. However, individual differences are more than just annoying departures from the norm. They are expressions of human variability that can be accommodated by a system if the technology is mature enough and if the designers are clever enough. In fact, systems designed to the aggregate do not allow the best performance on average; they only allow the best performance for a single instantiation of a design, on average. Systems designed to take advantage of individual differences may, in fact, allow optimal performance.

This chapter has identified some individual differences which designers should be aware of when developing virtual environments. It has paid particular attention to collaboration in VEs, which appears to be an important emerging application of that technology.

Physical individual differences are of course important in the ergonomics, strictly speaking, of any system, but the focus of this chapter has been on psychological differences. For example, individuals vary in their social and teamwork skills, and one can expect differences on these dimensions that are observed in the real world to carry over into the virtual. It appears that this is so, but there may be a moderating impact of other user characteristics, specifically, for example, technical aptitudes. Differences in attention allocation skills affect not only a user’s own experience of a VE, but also the type of interactions that occur within a CVE and group performance.

It seems, therefore, that there exist two classes of individual differences that are important for VE development. First, there are individual differences related to how a person interacts with a virtual environment. These differences are, most importantly, cognitive and affect how the person functions within a virtual environment. Specific variables have been identified and include attention allocation, predisposition toward presence experiences, and technological aptitudes, among others. This class is generally important; that is, it applies to all VE applications. Second, there are individual differences related to how a person interacts with other persons within a CVE. These differences are, most importantly, social skills. These include interaction style, interpersonal skills, and tendencies toward particular roles within a group dynamic, among others. This class is important in the case of CVEs.

TABLE 18.1
Virtual Environment Application Design Recommendations

<i>Design Features</i>	<i>Recommendation</i>
Realism	<ul style="list-style-type: none"> ● Ensure VEs provide for rich multisensory experiences like reality (and VE system interfaces are suited to innate abilities of users). ● Ensure VE and its objects make up realistic or believable surroundings. ● Preserve features of real spaces to encourage user creativity in virtual task performance (Acker, 1995). ● Make CVE applications and user interactions as realistic as possible to ensure cognitive loadings in VE tasks are similar to loads experienced in real-world tasks ● Match cognitive loading to reality, in addition to considering user perceptions and experience. ● Minimize disparities in functional fidelity of VE from reality to prevent breakdowns in user interactions in CVEs and prevent users from making incorrect assumptions on collaborative activities.
Interface	<ul style="list-style-type: none"> ● Create more natural control interfaces to promote novice user spatial positioning performance or to take into account user experience in assigning virtual tasks or provide training in virtual motion. ● Structure displays to ensure user perception of stimuli in VEs for task performance. ● Structure, for example, visual, auditory and tactile interfaces to allow all persons to interact effectively with virtual environments. ● Provide capability to address physical disabilities of users including hand-control navigation techniques and voice driven input. ● Carefully consider design of interfaces to CVEs (system displays, hand controllers, and user representation) as they affect individual sensations of realism about VEs and continuity of user interactions. ● Exploit unique capabilities of VEs to resolve some of effects of individual differences in perceptions of virtual worlds including: ability to provide single user with multiple viewpoints of environment, such as viewpoint of fellow collaborator
Individual differences	<ul style="list-style-type: none"> ● Focus design efforts on age-related individual differences in vision and hearing. ● Consider user ability to develop knowledge on complex virtual environments. ● Consider degenerative effects on physiology, particularly the senses (e.g., vision and hearing) in VE application design. ● Present displays and interfaces to allow aged persons to develop understanding of spatial positioning and navigation in VEs in advance of presenting them with virtual task objects and showing them representations of other users in CVE. ● Consider user attention allocation capabilities, and creativity and long-term memory storage in application design. ● Consider geriatric effects on spatial orientation and memory, as well as technical aptitudes for reasoning in VE design. ● Consider interaction effect of user characteristics including age, information processing abilities, and experience on user sensations of presence in VEs and virtual task performance. ● Offer methods for dealing with perceptual-cognitive limitations including multimodal representations of stimuli (e.g., visualizing sound for the hearing impaired).
Matching	<ul style="list-style-type: none"> ● Consider individual differences in culture to enhance matching. ● Match the structure of virtual interactions among CVE users to real human-human communication through consideration of: user self-representations, the interfaces to user virtual embodiments, the sensory modalities available for communication, and the clarity of communication provided. ● Match SA requirements in VE to reality, specifically in VE trainer development for experienced users toward ensuring virtual skill transfer to reality.

(Continued)

TABLE 18.1
(Continued)

<i>Design Features</i>	<i>Recommendation</i>
VE technology/general	<ul style="list-style-type: none"> • Match user perceptions of behavior of self-representations in VEs to, for example, the control interfaces they use to move their virtual embodiment. • Eliminate or reduce effects of (temporal, spatial, and filtering) perturbations. Factors include: application resolution, update rate, level of environment detail, and others. • Design networking capabilities for supporting CVEs to provide near real-time application responsiveness and system synchronization, or at least meet requirements of most sensitive user during any given deployment.
Teaming/VE sociology	<ul style="list-style-type: none"> • Consider group dynamics in CVE application design. • Configure virtual groups to prevent social issues from degrading organization. • Exploit user social skills toward organizing virtual groups. • Devise methods to ensure users of CVEs are aware of professional status of other participants if individual perceptions of relevance of professional hierarchies in virtual spaces are critical to application success. • Design virtual tasks with user aptitudes in mind. • Design CVE teams to include users with specific aptitudes and experience to ensure error-free performance. • CVE design for distributed user teamwork in virtual tasks should consider user experiences in real world for forming effective virtual teams. • Ensure that users immersed in CVE participating in virtual group have similar level of team experience to promote collaborative virtual task performance. • Consider level of adaptation of users to VEs for promoting virtual task performance. • Allocate decision-making power and virtual task roles to be assumed by users in a CVE to optimize user collaboration.
Presence	<ul style="list-style-type: none"> • Consider individual differences in designing for shared presence including: a user's background, interests, viewpoints, and sensitivities. • For shared presence in CVEs, provide a means for users to experience sense of physical presence in common VE, as well as user-user interaction.

Although it seems clear that individual differences are important to how people function within VEs and CVEs, it is not as clear how to design VEs to accommodate, or even take advantage of, those differences. It seems that VE affords designers with the flexibility to shape each user's experience to his or her individual needs, but it is not obvious exactly how to accomplish this objective. Does a person with limited attention span, for example, benefit from the appearance of a halo around the head of a collaborator in a CVE when that person speaks? Development of ways and means to classify individuals on the basis of their differences, and to modify a VE to best match those differences, is a research topic of great complexity but with concomitant potential benefit to VE users.

Table 18.1 summarizes the VE design features discussed in this chapter. The table offers general recommendations toward accounting for individual differences in VE application design through these features. Due to the relative immaturity of VE research into individual difference effects on application design, “hard-and-fast” rules for ensuring each recommendation is upheld cannot be offered, but rather rules must be formulated based on future empirical research. Virtual environment application parameters should be explored to learn specific acceptable ranges of, for example, virtual control latency, for different types of virtual tasks. These parameter ranges will serve to describe overall design features and systems capabilities.

1. INTRODUCTION

Skills are generally acquired by learning a set of facts about a task and developing appropriate procedures. For example, to learn to fly a plane, you first might learn the function of the flight controls and their locations and then practice manipulating the controls in appropriate sequences for a flight procedure. The practice part of training often cannot be done in the actual situation; a plane may not be available or the cost of the plane and an instructor on a regular basis may be prohibitive. In these situations, training is provided in alternative environments, or simulators, that mimic the target task. Designing simulators that will produce effective training has been a long-standing goal for those involved in skill acquisition, and the success of such simulations is generally measured by the effectiveness of subsequent performance on the actual task—the degree of “transfer” from the simulated to the real environment.

Among the most recent additions to training simulators are virtual environment (VE) systems that enable a person to interact with a computer-generated environment. Although there is a broad range of definitions describing this new technology, it is generally agreed that VE technology provides a new level of interaction and expands the application options that can be explored. As a computer-modeling technology that generates an immersive and interactive synthetic environment, VE is typically less dependent on physical properties of context and materials than most other simulations.

The purpose of this chapter is to discuss several issues related to the use of VE simulators for transfer of training. First, the meaning of transfer in an abbreviated historical context is examined. Second, one of the key differences between real-world and VE transfer is explored, the match to the actual task, known as the fidelity. Third, measures of transfer are discussed, concluding with an examination of several applications in which VE simulators play a role.

2. HISTORICAL CONTEXT OF TRAINING TRANSFER

A standard technique for determining the effectiveness of any training is the success in the application of that training in the actual performance environment. Does a particular flight simulator result in better in-flight performance? Does training in a simulated building improve firefighting skills? It is generally acknowledged that the answer to these questions will depend on properties of the training environment. In some instances, classroom training is assumed to provide an adequate learning context, combining descriptions and images with general principles. In the case of simulations it is often assumed that the rate of skill acquisition depends on what has previously been learned in “similar” contexts. It is generally believed, for example, that a pilot who has flown one aircraft is more likely to learn to fly a new plane more quickly than a novice. Nonetheless, there is substantial debate about what constitutes a “similar” context and how useful is such prior training. Virtual environments can be designed to test an operator’s ability to perceive and act upon simulated information. But, how will the same operator perform when faced with similar data in a real environment? This is known as the problem of *transfer of training*.

One common belief about transfer is that mental performance can be improved by general “conditioning” of the mind, analogous to the way in which an athlete might condition his or her body. This mental-muscle view was prevalent among a number of psychologists in the early part of the 20th century and was known as the Doctrine of Formal Discipline (Angell, 1908). The mind was thought to have general faculties that when exercised appropriately would lead to fairly broad transfer. Many current educational practices are still based on this conception that training in basic skills will improve performance in a wide variety of domains. This was, and to some extent still is, the basis for emphasizing foreign language training as improving general education. It has proven difficult, however, to provide any evidence supporting this very general view of learning.

An opposing view of transfer, emphasizing the specificity of learning, was the *theory of identical elements* (Thorndike, 1906). This theory suggested that transfer occurred only when two tasks shared identical elements. The presence of specific common elements, it was suggested, led to the illusion of transfer based on general reasoning. A number of studies have supported the finding of specificity of transfer. Chase and Ericsson (1982), for example, trained a person to increase short-term digit recall from the typical digit span of about 7 or 8 items to 81 digits following some 200 hours of practice. However, they found that this memory span increase did not transfer from digits to letters.

In an extensive review of the transfer literature, Singley and Anderson (1989) suggest that the identical elements view is too restrictive. Although transfer does exhibit some specificity, rather than requiring a specific match of surface situation-response elements, transfer occurs when two skills exhibit the same logical structure. Thus, the ability to navigate through a town in one type of vehicle may improve the ability to navigate the same town in another vehicle.

3. TRAINING ENVIRONMENT FIDELITY

Transfer of training may in some ways depend on all aspects of a given context. The optimal way to learn a specific procedure, in this view, is to learn a procedure precisely as it will be tested,

including matching the context in which learning occurred with that in which performance is measured (see Tulving, 1983, on encoding specificity). This is in part the rationale behind on-the-job training. At the same time, this ideal match rarely occurs, and the exact conditions of performance are usually not known in advance or stable across time. Firefighters cannot test their navigation in the actual building as it is burning, and surgeons cannot practice on actual patients. So the goal is to find conditions in which training provides an adequate match.

To the extent that skill acquisition reflects substantial specificity, training transfer should be best when training mimics performance as closely as possible. Virtual environments provide a means to fulfill the objective of training in the target environment without really being there. The extent of this match is the training environment's "fidelity". With perfect fidelity, a training environment (virtual or real) would be indistinguishable from the actual task environment. Thus, one set of questions about VEs is the extent to which they can be used to replace real environments for training and transfer. A closely related question concerns which aspects of a VE are essential and which are secondary for training a specified set of tasks.

Another set of questions of equal or greater import concerns how VEs can be transformed from the normal appearance and behavior of the real world in ways that might benefit learning and transfer. Because of their wide-ranging flexibility, VEs provide a powerful framework for assessing a range of possible applications. By providing new situations in which structures can vary from "reality," VE technology evokes a new set of design questions about developing transfer that is not strictly dependent on the degree of training-performance match.

3.1 VE as a Real-World Replacement

Few current VEs provide a sustained experience that is perceptually and experientially indistinguishable from reality. Typically, there is some trade-off among different aspects of fidelity. For example, high-quality visual images usually result in a longer lag in tracking (see chap. 21, this volume). How much fidelity is required for any given performance objective remains an empirical question. There is still much to be learned about how specific changes in properties of VEs influence training or transfer performance. In some ways, the key is to map the demands of any given VE to human-information processing constraints (Card, Moran, & Newell, 1983). In the limit case, for example, a lag of a few milliseconds should make little difference to the visual processor while walking through a virtual building, whereas a lag of half a second might result in a number of difficulties, including walking into walls (see chap. 3, this volume).

The requirements for training environment fidelity will also depend to a large extent on the attentional demands of the specific task being performed. For example, in navigating a simple building, wall texture might have little impact on training (see chap. 24, this volume). However, in a complex structure, in which hallways are differentiated primarily by their appearance, wall texture might have a substantial impact on learning. In our own studies, although the issue has not been studied systematically, a variety of textured surfaces have been used in evaluating route learning. Although greater fidelity is recognized and appreciated by participants, no convincing evidence has been found that it influences learning in the building environments examined. Results in other domains also suggest that high fidelity may not be essential to certain kinds of procedural or part-task training. Of course, the quality of the environment may also have other consequences because performance measures cannot be strictly separated from other measures of motivation or utilization (see chap. 35, this volume). If fidelity during training is poor, learners may refuse to use training materials unless required to do so by the job.

3.2 Going Beyond the Real World

Virtual environments can be transformed from the normal appearance and behavior of the real world in ways that might benefit learning and transfer. For example, flying through a building

might provide additional information to that acquired from walking through it. Transparency of walls might permit the development of a better comprehension of spatial structures and relations. This is discussed further in section 5 in the context of learning to navigate through an environment.

A virtual simulation may also present some *parts* of a task that normally cannot be separately controlled in the physical world. For example, a flight simulator may allow an operator to land an airplane repeatedly or a surgical simulator may be set to just test suturing skills and not a whole medical procedure. However, it is important to keep the part-task learning in the context of the whole task, as mastering either task alone clearly would not satisfy the training needs of a pilot or a surgeon respectively.

4. MEASURES OF TRANSFER

The effectiveness of a simulator is determined by how much an operator's performance is improved on a real-world task due to training in a simulator. Despite the wide acceptance of simulators as valid training tools, few studies exist that actually measure this transfer. Measures of simulator effectiveness require collection of operator performance data. Often, it is necessary to collect performance data before simulator based training begins or measure performance in control groups that do not train in simulators. Table 19.1 presents methodologies for measuring data necessary to assess simulator effectiveness. The data contained in this table are taken largely from a study undertaken by the NATO Advisory Group for Aerospace Research and Development (1980).

From an experimental design perspective, the approach that offers the greatest rigor in assessing training transfer is the transfer of training (ToT) method. When using this method it is important to derive measures of how long it takes to learn the task, how effectively the task is subsequently performed in the real world, and how much training that is normally conducted in the real world is saved with the simulator. The transfer effectiveness ratio (Taylor, Lintern, Hulin, Talleur, Emmanuel, and Phillips, 1997) estimates simulator effectiveness as the difference between presimulator training performance and postsimulator training performance, divided by time spent in the simulator.

Transfer effectiveness ratio (TER)

$$= \frac{\text{Presimulator performance (e.g. time for task completion)} - \text{Postsimulator performance}}{\text{Time spent in simulator}}$$

The transfer effectiveness ratio provides a measure of savings gained by using the simulator (e.g. a TER of 0.50 means that every hour in the simulator saves a half hour of real-world training). Another measure of effectiveness reports the percent of transfer by comparing control-operator performance to operators trained in a simulator. Both of these proportions require control and experimental data.

It is possible to have a decrease in performance following simulator training. This is indicative of a so-called negative transfer of training. In this case the experimental group exhibits performance that is significantly worse than the control group that did not train in the simulator. In the case of negative transfer, the introduction of a simulator, or modification to an existing simulator, is a detriment to existing training methods.

5. TRAINING APPLICATIONS: SPATIAL NAVIGATION

Since VEs make possible “presence” in physically distant locations (see chap. 40, this volume), they provide a natural context for learning about movement through unfamiliar spaces, ranging

TABLE 19.1
Methods for Measuring Training Transfer from VE-based Simulators to Real-World Performance

<i>Method</i>	<i>Description</i>	<i>Remarks</i>
Operator opinion method	Operators, instructors, training specialists and students are asked to give their opinions on the perceived training value of a simulator, features of the simulators, or probable impact of simulator based training on subsequent real world performance.	Useful when operational training or performance testing is not feasible. However, assumes the operator, instructor, or trainee is able to assess objectively how much is learned from the simulator. May fail to recognize that such opinion is based on previous knowledge and experience.
Assessment of fidelity	Describes the physical similarity between the simulator and the real-world environment, equipment, interface, or facility.	This method assumes that higher fidelity will yield higher transfer. It is commonly used by the commercial aircraft industry. Regulatory authorities often impose high physical and dynamic fidelity requirements so that instrument rating and proficiency checks can be carried out in the simulator rather than in a real aircraft. In such a role simulators are being used as assessment tools, not training tools. Training may be possible with far less sophisticated devices. In addition, it appears that high fidelity generates user acceptance, but this does not of itself mean that a device is more effective at training operators.
Transfer of training (ToT) method	Involves two groups of trainees, an experimental group, which receives simulator training prior to further training for performance testing and a control group, which receives all of its training in the real world. Alternatively, the experimental group could be participants using a newly developed simulator, and the control group could use an existing simulator program. Groups must be equated in terms of relevant prior training and experience.	This model is generally most appropriate to determine whether simulator training has improved subsequent operational performance.
Self-control transfer method	This method uses an experimental group to serve as their own controls. Operational performance is assessed, simulator based training is introduced, then subsequent operational performance is assessed and compared to the first performance assessment.	When using this method, the time interval between performance assessments must be taken into account. One problem with this model is that it assumes the trainee's subsequent performance on the operational task has improved as a result of simulator training.
Preexisting control transfer of training method	Determines transfer of training using the new simulator, as performance data already exists for the control group.	Often a simulator is introduced after an established training protocol is in place. This model is then similar to the transfer of training model.

(Continued)

TABLE 19.1
(Continued)

<i>Method</i>	<i>Description</i>	<i>Remarks</i>
Uncontrolled transfer method	Simply determines if naive subjects can perform a particular task in an operational setting following simulator training.	A crude way to determine training transfer. This is useful to quickly evaluate features or improvements to a simulator but does not provide measures to accurately quantify transfer.
Inverse transfer of training method (or backward transfer method)	Experts at the operational task perform the same tasks, without practice, in a simulator. A positive result assumes that a suitable training program exists for the simulator.	The experienced operator is already proficient at the task and may have highly generalized skill. The simulator may be suitably designed for the evocation of a particular set of behaviors from a skilled operator.
Simulator-to-simulator transfer method	A lower fidelity simulator is used in part task training and is followed by whole-task testing (or part-task) on a higher fidelity simulator.	Valuable in reducing the use of more complex simulators. A related method, the simulator fidelity method, assumes that a higher fidelity simulator will yield higher transfer and a lower fidelity simulator will yield less or negative transfer.

from a new office complex to a building from which hostages need to be rescued. In learning to navigate a space there are several different kinds of knowledge that are used, and these are typically described as successive components in learning (Siegel & White, 1975; see chap. 24, this volume). Landmarks are used to establish reference points without any specific connection. A path through a space is described as a route; such “route knowledge” is often fairly specific and may reflect a rigid procedural sequence. A more global grasp of a space provides greater flexibility and less dependence on a specific sequence. This “survey knowledge” is typically accompanied by the ability to identify the relative locations of objects separate from a specific path.

Two uses of VEs for transfer of training in such navigational contexts are explored in the following sections. First, can reasonable fidelity provide transfer of training from virtual to real environments? Second, how can transformations of the VE be used to modify the utility of training and transfer of navigational skill? The ToT experimental method of measuring transfer was used to address these questions. Control groups were trained and tested in a real-world environment while other groups were trained in VE or through other methods such as map reading.

5.1 Medium Fidelity Environments

Most research on navigation has focused on characterizing route and survey knowledge. We examined transfer of training based on these two aspects of navigational learning. The first issue is whether or not people can learn a specific route based on training in a virtual environment. The answer to this question depends both on the VE used and the task; in this case, the typical task is following a specific real-world route that matches one learned in the virtual environment. Successful transfer of such route training has been demonstrated using

very-high-fidelity visual displays, combined with maps (Witmer, Bailey, Knerr, & Parsons, 1996). In our studies (Clawson, Miller, & Sebrechts, 1998) we have emphasized medium fidelity visual displays; in addition, in order to assess VE utility, providing supplementary map displays has generally been avoided. Consistent with other findings (e.g., Waller, Hunt, & Knapp, 1998), our results, based on measures of correct turns, hesitations, and distance traveled, have supported transfer of training from virtual to real environments comparable to that using maps or real world training. However, these results indicated that VE route training showed substantial specificity (see chap. 24, this volume). Participants hesitated significantly more when moving through a building in a direction opposite to that of VE training than when moving through the building in a direction aligned with VE learning. This specificity was not present in matched map or real-world learning conditions.

With respect to survey learning, research also shows reasonable transfer as well as specificity. When participants followed the route learned during VE training, their ability to identify the relative locations of real-world objects through pointing was comparable to that of participants who learned in the actual building. However, when testing was in the direction opposite to that of training, VE-trained participants' performance was substantially worse than that of real-building-trained participants. A similar specificity was also found for distance estimates; relative direction of testing had more of an effect for the VE-training group than for either map or real-world trained groups.

These results leave open some issues about fidelity. Since real-world route training does not produce the same specificity, there must be VE characteristics that produce differential performance. One possibility is that the way in which route following is conducted changes the way in which the space is perceived. Route-following in VE may induce constraints on the way in which the space is viewed. This was addressed in part by another set of our experiments that used exploratory learning instead of route following (Sebrechts, Mullin, Clawson, & Knott, 1999). In these studies, participants explored a building, locating fifteen different regions of the building using either a VE or a map. They then were required to move between specific locations in the real building using the most efficient path possible. In these studies, the VE-trained participants found significantly more efficient paths than the map-trained participants. A potential explanation for these results is that the exploratory learning task induces more scanning of the environment, thus reducing the transfer specificity previously found for VE relative to map or real-world training.

5.2 Transformed Environments

The majority of research on navigational training and transfer from VEs has emphasized varying degrees of fidelity, helping to define the conditions needed for transfer. However, one of the central benefits of a VE is that it facilitates deviation from the real or normal context. Some of these transformations are relatively minor. For example, in the exploratory studies described above, research indicated that people failed to fully explore a virtual building in the absence of additional cues. When virtual spheres were placed in the building, which spoke their location names and changed color after being encountered, completeness of exploration improved dramatically. Other transformations can be substantial, such as allowing a person to "fly" through a virtual building.

A number of our recent studies have focused on one particularly promising transformation—transparency (Sebrechts & Knott, 1998). Comparisons were made between participants walking through a virtual building with traditional "opaque" walls, and an identical building in which the walls had been made "transparent" such that objects could be seen through the walls, although their locations were still evident. After learning the location of 21 objects in the building to a specified criterion, the participants' mental models of the building were assessed

using a task that required participants to identify the relative location of objects they had seen in the building. The mental models of participants who learned from an opaque VE reflected distances along a path through the building, described by a city-block or route-based metric. In contrast, mental models of participants who learned from a transparent VE reflected a straight-line or Euclidean distance in addition to a route-based distance.

Differences between training environments were also reflected in drawings of the building. Both groups easily identified the objects in the building; however, the transparent group was substantially more accurate in identifying the structural layout of the building including the relative size and positioning of rooms. Overall, these results suggest that a transparent VE may help to facilitate the acquisition of survey knowledge, a task that frequently requires substantial experience in the real world.

6. TRAINING APPLICATIONS: COMPLEX MOTOR LEARNING

Complex motor learning, such as learning to pilot an airplane or to perform surgery, poses another interesting set of challenges in using VE systems for training. Similar to the navigation task described above, the fidelity of the VE simulator is of importance. However, because of the complexity of the task, the interface is usually much more than a visual display and may include mechanical components as well. For example, a flight simulator may have a high-fidelity physical control panel, medium-fidelity visual graphics, and a low-fidelity mechanical simulation of aircraft movement.

The need to manipulate objects in the environment is another distinguishing aspect of learning a motor task versus the navigation tasks described above. This poses additional questions concerning the modality of the interface. Haptic (force) feedback may become increasingly important (see chaps. 5–6, this volume). Experiments examining transfer of training of manipulation tasks from VE using low-fidelity graphics and no force feedback present conflicting results (Kenyon & Afenya, 1995; Kozak, Hancock, Arthur, & Chrysler, 1993). Using a task that required picking up and placing a can in a target location, Kozak et al. (1993) found no significant transfer-of training benefits from VE training as compared to real-world and no training conditions. However, using a similar task, Kenyon and Afenya (1995), found that VE trained subjects outperformed untrained subjects on the first trial of the real-world task. Apparently the difference in outcome was a result of the improved training environment and its higher fidelity. Kozak's task used a virtual hand that had to be synchronized with the real hand, resulting in an average completion time of 63 seconds. Kenyon's task used an augmented reality setup in which participants could see their real hand moving virtual objects, resulting in an average completion time of 19.2 seconds. In both studies, task completion in the real world required roughly 6 seconds. Kenyon et al. make a compelling argument that limitations in fidelity of the VE produced these substantial time differences, and that the improved, but limited transfer, stems from a better match between the VE and real world tasks. Limitations in the VE, including time lags, may result in different task performance. As a consequence, many such environments do not yet show the expected benefits of VE training that more closely matches normal human performance (see Stanney, Mourant, & Kennedy, 1998).

A key to developing a simulator for training an operator on a complex motor task is defining the relevant performance metrics for evaluating success. For example, the medical community is looking at VE as a tool for continued medical education and even as an accreditation tool for medical students (see chap. 47, this volume). However, there is still much work to be done in understanding what performance metrics should be used in evaluating surgical effectiveness in general. In other words, short of a simulator that is indistinguishable from the real world for the learner, it is still not clear what exactly should be simulated.

6.1 Flight Skills and the Simulation Training Environment

Despite the several hundreds of articles since the 1950s on pilot training, a recent review (Carretta & Dunlap, 1998) found that there are fewer than 40 studies that addressed transfer of training from a VE-based flight simulator to the real world. However, flight simulators have gained enough acceptance that the Federal Aviation Administration (FAA) allows the use of certified simulators in many contexts. For example, simulator training can substitute for some hours of in-flight instrument certification.

Because of the existence of “certified” VE trainers, the simulator-to-simulator method of measuring transfer may be used to test the efficacy of a new or low-fidelity simulator. The inverse transfer of training method is also used quite often in high fidelity simulators to test their validity. Experienced pilots perform a task in the simulator and are expected to do well because they are top performers in the real world and in certified simulators. Degradation in performance is attributed to a lack of simulator fidelity in the trainer under evaluation.

Training landing skills is the most common objective in using a VE flight simulator (for review see Carretta & Dunlap, 1998). In landing-skills acquisition the results indicate that neither scene detail nor field of view influence effectiveness of transfer from the simulator to the aircraft. However, pilots receiving more simulator trials exhibit better landing skills than those who receive fewer simulator trials. Another study (Lintern, Roscoe, Koonce, & Segal, 1990) used a transfer of training methodology to test the landing capabilities of a group of flight students, first allowing them to practice landing using a simulator, whereas a follow-on control group did not train in a simulator. The experimental group required 1.5 fewer presolo flying hours than the control group. Generally, results indicated that performance improves after using a simulator and that successful transfer may not require high-fidelity simulators for whole task training.

Efforts have been made to validate low-cost desktop VE flight simulators because “certified” trainers are usually high-fidelity, high-cost, multisensory environments. Because of the frequent use of simulators in flight training, potential measures of transfer from VE to the real world have already been established. Using a desktop personal trainer, Taylor et al. (1997) showed TERs of 0.15 to 0.50. Practically speaking, this meant that 10 hours of simulator training would save approximately 1.5–5 hours of cockpit training time depending on the task.

6.2 Surgical Skills and the Simulation Training Environment

The medical community has much to gain from the development and use of VE simulators for training, and many prototype VE systems to train surgeons in surgical procedures have already been developed (Lathan, Cleary, & Traynor, 2000; see *Medicine Meets Virtual Reality Conference Series*, Westwood, Hoffman, Stredney, & Weghorst, 1994–2000; see chap. 47, this volume). Current training methods essentially consist of the “see one, do one, teach one” philosophy, supplemented with limited access to animal models and physical simulators such as mannequins. Assessment of skill level is primarily through structured observation. A digital or virtual patient simulation would allow the surgeon to train on a variety of scenarios using simulated patients differing substantially in physical characteristics.

However, many surgeons feel that successful surgical training must be based on highly realistic simulation trainers even though low-fidelity simulators have been effective for training in many other domains. This is problematic given the current state of computer graphics and haptics in VE technologies. In addition, concerns about a lack of face validity of the current generation of surgical simulators may slow adoption of this technology for medical training.

One approach to the development of surgical simulators has relied on methods that have been used for simulator development in air combat training (Hettinger, Nelson, & Haas, 1994). In this approach, identification of critical tasks, related skills, and candidate metrics for assessing skills are accomplished primarily by users and human factors experts. User-centered design teams composed of surgeons, simulation engineers, and experimental psychologists use task analysis to decompose prioritized procedures into elemental skill modules that can be developed into part-task trainers. Candidate metrics are empirically validated using the ToT method and simulator-to-simulator validation. Ultimately, correlation of performance on the part-task trainer and prediction of performance in the “real world” determines the acceptability of a metric.

One issue that has emerged from task analysis of surgical skill acquisition and performance is the quest for a common task for assessment of surgical performance. Rosser, Rosser, and Savalgi (1998) have argued that intracorporeal knot tying is a good indicator of surgical skill (for both laparoscopic and open surgery) and should be adopted as a reference standard for surgical performance. They have used a variety of VE systems for assessing laparoscopic skill, including: suturing, thread manipulation, spatial and localization tasks, and manipulation of blocks. Knot tying was found to be a sensitive indicator of surgical performance, and thus this task could potentially serve as a standard for assessment.

Cuschieri (2000) has suggested that performance tracking using simulation technology should focus on component abilities. Thus, simulation tasks such as suturing should emphasize abilities such as eye–hand coordination, spatial abilities, and motor coordination. In surgical training there are no well-established simulators as there are in flight training, so the development of VE simulations and of standards to evaluate transfer from simulators to the real world are taking place at the same time. The work on specifying key components of surgical skill will establish the measures that must be used to evaluate such transfer.

7. CONCLUSIONS

Several themes have run through this chapter: fidelity of the simulator, simulator task, and methods of determining transfer. Each of these issues needs to be considered when designing and testing a simulator system.

Simulator Fidelity: In general, it is assumed that higher fidelity means better transfer. Technology is not to the point of creating a simulation that is indistinguishable from the real world. However, advances in technology may change that, which will open up a host of opportunities in simulation. For example, there has been a growing interest in the use of haptic or force feedback to improve task performance. Haptic feedback has been shown to improve performance in tele-operation tasks, particularly when used in conjunction with visual feedback (Burdea, Richard Coiffet, 1996; see chap. 21, this volume). Effective integration of multimodal sensory inputs and understanding their interaction will be key to increasing simulator fidelity and human performance training. Increased fidelity will also afford new opportunities to train under heretofore unknown or unexpected conditions and situations. For complex tasks and tasks performed in extreme environments such as outer space or underwater, there will be a need for increasingly complex and realistic simulators. In addition, VEs that differ from the real world and that are designed not to mimic the real world in important ways, such as violating laws of physics or exploiting unreal transparency, may be equally important as high-fidelity virtual environments.

Simulator Task: Deciding what part-tasks should be executed through VE simulation and what tasks should be practiced in whole is one of the issues that will be addressed by VE simulation development. Is transfer better when an entire task is simulated or when the simulator is broken down into part tasks? Which part task would be most appropriate for VE simulation? Virtual environments provide the flexibility to discover some of the answers to these questions

to develop an optimal training environment. In fields in which simulators have not been used routinely, VEs are being used as a tool for establishing which parts of a task can be effectively trained separately.

Measuring Transfer: Measurement of training transfer is not unique to VE simulation. Rigorous methods of testing transfer must be employed independent of training method. However, the very advantages of using VE, such as being able to simulate extreme environments, may limit the methods that can be used realistically to measure transfer. Every simulator does not need to be tested using the ToT method of experimental and control groups. Logistics such as cost or availability of the real-world environment may prohibit that level of examination. Regardless of method chosen, some operational outcomes should be documented, such as the following: 1. How long is the task performed in the simulator? 2. How effectively is the task subsequently performed in an operational setting (whether that setting is the target environment or one correlated with performance in the target environment.) and 3. What is gained by using the simulator?

Virtual environments provide enhanced simulation that promises to improve transfer of simulator training to operational performance. At the same time, by relaxing the inherent constraints of physical simulators they raise a number of new issues about design. This chapter begins to address these emerging research issues that make VE simulation fertile ground for future research.

1. INTRODUCTION—COGNITIVE ISSUES FOR VIRTUAL ENVIRONMENTS

The uses of virtual environments (VEs) raise a variety of cognitive issues. Virtual environments provide information to users, and, in many cases, they provide users with the ability to interact with the environment in response to the information that the environment conveys. Many different cognitive factors play roles in the use of VE applications. These include issues related to perception, attention, learning and memory, problem solving and decision making, and motor cognition. Research and experimental applications of virtual environments have clarified some cognitive aspects of VE usage, but many questions have been raised for further research.

1.1 Perception

Cognitive research has revealed that perception is an active process, not merely an automatic bottom-up conveyance of sensory data such as visual images to higher order cognitive centers. Expectations and experience exert a top-down contribution to perception, which results from the active interpretation of sensations in the context of these expectations and experience. A number of characteristics of presently available VEs raise issues for perception. Among these are the very poor resolution of displays (in terms of number of pixels presented per degree of visual angle, for example), the frequent problems with alignment and convergence, and

*The views of the authors do not necessarily represent the policy of the U.S. government.

the often primitive three-dimensional (3-D) models and texture maps presented on displays. These characteristics place substantive constraints on the role of bottom-up data processing in perception in virtual environments, and they therefore increase the importance of the top-down contributions of expectations and experience. A question that has not yet been resolved is the extent to which perceptual *experience* with VE representations is required to ensure accurate perceptions. People living in a culture with artifacts that include visual representations learn how to interpret those representations. In modern high-technology culture, people are able to interpret the graphical representations on television and on computer screens. To what extent must people learn to interpret—learn to *see*—what is presented in a virtual environment?

1.2 Attention

There are several aspects of VEs that have potentially important consequences for the role of attention processes during VE experiences. A VE system has access to clues about the focus of a user's attention that are not available in an ordinary screen-presented graphics system. Both the field of view and resolution provided by current VE systems are so limited that a user must often carry out navigation and orientation actions (see chap. 24, this volume) so that the matter of interest is brought into view. These actions constitute an announcement—a sort of nonverbal protocol—about what the user is currently attending. Additional precision could be obtained by including eye movement observation systems in VE, but, until higher resolutions are commonly available in virtual environments, for many VE applications it will be enough to know what is in the user's field of view.

1.3 Learning and Memory

A number of research projects have studied the application of VE technology to learning environments, including advanced technical training and intelligent tutoring systems. The results of these projects provide useful guidance for the developers of VE-based learning environments, but a number of important questions remain to be answered. Some of these questions relate closely to issues of perception and attention. How can student attention most effectively be directed in virtual environment? How can a tutoring system know whether a student has perceived a feature of an environment? How much fidelity is required to produce desired levels of learning transference to a real-world context, such as on-the-job task performance? To what extent do the special cognitive demands of the VE experience interfere with learning? Does VE-based learning offer special advantages for conveying some types of knowledge but not for others?

1.4 Problem Solving and Decision Making

The same concerns about the cognitive demands of VE experiences that are of concern for learning are also very relevant to problem solving and decision making in the context of virtual environments. A VE makes it possible for a user to quite naturally find new perspectives for a graphically represented problem or set of data; this offers the potential for VE-based aiding systems for analysts and decision makers. On the other hand, the additional cognitive processing required for perception and for the VE navigation actions could tie up cognitive processing resources, reducing the effective deployment of higher level cognitive processing functions in some contexts.

1.5 Motor Cognition

In many real-world tasks, people must move about and change their physical orientation in order to make observations and to carry out actions. Infants and children spend many years acquiring the motor skills that make it possible, in most contexts, to carry out these navigation and orientation actions in a largely or even completely unconscious manner. In many virtual environments, the full set of motor skills used to navigate and orient in the real world is not wholly transferable to the virtual environment. To what extent does the nonautomatic nature of navigation and orientation in some VEs interfere with other cognitive processes?

Much of what is known about the cognitive aspects of VE design is a result of work done on using VE for learning environments and for training. The next section of this chapter discusses cognitive issues in the context of VE training. Virtual environment technology has implications for human information processing, mental models, and metaphors and analogies for the design of training systems that make use of immersion. Cognitive issues in training are discussed, and recent VE systems used by the navy to teach cognitive tasks are described. The overall intent of this chapter is to give the reader some insight into the design of VE that lends itself to teaching cognitive skills. The work is in progress. There are many unanswered questions in this area. However, great progress has been made with the systems that have been tested so far. A series of applications will be discussed that have been sponsored by the Office of Naval Research, Code 342. These have examined increasingly more complex cognitive skills. Early work examined maintenance training in a laboratory setting. Harbor navigation was explored next, and a test bed was developed to evaluate VE in a training environment. Then, complex-maneuvering skills in the open ocean were examined. This led to development of objective performance measures. Virtual environment modalities included visual, audio and haptic. The chapter concludes with a set of guidelines for system design and conclusions about future work.

2. COGNITIVE ISSUES IN VIRTUAL ENVIRONMENT TRAINING

2.1 Knowledge Type and the Acquisition of Knowledge in VEs

The cognitive factors listed above must be considered with respect to the types of information that are being conveyed in a virtual environment. Consider these major types of information that may be presented in a VE: location knowledge, structural knowledge, behavioral knowledge, and procedural knowledge.

For each type of information that can be presented to or learned by a user of a virtual environment, there are potential issues to be addressed in determining how to best support the cognitive processes—perceptual, memory, decision making, and motor—that are brought into play in interacting with or learning the information. This can be viewed as a matrix of cognitive processing issues by types of information.

2.1.1 *Location Knowledge*

Several types of knowledge about location may be particularly amenable to conveying with VE rather than through more conventional means. Many VEs give their participants the facility to change their location and their orientation while observing objects in the environment. This type of experience can give the participant a richer set of information about the relative locations of simulated objects, about how to get to a location, bring objects into view, and access and manipulate them.

2.1.1.1 *Relative Position Knowledge.* To teach the relative location of objects in a two-dimensional (2-D) plane, it is enough to present a map or a picture that shows the layout of the objects in two dimensions. Drill and practice or mnemonic techniques can be used to fix the information in the student's memory, but his or her basic understanding of the position relationships in 2-D space is an immediate apperception when the map or image is presented and the relevant relationships are pointed out. When objects have more complex relative locations in a 3-D layout, a single visual map will not suffice ordinarily. Students often require a variety of visual and/or positional experiences in 3-D in order to understand relative positional relationships. Two-dimensional presentations are particularly insufficient when the parts of two complex objects overlap because they have complex relationships to each other in the third dimension. However, in a VE a student can move about while looking at such "intertwined" objects, and can, thereby, quickly develop an accurate understanding of their relative positions.

2.1.1.2 *Navigation Knowledge.* Regian and Yadrick (1994) have shown, under controlled experimental conditions, that VEs promote more rapid acquisition of personal navigation knowledge in a complex environment of corridors and stairways than can be accomplished with an otherwise similar 2-D graphical trainer. Results suggest that accurate textural detail in such environments may enhance personal navigation learning.

2.1.1.3 *"How to View" Knowledge.* Many real-world tasks require that the worker know where to position himself and how to orient in order to make a necessary observation. Viewing a conventional 2-D representation of the environment may not provide a learner with enough information about what can actually be seen from where. A VE provides students an opportunity to find available lines of sight for viewing indicators, etc.

2.1.1.4 *'How to Use' Knowledge.* Knowledge about how to use objects in an environment includes two characteristics. First, a student must know how the object can be accessed. Is it necessary to open a door? Must one reach through an opening or between two other objects? Second, the student must know how the object should be manipulated. Should it be pushed away, grasped and twisted, pulled toward one, pushed down or pulled up? Is some more complex manipulation required? Virtual environments offer good potential for teaching how to access objects that are to be manipulated. Given the limitations of current technologies for manipulation in VE, the potential for teaching the details of manipulation are somewhat limited. Many VE systems have only one or two types of possible manipulation action (such as "pinch" and "release"). In these virtual environments, the simulation software typically interprets the action that is taken as being the one appropriate to the device that is being touched. Of course, there is every reason to expect that finer motor performance will be possible in future VE systems.

2.1.2 *Structural Knowledge*

Virtual environments have the potential to convey a rich variety of structural information, although only a subset of those possibilities have thus far been exploited.

2.1.2.1 *Part-Whole Knowledge.* Participants in VE rely on their real-world knowledge of the represented world to perceive part-whole relationships. If an environment includes a display panel with many lights and labels, an observer is likely to conclude that the labels and lights are part of the panel. When less-familiar complex objects are presented in an environment, it may be necessary to give the participant means for exploring part-whole relationships. One

such means is to give the participant the ability to move objects. A set of objects that move together may reasonably be construed as the parts of a whole.

2.1.2.2 Support-Depend Knowledge. If object A is above and flush with object B, then a participant can draw on ordinary pragmatic knowledge to conclude that object B supports object A, at least in VEs that simulate conventional gravity conditions. If the environment allows the participant to move object B out from beneath object A, then the participant can test the hypothesis that B supports A.

2.1.2.3 Containment Knowledge. Those VEs that permit a participant to open one object and manipulate or move another object within the first one provide a means for learning containment relationships.

2.1.3 Behavioral Knowledge

There are several types of behavioral knowledge that can be effectively conveyed in a virtual environment. By *behavioral knowledge*, we mean knowledge about how objects in the VE interact with each other and with participants.

2.1.3.1 Cause-And-Effect Knowledge. Cause-and-effect knowledge lets a participant predict that if one state change takes effect, then another state change will also occur. For example, “If the power switch is depressed when the system is functioning normally, then the ‘Power On’ light will be lit.” Cause-and-effect knowledge can be acquired by observing a system as it changes. Such knowledge is more likely to be acquired, however, if the participant has the ability to effect state changes directly. This makes it possible for participants to observe cascades of state changes and to develop cause-and-effect knowledge as a result.

This does not mean that exploratory environments are enough, in themselves, to assure learning of cause-and-effect knowledge. For most students, it is necessary to guide exploration and to point out explicitly the causal relationships.

2.1.3.2 Function Knowledge. Function knowledge is related to cause-and-effect knowledge. It has to do with the use of an object, that is, with what the object is *for*. Given the actions that can be taken on an object, the sets of intended effects of those actions constitute the function of the object. Again, a VE with interactive behavior can offer participants the opportunity to learn by experimenting, but guidance and tutorial exposition will typically be required to ensure effective learning for many students.

2.1.3.3 Systemic Behavior Knowledge. Some VEs are designed to help students to come to appropriate generalizations about behavior. Simulations of Newtonian mechanics systems, for example, can be constructed so as to work with tutors that help students to understand Newton’s model for the behavior of masses subjected to accelerations. In these VEs, students are expected not to learn simply the behaviors of particular objects, but rather the principles that explain the behaviors of whole classes of objects.

2.1.4 Procedural Knowledge

Virtual environments may also be appropriate for conveying knowledge about how to carry out procedures. Behavioral knowledge alone is not enough to determine how procedures should be carried out. In many cases, there are many action sequences that will result in a desired goal, but some will be more desirable than others for reasons of cost-effectiveness, safety, or speed.

2.1.4.1 Task Prerequisite Knowledge. Before a procedure can be undertaken, an initial state must often be achieved. This state has characteristics that are the prerequisites for successfully carrying out the task. A VE is a particularly apt context for teaching task prerequisites based on the positions and orientations of objects or of the participants who are to carry out the task.

2.1.4.2 Goal Hierarchy Knowledge. Task knowledge can be viewed as knowledge of a goal hierarchy and sequences of actions that can achieve transitions to subgoal states. Again, VEs are particularly useful for teaching procedures in which there are subgoals that prescribe positions and orientations, or states of relative movement.

2.1.4.3 Action Sequence Knowledge. The simplest procedures can be represented simply by a sequence of actions and a final goal. The subgoals of more complex procedures also have associated action sequences that are capable of bringing about the subgoal states. When these action sequences include movements and/or orientation changes, whether of the participant or of objects under the participant's control, a VE may be an appropriate learning context.

Hall, Stiles, & Horwitz (1998) conducted a study that can serve as a standard for evaluating the effectiveness of competing designs for learning how to move about in a complex environment in order to carry out a procedure. Two sets of students were trained to carry out a moderately complex task that involved moving among electrohydraulic machines onboard a ship to make observations and to set controls. Students had to learn both the sequence of actions (observations and manipulations) that were to be carried out and where to go to carry out the actions. One group learned the task in the virtual environment technology (VET) facility (Johnson, Rickle, Stiles, & Munro, 1998; Stiles et al., 1996), while the other learned the task in a 2-D graphical simulation environment. In both cases, the simulation was under the control of the same simulation, which was developed with the Virtual Interactive Intelligent Tutoring System (ITS) Development Shell (VIVIDS) simulation development-and-delivery system (Munro & Pizzini, 1998). Students from both groups were evaluated by asking them to perform the task in a real-life mockup environment modeled after the actual shipboard systems. There were no significant performance differences between the two groups, suggesting that, at least for this procedure, simulation training in a 2-D graphical environment may be as effective as virtual environment-based training.

2.2 Tutor Architecture

Figure 20.1 below presents an architecture for VE tutoring systems (Munro, Surmon, Pizzini, & Johnson, 1997). On the left side are those components responsible for the user interface and for the interactive behavior of the environment. On the right are the components that manage the course of instruction, maintain a model of the student, and conduct the moment-by-moment details of tutorial interactions. Some of the text in the right side of the figure is obscured because it is notional text.

The User View has subcomponents that are the responsibility of the VE software. An example of these components in use is shown in Fig. 20.2 below.

A user view is responsible for everything that can be seen (or heard or touched, etc.) by a student during simulation learning. Its model view component is responsible for rendering the simulated world prescribed by the behavior model and for detecting user events and passing them on to the behavior model for semantic processing. Presentation channels may include text, speech, audio, HTML, and video presenters, to name a few. Entries are user interface components that students can use to answer questions that cannot be answered by actions in

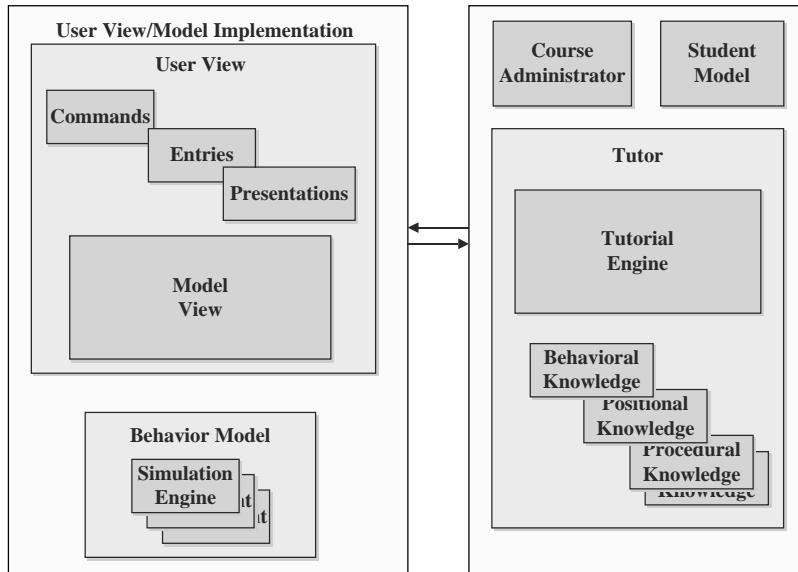

FIG. 20.1. A generic architecture for simulation-centered tutors.

the simulated model view. Commands are interfaces for higher level student interactions with the tutorial system, such as pacing instruction, asking for help, and so on.

A variant of this architecture, shown in Fig. 20.3 below, is capable of supporting implementations in which multiple students collaborate with each other in a simulation environment. Each student has a user view, including a model view that is under the control of a central behavior model. In this way, other students can view the cascading effects of actions taken by one student. The model views shown to different students need not depict the same scenes. Team members often work with different parts of a complex interconnected system and are able to see only one part of it at a time. The single behavior model determines the values of simulation attributes, and some of these value changes cause changes in what is displayed in the model views.

The instruction control components are responsible for the configuration of the complete learning environment, including the availability and positioning of the possible user interface elements. The tutorial engine component is a service requester for many of the other major components: It can ask a presentation channel to fetch and present a video. It can ask the

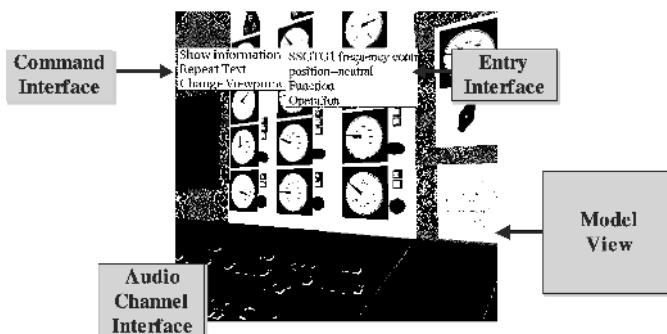

FIG. 20.2. A user view in a virtual environment.

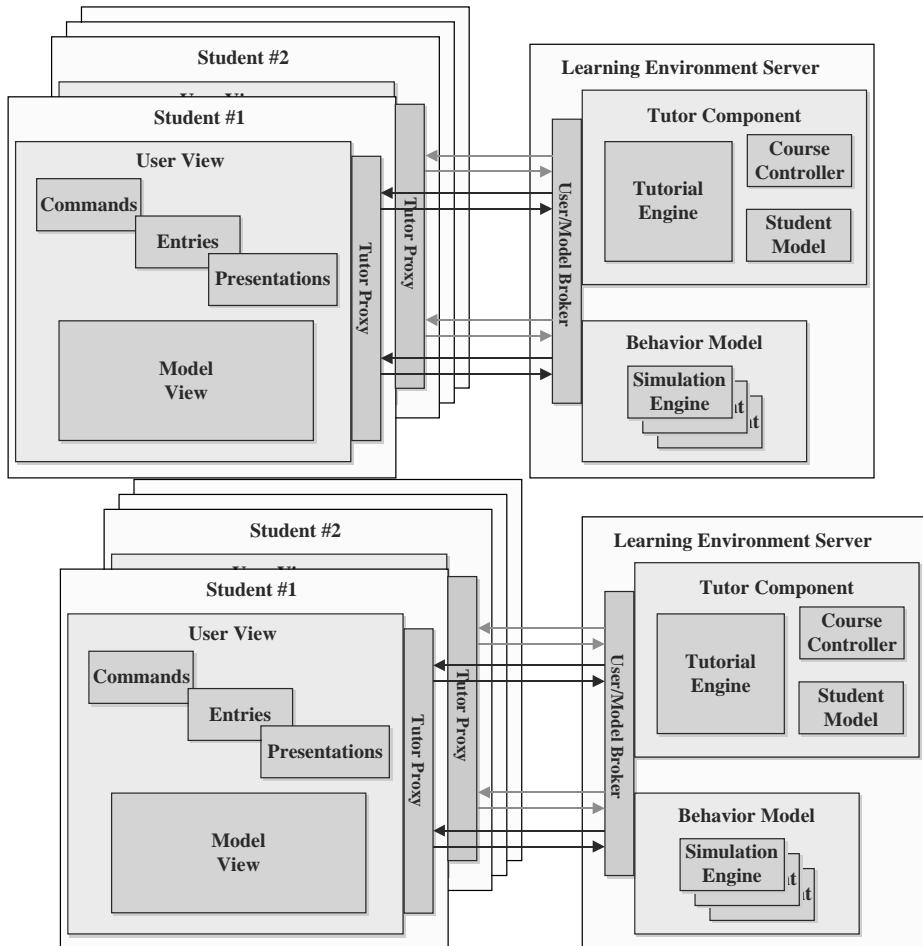

FIG. 20.3. One possible architecture for simulation-centered team training.

behavior model to put the simulation in a particular state. It can ask the model view to stop responding to user actions for a time so that the tutor can demonstrate a sequence of actions without student interference.

2.3 Task Analysis

Large-scale instructional systems developed for sophisticated clients must have a rigorous foundation in instructional design. A military or large business unit would no more contract for the development of a large training course without a detailed instructional design than a corporation would contract for a new headquarters building without an architectural plan. Instructional designs are typically constructed so as to realize objectives. In many cases, these objectives are best understood in terms of the desired quality of performance of a task. Students are to learn enough, as a result of the planned instruction, that they will be able to carry out some task at a specified performance level. This type of objective requires that the task that the trained student is to perform must be analyzed well enough so that the analysis can guide the design and development of the instruction. A number of approaches to task analysis for

instructional design have been summarized in such works as those of Leshin, Pollock, and Reigeluth (1992), Jonassen, Hannum, and Tessmer (1989), and Jonassen (1999).

Several characteristics of VE training require special attention to certain task characteristics during the task analysis process. Virtual environments may be especially well suited to teaching students where to move and where to direct their gaze during a task. It is important that an analysis of a task should pay attention to elements of the task that require moving or orienting actions, so that those steps in the task will be effectively taught in the VE training system. If a task requires either that the student learn to move and/or orient himself or herself or that the student must learn to move and/or orient objects, then the VE training can be structured to explicitly teach the student to carry out these steps.

3. COGNITIVE TASKS APPROPRIATE FOR VEs

Although some progress has been made with applications, it is doubtful that all possible avenues of VE presentation have been explored. That is, if the logical assumption is true that increasing the bandwidth of information input will facilitate learning, then it follows that multimodal presentation will facilitate learning. If information can be received via vision, sound, and touch, then it seems to follow that the learner will experience a richer learning environment and will learn better, faster, with longer retention. Virtual environments are only beginning to be exploited as a multimodal training medium. Additional research is needed with olfactory, temperature, and large movement haptic displays.

3.1 Navigation and Locomotion in Complex Environments

Research conducted at the Air Force Research Laboratory (Regian, 1997) taught subjects to find a route through a complex building, using several modalities to carry out the instruction. One result of this work is that providing a richly decorated VE may have the effect of improving how well a student learns to navigate in the environment. If a student is to learn how to find his way in a building with many corridors and many turns, then the texture maps in the VE should include the pictures that can be found on the walls of the real building.

3.2 Learning Abstract Concepts with Spatial Characteristics

Several experiments on teaching scientific concepts in a VE context have been explored by Bowen Loftin and his colleagues. These include the Newtonian mechanics of NewtonWorld, the electromagnetism of MaxwellWorld, and the chemical bonding of PaulingWorld. One of the interesting findings of this work is that it may often be necessary in VE training to provide constraints on students' virtual locomotion (see chap. 11, this volume) and orientation changes (see chap. 24, this volume). In a virtual environment, students may miss a crucial demonstration because they face the wrong way or position themselves far away from what should be observed.

3.3 Complex Data Analysis

Some types of complex data can be presented in 3-D space in a manner that illuminates characteristics of the data that would not be evident in conventional 2-D presentations. Furthermore, users can be given the opportunity to manipulate the representation and to view it from any angle.

3.4 Manipulation of Complex Objects and Devices in 3-D Space

When there is a requirement to train someone on the physical manipulation of a complex object in 3-D space, training that makes use of the actual object under the conditions that prevail on the job offers the highest probability for good transfer to the actual task. In certain cases, however, the use of the actual object for training is inappropriate or impossible. If the training involves the handling of an extremely delicate and valuable object that can be damaged through inappropriate handling, it may be advantageous to train with a VE simulator. In other cases, danger to the operator or to others may argue for training in a simulation. For example, an inadequately trained crane operator on a construction site could carry out actions that would cause his crane to topple, possibly landing on other workers or bystanders, and pulling the operator's cab off its pedestal.

3.5 Decision Making

Where the domain of decision involves relationships that must be understood in three dimensions, and, especially, when spatial relationships are changing over time, VEs may prove extremely valuable. Ship-handling tasks require the conning officer to develop the "seaman's eye" (Crenshaw, 1975). Part of that skill appears to be recognition of relative motion of objects in the path of own ship. Another part of that skill appears to be maneuvering own ship to avoid obstacles. Now, wind and sea currents affect the direction the ship must point in order to achieve a desired course through the water. As they exert force upon the ship to push it in one direction and the ship's crew desires it to go in another, the heading of the ship must be adjusted slightly to compensate. It appears that one method to teach this compensation angle computation would be a mathematical formula. It also appears that one way of augmenting the concept might be to actually experience the forces of wind and current. There are a number of ways to accomplish this, which have been considered in our work. One would be to use VE to enlarge the user to the size of a giant so that they could actually hold the ship in their hand and feel the force of the wind and current acting on the force of the ship. This would be achieved both visually and with a haptic device for the hand. Other laws of force and motion might be taught by having one feel the forces with a haptic device. Current haptic devices do not appear to be robust enough for sophisticated forces acting in multiple dimensions. Thus, this area requires further work.

4. APPLICATIONS OF COGNITIVE TRAINING USING VEs

Martin and his colleagues (Breaux, Martin, & Jones, 1998) sought to lay a foundation for application to VE of a technique whereby the learner codes information both visually and verbally (see Pavio, 1991). This was intended to explain why VE immersion could be effective in developing a mental representation of an environment. Consider the VE that contains visual, haptic, and audio components to teach shiphandling skills. The intent of traditional training is to apply the concepts described by the teacher verbally and with mathematics in the classroom, and augmented with static depictions of course tracks. The real-world application is, instead, a dynamic, interactive environment of ships at sea maneuvering to avoid one another and to achieve a desired course to reach their destination. The intent of VE-based cognitive training is to solidify a relationship between the verbal concepts of the classroom with the dynamic visual environment of the simulation. Virtual environment training is intended as a method to coalesce the cognitive model from components of dynamic interactive objects of the visual scene with static linguistic concepts from the classroom. The model

thereby developed by the learner is expected to be a richer, more robust model that generalizes to novel ship maneuvering situations. A more detailed explanation of specific tasks will follow.

Another challenge posed for VE by the work of Breaux et al. (1998) was the potential for VE to shape mental behavior. Let's say one seeks to teach a complex concept of adjusting the heading of a ship to correct its path through the water because wind and sea current forces acting to push the ship off course have disturbed it. If the student adjusts the course too much or too little, one may want to understand what it is about the student's mental concept that results in the errors. If a model of the student's behavior of adjusting too much or too little can be created, then one can claim to understand the misperception of the student. That model may be computationally intensive. However, if VE can project the path of the ship with the error introduced by the student, this may depict the current mental model being used by the student. The instructional intervention that VE allows is then to demonstrate visually and haptically how the forces are in fact acting upon the ship's path. Next, VE can dynamically transition the immersed student from the misperception to the correct perception by the use of visual and haptic displays to adjust what the student is experiencing visually and haptically. Consider the analogy of the teacher taking the hand of the student and moving it through the motions required in drawing, say, an image on paper. Now, extend that analogy to a VE adjusting the image and forces felt so that a student sees and feels the proper forces acting on a ship. This is what was intended by the concept espoused by Breaux et al. (1998) of morphing the student's misperception into the proper perception.

Let's move now to some specific applications of VE to training. Applications of submarine navigation, shiphandling, and electronic maintenance are considered.

4.1 VESUB Harbor Navigation

Hays, Vincenzi, Seamon, and Bradley (1998) provide a description of a VE training test bed, the Virtual Environment for SUBmarine (VESUB) training that evaluated the effectiveness of teaching harbor navigation using an immersive visual system with audio (see Fig. 20.4). The officer of the deck (OOD) stands in the open air while a submarine is on the surface and gives commands to the crew for speed and direction of the submarine. The surfaced submarine must navigate its way through the harbor, avoiding obstacles, and tie up at its pier. Current training is typically on the job, so this VE system was designed to provide concentrated training for a variety of situations, including various harbors, weather conditions, traffic, and time of day. Because of the expense of running aground or collision of the submarine with other objects, it is seldom that an inexperienced OOD has the opportunity to train in a real submarine. Therefore,

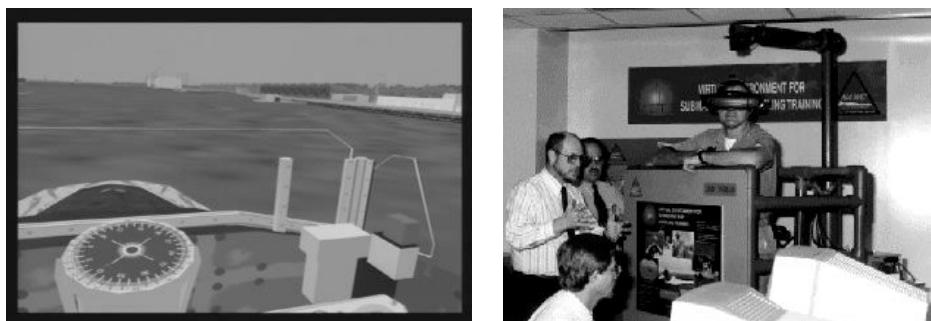

FIG. 20.4. VESUB harbor navigation training.

the system can provide much needed training for inexperienced officers as well as refresher training for the “old hands.”

To make the system look like a real submarine, the visual system depicted a very detailed harbor and displayed various ship instruments on the bridge. A computer voice recognition system captured the commands from the student and translated them for use by the computer mathematical models driving the visual display. The computer models generated sounds of the water, foghorns, and other relevant audio cues as well. An instructor was present to create and observe a particular scenario for the student and to evaluate performance.

One of the features of this system is team communication. The computer expects the student officer to issue proper commands using proper terminology. Also, the instructor is available to provide feedback and manipulate the scenario to challenge the student’s knowledge and skills. Unlike the real task where the commanding officer, acting as instructor, must be ever vigilant to the danger of an error that can be very expensive or even life threatening, the VE system can provide the instructor a less-intensive work pace with concentration on teaching the student.

Hays et al. (1998) reports that the evaluation of VESUB was quite successful. Two navy training facilities spent three weeks each evaluating the system, using 41 participants. Of the 15-shiphandling variables tested, improvement ranged from 13% to 57% on 11 of them. It was proposed that in order to perform the task of navigating the submarine through the harbor, one must develop a mental model of not only the task at hand, but also the relative motion of other water traffic and the effect of tides, current, and wind on the submarine. Some of the cognitive components of the task include: the relationship of what one sees in the environment to its representation on the harbor chart; the relative size and height of objects with the angle on the bow of the submarine; the relative motion of the objects; the prioritization of other water traffic that may conflict with the submarine’s course; and how to maneuver the submarine out of danger.

4.2 COVE Underway Replenishment

Following the apparent success of the VESUB project, the Navy undertook application of VE to more complex cognitive skills. The Conning Officer Virtual Environment (COVE) project sought to combine VE with computer-generated performance assessment. In his thesis, Norris (1998) describes some of the cognitive components of the task of commanding a ship. The challenge for the COVE project was to ascertain and develop methods by which the VE could provide measures of the student’s performance and then use those to deliver diagnosis, feedback, and prescriptive tasks to the student. COVE sought to divide the task into cognitive and perceptual components. The VE not only presented the environment to the student, but also allowed measures of the objects in the environment, indications of where the student looks, and computer speech recognition of the verbal commands that are given.

The task most studied in preparation for the COVE project was that of underway replenishment (UNREP). In this task, a supply ship is steaming a set course, and the ship to be replenished steams to an alongside position (see Fig. 20.5). Both ships then continue to maintain their course and speed while supplies are transferred across approximately 120 feet separating the two ships. The perceptual components include distance, speed, and relative position of the ships. The cognitive components include issuing verbal commands to guide the ship through four different phases of the task. Each of the four phases requires slightly different skills.

The following were proposed as phases of the UNREP task:

- Approach
- Slide-in
- Alongside
- Station
- Breakaway

FIG. 20.5. Under way replenishment.

The approach is defined as being from an arbitrary starting position behind the replenishment ship to a point where the officer must order an initial deceleration to slow to a speed matching that of the replenishment ship. Slide-in is from the initial deceleration to a point where the bow of the receiving ship crosses the stern of the replenishment ship. The alongside phase is from the bow–stern crossing to a point where the two ships are even with one another and at the same speed. The station phase is maintaining the position so that replenishment can occur. Breakaway phase is from separation of the two ships to the end of the scenario. The slide-in and alongside are transitional phases, the slide-in being the end of the approach and the alongside representing the beginning of station. It was proposed that the phases require different combinations of component skills, some of which include:

- Ship control
- Perception
- Decision making

Ship control refers to the ability to effectively control the speed and direction of the ship. Some implicit parameters include ship mass, hydrodynamics, and acceleration. Perceptual skill includes relative motion, the sensation of the visual scene flowing by the conning officer, and distance estimation (both range and lateral separation estimation). Decision making entails the processes involved in monitoring speed and position as well as the ability to stay ahead so as to prevent errors and to identify critical incidents. It was proposed that decision making, perception, and most particularly, ship dynamics best lend themselves to training in a VE.

These component skills were proposed to vary across the different phases. The approach and slide-in require more distal perceptual cues with larger, ballistic-type ship movements (and commands) and simpler, slower decisions. The alongside and station phases requiring more proximate perceptual cues with small, iterative ship movements (and commands) and quick decisions with foresight. Finally, the breakaway was proposed to involve transitioning from proximate cues and small, iterative movements to distal cues and large, ballistic movements. Decision making appeared to require analysis of errors and critical incidents, but unfortunately Norris (1998) did not provide operational definitions for errors and critical incidents.

At the time of this writing, the COVE project was in the formative stages. The benefits that were expected from a COVE system included:

- Training perceptual skills through multiple modalities in VE (visual and auditory)
- Tutor software to teach complex hydrodynamic concepts
- Techniques to teach spatial and temporal orientation of ship movements relative to one another

The preliminary work on planning the COVE project included development of measures of the cognitive components of the task. These will be discussed next.

4.2.1 Performance Measures

The underlying cognitive components of the COVE task were discussed above and include issuing verbal commands to guide the ship through four different phases of the task. In order to arrive at more specific components that would lend themselves to being useable for feedback, diagnosis, and remedial tasks, the preliminary COVE work sought to determine specific measures of cognitive ship-handling skills. Although Norris (1998) provided a task analysis, what were needed were specific measures that correlated with a “good UNREP.”

Patrey, Breaux, Mead, and Sheldon (in press) proposed the application of a perceptual-action task model. This requires one to acquire and use spatial knowledge in order to be successful at ship handling. Actions that the officer of the receiving vessel can accomplish include giving heading and speed commands for the ship. This means that the officer must be aware of water traffic, some of which may be on a collision course, and a hypothetical position that would put the receiving ship in the proper position with the replenishment ship. Patrey et al. (in press) defined four characteristics of a ship’s dynamics, position, heading, velocity and acceleration, as its “moments.”

In their study, subjects spent about 1.5 hours to perform two UNREPs. They were evaluated by six expert shippers and the average rating was correlated with 13 moments that were measurable in the virtual environment. Four of the moments proved significant: lateral separation of the two ships, bearing, speed, and acceleration. In addition, it appeared that 83% of the performance of the UNREP could be explained by these four moments at the point when the bow of the receiving ship passed the stern of the replenishment ship. This is the transition point between slide-in and alongside phases of the UNREP.

The conclusions drawn in this study contradicted current thinking about UNREP performance. Experts typically suggest that there is no single best way to UNREP. There are many variations that are just as good. However, Patrey et al. (in press) suggested that the fact that certain moments correlate so highly with performance rating indicates that it is possible to quantify what is traditionally thought of as a qualitative task. Further, typical training for UNREP done at sea is a trial and error proposition. This study suggested that there are in fact measures that may indicate the strength of the cognitive model used by students to perform the UNREP. Furthermore, it was suggested the VE training, by its ability to measure the entire environment, will allow more structured training of the cognitive model than will occur by trial and error training. One approach would be that the moments would be used to develop remedial exercises, or part-task exercises. For example, it may be that UNREP skills develop quicker if a student practices just the slide-in and approach phases until their performance is high and then moves on to approach, station, and breakaway. These hypotheses were under examination at this writing.

4.3 VETT Maintenance Training

Davidson (1996) describes a system designed to teach electronic maintenance skills using a commercial haptic display called the PHANToM, manufactured by Sensible Devices (see Fig. 20.6). The PHAMToM served as an electronics probe to test circuits. Traditional training

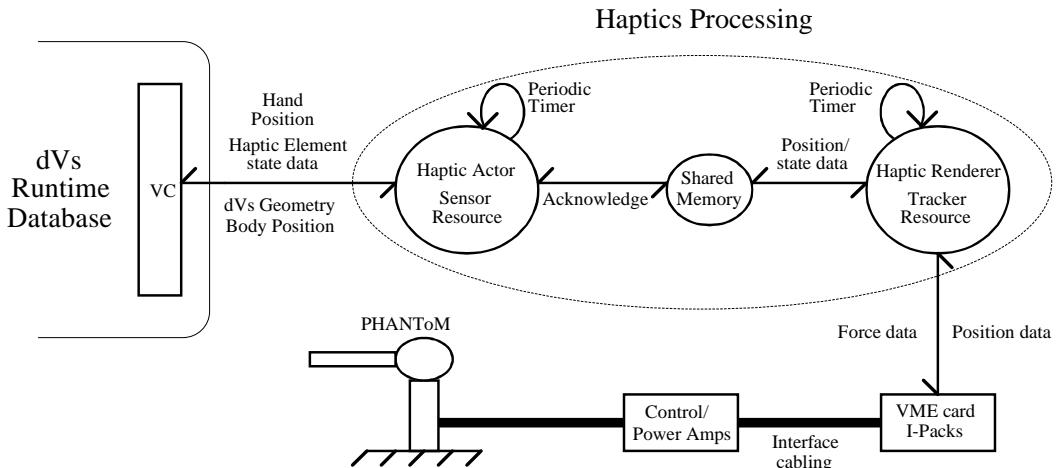

FIG. 20.6. Architecture of a VETT maintenance trainer.

uses the NIDA Model 130 Test Console, shown in Fig. 20.7 below. Various circuit cards can be inserted into the console, and the student must ascertain the fault that is contained on the card.

To replicate this task using VE, a visual system was devised as depicted below and interfaced with the PHANToM. This allowed a combination of seeing a simulated circuit card in a helmet display while at the same time feeling a simulated probe on the circuit card (see Fig. 20.8). In addition to simulated resistors, there were simulated toggle buttons and a simulated multimeter for test readings.

Unfortunately, this task was cancelled before a controlled experiment could be conducted. However, Davidson (1996) suggested that haptic interactions could provide a viable alternative to actual circuit cards for training troubleshooting concepts. Further, haptic displays can provide force feedback cues not available from other tracking systems.

4.4 Operations Training with VEs

In the Virtual Environments for Training Project (Johnson et al., 1998; Stiles et al., 1996), there was a concerted effort to generalize features of the training environment to exploit cognitive

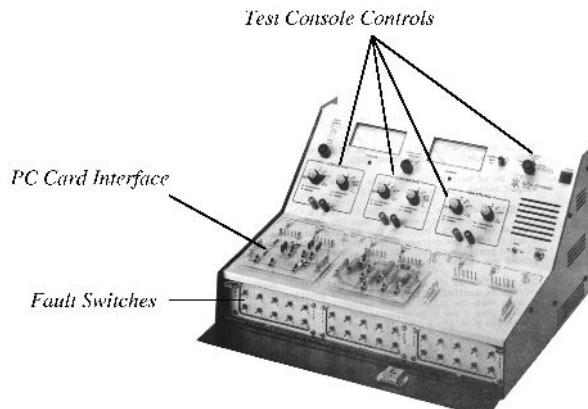

FIG. 20.7. NIDA Model 130 test console.

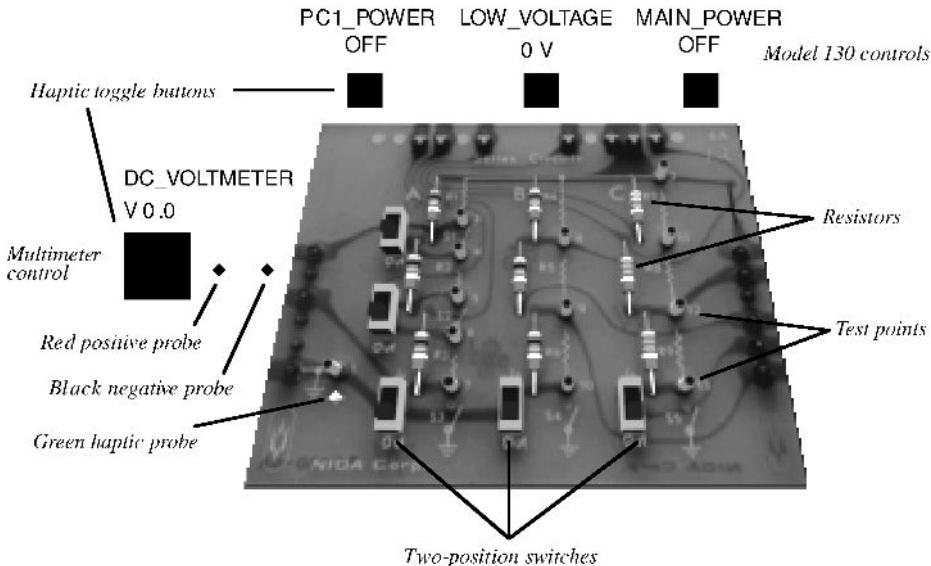

FIG. 20.8. A circuit card.

characteristics of operations training in a virtual environment. This project made use of Virtual Interactive ITS Development Shell (VIVIDS) (Munro et al., 1998; Munro & Pizzini, 1998), a tool for authoring interactive graphical simulations and tutorials that are delivered in the context of interactive graphical simulations. VIVIDS includes a deep representation of the notions of effectuating actions and observations. As a simulation author builds a simulation, the author designates those attributes that store the immediate results of effectuating actions and those attributes that store directly observable values in the simulation. Because the simulation is coded with these cognitively relevant concepts, it is possible to use the VIVIDS tool to rapidly author procedural lessons simply by carrying out the procedures that students are to learn.

VIVIDS provides a set of direct manipulation interfaces for building simulations and tutorials. A number of features support productive simulation authoring. Authors can select from libraries of behaving objects to add interactive components to a simulation. Alternatively, authors can draw new objects (or import object images) and then write rules that control the interactive behavior of the objects. A simulation engine that supports constraint-based effect propagation makes it possible to author complex simulation behaviors without attending to details of the flow of control of simulation effects. In the right portion of Fig. 20.9 below, a portion of the behavior-authoring interface is displayed. An object data view displays the attributes of a simulated shipboard throttle. Authors can add and delete attributes, change their values, and write constraint rules that prescribe the values of given attributes. Such rules specify values in terms of the values of other attributes and in terms of student actions. In this figure, the author has marked an attribute named "mode" as a *control attribute*, that is, an attribute whose value is directly determined by user actions. During instructional authoring and delivery, VIVIDS knows that it can make use of the values shown in control attributes to talk about student actions.

In the left portion of the figure is a snapshot of a portion of the VE that exhibits the authored behavior. The behavior of simulated devices such as the throttle shown here is determined by the behavior rules created in the VIVIDS authoring system.

VIVIDS supports productivity in tutorial development by exploiting the simulation author's designations of the cognitively relevant attributes for actions and observations. In the Fig. 20.10

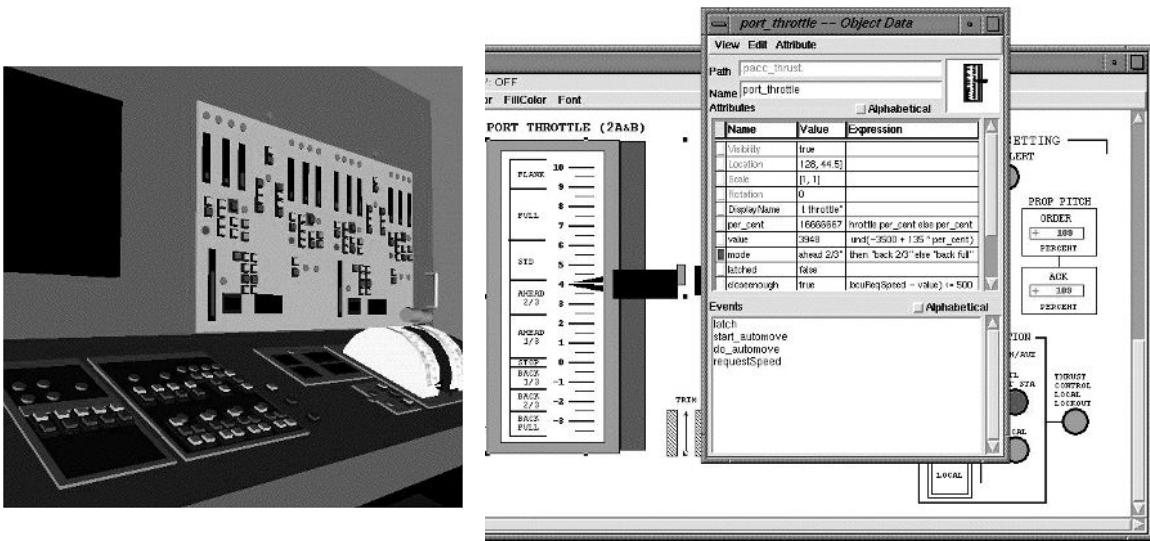

FIG. 20.9. VIVIDS' behavior-authoring interface.

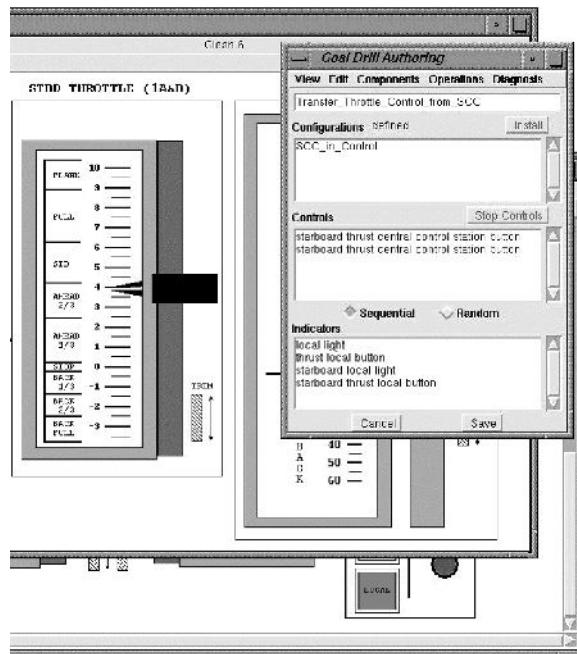

FIG. 20.10. Using VIVIDS to author a procedural tutorial.

below, for example, a simple procedural tutorial is being authored by carrying out a task and then pointing to the objects in the simulation that indicate that the task has been achieved. As the instructor carries out the steps in the procedure, the tutorial authoring system notes the actions and the associated changes in attribute values. It generates brief action descriptions, which appear in a list in the tutorial authoring view. When it is time to present the tutorial to the student, VIVIDS will be able to talk to the student in terms of these cognitively relevant action and indicator values.

The Virtual Environment Technology project supported more than one approach to tutoring procedures. An intelligent agent called *Steve*, developed by Lewis Johnson and Jeff Rickel at Information Sciences Institute, could be used in conjunction with VIVIDS. At the cost of some expert knowledge engineering, Steve could be given a robust representation of the structure of a task in terms of plans and subgoals. During instruction, Steve could watch student actions and monitor changes in VIVIDS simulation attributes to determine where the student might be in the plan structure. Because Steve has a richer representation of the decision process, it is capable of generating richer tutorial dialogs during instruction than is the easily authored native VIVIDS procedure lesson. For example, Steve can describe the reasons for actions. In Fig. 20.11 below, Steve is shown demonstrating to a student how to carry out a step in a procedure.

5. CONCLUSIONS

Cognitive issues in the fields of perception, attention, learning and memory, motor cognition, and decision making are all relevant to virtual environments. Research on and prototype developments of VEs for learning have dealt with these issues in ways that may help to inform future VE projects of many types.

A number of research and practical issues remain to be addressed in future research. These include such questions as "How should a user's attention be drawn to objects or areas that are

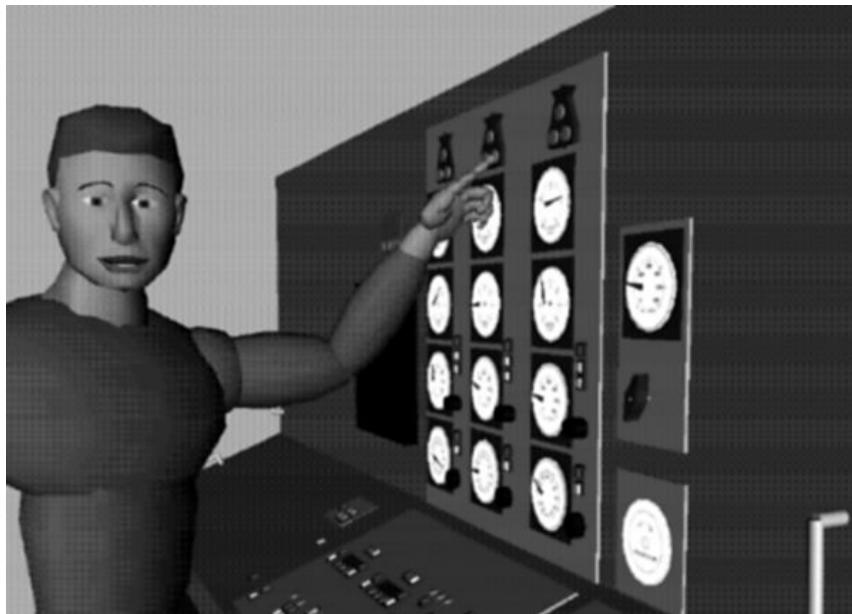

FIG. 20.11. Steve demonstrating a procedure.

currently outside of the student's field of view?" and "Under what conditions is it appropriate to assume that a user has perceived something that is in her field of view?"

Validation studies also remain to be conducted. Under what conditions does procedural expertise in a VE translate to competence in a corresponding real-world task?

As for training applications, where are VEs best suited? VE-based training may be appropriate for concepts that require mental images in conjunction with decisions about location, about relative location of things over time, or about the timing of location and direction changes. Virtual environments can help students to recognize, or visually imagine, patterns of time and location in tasks done before, so that the student can see a familiar pattern in a new situation and then do the job in the new situation.

Why should VE work well for training? The tutor can control the mental images, timing and location not only of objects, but also can control the location of the learner. This lets a learner explore relationships from different perceptual viewpoints so that the learner can later recognize the same kind of situation. Even if the situation looks like it is new, the learner can see that it is really the old situation presented at just a little different angle. The use of VEs encourages the presentation of many perceptual viewpoints to a learner so that an appropriate generalization of the concept can be rapidly acquired.

Another area of research to be explored is the further development of tools that encourage the production of VEs that take advantage of cognitive factors to ensure that such environments achieve their intended purpose in an effective and efficient manner. A key issue may be the development of familiar metaphors for VE that facilitate the learner's association of novel situations with more easily understood ones.

1. INTRODUCTION

Virtual environments (VE) represent advanced, immersive, human–computer interaction systems. Such interaction occurs through communication over several sensorial channels. Since the communication pathway between users and the simulation system groups several distinct channels, it is termed *multimodal*. The modalities used are primarily the visual, auditory, and haptic ones. The number, quality, and interaction between such modalities are key to the realism of the simulation and eventually to its usefulness. Thus the need for increased immersion and interaction motivates system designers to explore the integration of additional modalities in VE systems and to take advantage of cross-modal effects. The downside, of course, is increased system complexity, cost, and possible integration/synchronization problems. In addition, cross-modal interaction can lead to perceptual illusions that must be considered by system developers (see chap. 22, this volume).

Finding the best compromise between multimodal simulation realism and its cost and drawbacks requires a good understanding of each modality individually, and in combination. The first step is to have a model of the communication loop between the user and the computer(s) running the simulation, as illustrated in Fig. 21.1 (Schomaker et al., 1995). The Human Output Channels and Computer Input Modalities define the input flow into the simulation. The Computer Output Modalities and Human Input Channels define the feedback flow by which the user receives feedback from the virtual environment. The two communication channels form the human–VE interaction loop.

The processes involved at the human side of the interaction loop are perception, cognition, and control. *Perception* is the process of transforming sensorial information to higher

¹Currently with IBM Co., T. J. Watson Research, Hawthorne NY.

level representations (cognitive and associative processes; Schomaker et al., 1995). In the model adopted here, perception involves the machine-to-human communication flow. The corresponding perception channels are visual, auditory, and somatic (haptic, olfactory, gustatory, vestibular). Interface devices that need to be matched to a user's input characteristics mediate the user's perception of the computer output. In order to guide the design of such interfaces, numerous studies have been dedicated to human sensory and motor physiology. A comprehensive comparison of human sensory capabilities with feedback device specifications can be found in Barfield, Hendrix, Bjorneseth, Kaczmarek, and Lotens (1995).

The *control* process, in the context of VE systems, represents the translation of human actions into task-related information for the computer. Thus control involves the human output channels and computer input modalities. The control modalities of gesture, speech, gaze, and touch are used in conjunction with hardware interfaces. Such devices convert a user's output to computer digital input data as accurately and as fast as possible. Control and perception are not totally independent processes. The dotted line in Fig. 21.1 accounts for I/O channel coupling of the human information processing system, which will be discussed later in this chapter.

The *cognition* process takes place both at the user's side and at the computer side of the system. Human cognition processes have a far greater complexity, however, and can only be approximated by simplistic computer "cognition" algorithms. As with the perception modalities, present limitations lay at the computer side of the interaction loop.

The capacity and bandwidth requirements for the VE system communication channels vary with human information processing capacity (visual, auditory, haptic, etc.) and with human motor performance (eye motion, body motion). Other communication parameters, such as time delays, interchannel lags, and channel interference, are also important for integrating all the above modalities. There are no models available, however, for describing multimodal integration due to the complexity of human information processing channels. The design guidelines for multimodal integration are mostly based on experimental studies (human factors). Typically these studies focus on either input or output modalities and do not evaluate integrated systems. Therefore the following sections will treat separately the two components of the VE loop (input and output). The discussion of input–output coupling is limited to a short final section.

2. MULTIMODAL INPUT

Development of multimodal input for VE systems is essential due to the increased user control and interactivity required by recent VE applications (e.g., medical VE, VRCAD). Performance-oriented interaction techniques (Bowman & Hodges, 1999; chap. 13, this volume) address this need by proposing gesture-based metaphors, which appeal to user imagination (“magic” interaction methods). Multimodal input (gesture plus speech and gaze) can also achieve a high level of interactivity while increasing the naturalness of the human VE interface.

Human input in VE is mostly achieved through gesture-controlled input devices. Even though many of these devices are intuitive and easy to use, they cannot provide a fluent dialogue between the user and virtual environment. Natural interfaces extract more information from human output (speech, gestures, gaze) and use “cognitive” models to respond intelligently to a user’s input. These models integrate parallel streams of information from speech, gesture, and gaze, and provide real-time semantic interpretation. The present discussion on multimodal input starts with a presentation of performance and limitations of input modalities. This will highlight the need for integration of input modalities in order to improve the interface.

2.1 Input Modalities

The most prevalent input modality used in present VE systems is movement of the user’s body. Such movement may be limited to the wrist (when a joystick or spaceball are used), the fingers (when sensing gloves are used), or even the whole body (when the user wears a sensing suit). Joysticks, mice, or trackballs are simpler and cheaper but constrain the user’s freedom of motion, a very important ingredient for increased simulation realism (see chap. 40, this volume).

Sensing gloves and sensing suits preserve the user’s freedom of motion (within the range of three-dimensional [3-D] trackers) and are more appropriate for modern large-volume virtual environments. Furthermore, sensing gloves allow dexterous interactions, overcoming the limited menu of actions of simpler devices (button clicks, etc.). They are, of course, more expensive and more complex to program.

Hand gesture has been extensively studied as an efficient input modality. Gesture languages with different levels of complexity (starting from grasp-release commands to American Sign Language) have been proposed for various applications (Billinghurst & Wang, 1999; Kjeldsen & Kender, 1997; Pavlovic, Sharma, & Huang, 1997; Starner & Pentland, 1995). Large vocabularies necessary for a fluent human–VE dialogue cannot be implemented through gesture only because this requires extensive user training and memorization.

The efficient use of gestures resides in their integration with speech input. The speech channel has great potential for control in virtual environments. Being the dominant channel of human–human communication, speech can convey levels of abstraction inaccessible to other input modalities. Giving input through speech relies on speech recognition capabilities of the computer(s) running the simulation. Current speech recognition algorithms use real-time Hidden Markov Models (HMM; Dragon Systems, 1999; HTK, 1999; IBM, 1999; Microsoft, 1999). These speech recognizers can achieve high recognition rates (over 95%) if the user employs a limited, application-dependent vocabulary. The limitations in current language understanding technology prevent widespread use of speech-based user control of virtual environments. Speech input thus should be combined with other modalities, such as gestures, to provide better spatiotemporal information (Oviatt, DeAngeli, & Kuhn, 1997). Gesture can also help disambiguate speech sentences.

Another approach to help speech input is to add gaze input. During control tasks, gaze automatically focuses on the VE region of interest (Jacob, 1995). This can be exploited for navigation or object selection tasks. More elaborate tasks, such as moving objects from one

location in the VE to another, require user training in order to exercise eye movement control and to minimize eyestrain. Extracting the semantics of eye gestures is still a difficult problem. Eye movements represent a very fast way to communicate user intentions, but they also carry unintended (subconscious) content. These limitations make gaze input useful only in combination with speech and/or gesture.

The above discussion indicates why multimodal input is preferred to unimodal speech input. Furthermore, experiments done by Oviatt et al. (1997), Oviatt and Clow (1998), and Oviatt (1999) demonstrated that users have a strong preference for multimodal as compared to unimodal interactions, especially in the spatial domain. Experiments with a two-dimensional (2-D) map application showed that users were likely to express multimodal commands when describing spatial information (location, number, size, orientation, or shape of objects). User commands carrying spatial information were best sent to the computer through gestures. Simple speak-and-point interfaces were considered too rigid and of limited practical use.

The remainder of this section is organized around three aspects of multimodal input: namely software architecture; integration issues; and multimodal input applications. Interested readers should also consult Blattner and Glinert (1996) for a comprehensive review of multimodal input.

2.2 Multimodal Input Architecture

Virtual environments need to minimize time delays in system response, whether these delays are due to software processing, communication bottlenecks, or slow graphics. Real-time speech recognition, gesture recognition, and haptic rendering represent a significant computation load. This makes necessary a distributed computing platform, with modalities running on separate computers. The various input devices are therefore attached to their own computation platform running a driver and data processing software, and communicate through a network interface. The programming toolkits available to help developers integrate the different hardware interfaces are at the present time limited. Even in cases when the input device has an associated programming interface, integration is not easy. Most of the programming interfaces were not developed for multimodal input and have limitations when used as research tools.

Robust multimodal architectures integrate input modes synergistically in order to disambiguate input signals. This process takes advantage of modality-specific information content, redundancy, and complementary input modalities. Multimodal input software uses a layered architecture, with input devices at the lowest level and the application at the highest. Intermediate layers describe how input modalities are used and what tasks need to be accomplished. This modularity is important because it allows a better separation of application functionality from the user interface.

A layered model for modal input and interaction in VEs was presented in Schomaker et al. (1995) and is summarized in Table 21.1. The lower levels of the model contain the input devices and the associated events. The user VE interaction is realized through gesture, speech and gaze commands. When modalities are used in parallel, the interaction can be realized through multimodal commands. The multimodal input has uniform access to the pool of events received from input devices. The last two levels specify the application and the interaction tasks implemented by the command language. Tasks are modality independent, even though some modalities are better suited for certain tasks (e.g., gestures for object manipulation).

An example of a layered multimodal input platform is illustrated in Fig. 21.2 (Marsic, Medl & Flanagan, 2000; Sletterink, 1999). The first layer consists of modal software interfaces, which get data from input devices and detect input events (gestures, spoken units, mouse clicks,

TABLE 21.1

Layered Model for Interaction in VE (Adapted from Schomaker et al., 1995).

Application	Virtual reality, CAD, visualization, architectural design
Interaction tasks	Navigation, manipulation (move, rotate, scale), identification, selection, VE editing
Interaction techniques	Gesture language (grabbing, releasing, pointing), 3-D menu, speech commands, Gaze commands, multimodal commands
Events	Hand and body gestures, 3-D Motion, button click, force, 2-D Motion, torque, spoken units, eye motion, gaze direction
Input devices	Sensing gloves, trackballs, 3-D mouse, 6-D tracker, eye tracker, joystick, microphone, tactile gloves

etc.). These events are then transformed into text units and sent to the next layer. The second layer contains the central component of the software architecture, namely the *multimodal input manager* (MIM). The MIM receives streams of data from several modal interfaces and issues commands to the current application. The MIM in turn consists of four units, namely the *modality handler*, the *customizer*, the *multimodal integrator* and the *connection manager*. The modality handler allows adaptive use of available input modalities. It detects available modalities, decides which modalities are relevant for the current application and gets input streams from its corresponding modal interfaces. The connection manager handles automatic context by keeping track of a focused application (the selected window). Context switching increases the reliability of speech and gesture recognition modules by reloading the grammar and gesture sets through the customizer. Instead of implementing a large grammar that will reduce recognition performance, each application has its own grammar and a corresponding parser. The modal integrator implements the integration (fusion) and synchronization of input modalities, as described below.

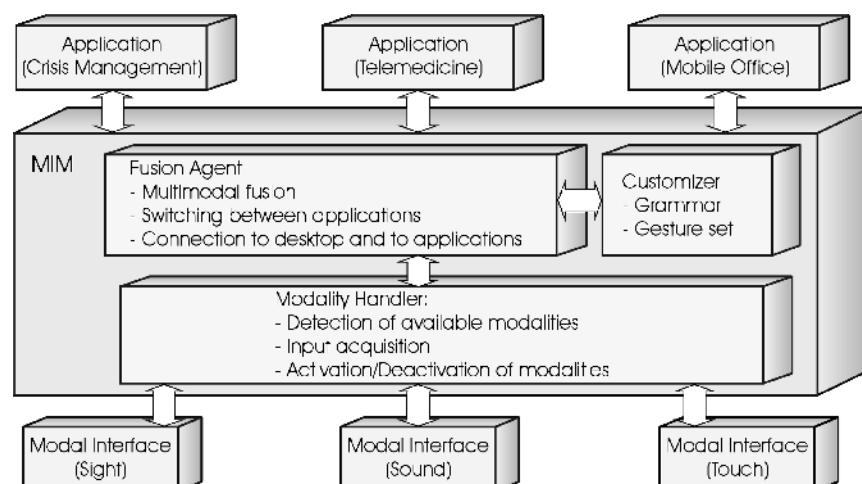

FIG. 21.2. Structure of the Multimodal Input Manager (Marsic, Medl & Flanagan, 2000). © IEEE.

2.3 Multimodal Input Integration and Synchronization

Multimodal integration performs the mapping of modal inputs into a semantic interpretation. The main elements of multimodal integration are: unified representation synchronization and semantic analysis. *Unification of data representation* is the first step after capturing the data from human output. To obtain a unified representation, each input data stream is translated into a sequence of tokens contributing to the semantic. These tokens could be, for example, time-stamped text items.

The second step is the *synchronization of the input streams*. The input streams are first buffered and segmented in order to create a context for semantic analysis. Then the tokens are aligned on the time axis based on synchronization models. These models take into account the temporal precedence of modes and intermodal lags. The last step is semantic data fusion. The semantic analysis module receives the temporally aligned input tokens and extracts the control sentences. Natural language processing methods can be applied to extract the semantics of human–VE interactions when using a unified textual representation of modal input.

The steps described above are typically performed in order, but feedback loops from synchronization and semantic analysis can modify some input tokens during the integration process. Several mechanisms have been proposed for implementing multimodal integration, involving frames, neural nets, and agents. The frame–slot integration mechanism applies the well-known artificial intelligence method (slot-filler) for multimodal fusion. In this method, information necessary for command or language understanding is encoded in structures called “frames.” For the multimodal input model shown in Fig. 21.2, a frame stores the information about multimodal input commands. The command frames are composed of slots, which are lexical units provided by the multimodal input. As an example, the “move” frame is composed of two slots: “object,” to identify the object; and “where,” to specify the final position.

A frame–slot-based method, with predefined and application-dependent frames was used in Medl et al. (1998). The multimodal architecture is illustrated in Fig. 21.3. The parser extracted the lexical units from different input modalities and filled the appropriate slots in the slot buffer. The concurrency of input modalities was handled on a first-come, first-served basis. The central component of the fusion agent was the slot buffer, which stored the information inputted by the user. This allowed back referencing of past lexical units (e.g., “it” could be used to reference the previously selected object), increasing the fluency and naturalness of the command language. Data fusion used lexical units drawn uniformly from input channels. The fusion agent continuously monitored the slot buffer checking for filled frames. Once a frame was filled (enough information to generate a command), the fusion agent sent it to be executed. The main advantage of this architecture is the uniform access of the input modes.

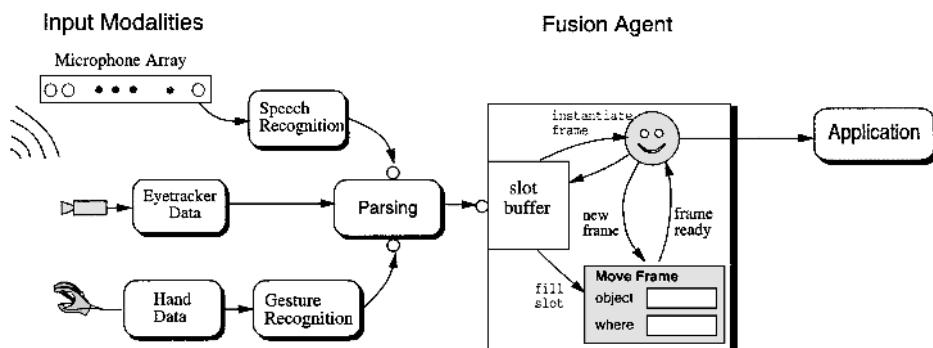

FIG. 21.3. Frame-based multimodal input integration (adapted from Medl et al. 1998). Reprinted by permission.

Neural networks are adaptive systems designed to model the way in which the brain performs a particular task. Their main quality is the capacity to learn complex relations between their inputs and outputs. This characteristic makes neural nets useful for multimodal input integration. Vo and Waibel (1993) were among the first to use neural networks for multimodal systems. Each input modality used time-delay neural nets (TDNN) for temporal alignment, which allowed simultaneous processing of data received over a period of time. The design exploited the temporal precedence of hand gesture (writing) over speech. Later designs used a connectionist network for multimodal semantic integration (Vo & Waibel, 1997). In this model the input modality channels were considered parallel streams that could be aligned in action frames and jointly segmented in parameter slots. Temporal alignment was based on time stamps associated with input tokens. The integration mechanism used a mutual information network architecture and a dynamic programming algorithm to generate an input segmentation. After obtaining the frames with the corresponding slot information, grammar-based algorithms were applied to capture syntactic elements and extract their meaning.

Another approach to multimodal input integration is the use of a set of hierarchically organized entities (agent-based algorithms). An agent implements a certain function (task) of the multimodal input manager. The agent has a specified set of sensors (inputs), a model to process the information, and a set of effectors (outputs). The agent-based multimodal input architecture contains three layers. The first layer consists of modal agents processing the data from input devices. The next layer contains language recognition agents. A language recognition agent gets input from a modal interface (speech, gesture, etc.) and generates a potential interpretation based on the specified language model. This layer is responsible also for unifying the modal data representation. The third and last layer contains a multimodal fusion agent, which receives language units from recognition agents and integrates them to produce the best possible interpretation of the user's input.

An agent-based fusion of speech and gesture modalities was presented in Johnston et al. (1997). Their multimodal architecture used six agents: interface client, speech recognition, natural language processing, gesture recognition, multimodal integration, and bridge (a command execution agent). The fusion agent used a probabilistic model. Probabilities were associated with each modal input, with the highest unified score interpretation being selected. This allowed grammar-based techniques employed in natural language processing to be used in the semantic integration process as well.

2.4 Examples of VE Applications Using Multimodal Input

Computer Aided Design (CAD) systems have a great need to replace the current windows-icons-menu-pointer (WIMP) paradigm with more-natural user interfaces. This is especially true in the early “concept” phase of the design process. The main limitations are related to the inability to create 3-D shapes intuitively and provide interactive 3-D visualization. Chu, Dani, and Gadh (1997) investigated the potential use of multimodal input for COVIRDS (conceptual virtual design)—a VE-based CAD system. Candidate input modalities were gaze, voice commands, and hand gestures. Multimodal interface requirements were analyzed for three stages of product design: part and assembly generation, part and assembly modification, and design review. Sets of interaction tasks (commands) were produced according to application requirements. Subjective evaluation tests showed that voice and hand gestures were the preferred modes of interaction, whereas gaze input was found useful for “select” commands. No comments referring to sensory input fusion or modalities concurrency were given in this study.

Speech and gesture inputs were subsequently used to develop an intuitive interface for concept shape creation (Chu, Dani, & Gadh, 1998). A series of tasks were implemented using different modalities (e.g., zoom-in, viewpoint translation and rotation, selection, resizing, translation). Evaluation of the interface was based on user questionnaires. Voice was intuitive

to use in abstract commands like viewpoint zooming and object creation and deletion. Hand gestures were effective in spatial tasks (resizing, moving). Some tasks (resizing, zoom in a particular direction) were performed better when combining voice and hand input. The command language was very simple and the integration of modalities was implemented at syntax level. Therefore, in some cases users showed preference for a simple input device (a wand with five buttons) rather than for multimodal input.

Researchers at Beckman Institute (University of Illinois, Champaign-Urbana) developed MDscope—a VE testbed for visualization and interactive manipulation of complex molecular structures. Multimodal input (speech, hand gesture and gaze) was integrated in the VE in order to improve virtual object manipulation. The multimodal framework for object manipulation (Sharma, Huang, & Pavlovic, 1996) used a HMM speech recognizer. The hand gesture input module used a pair of cameras and HMM-based recognition software. Speech and gesture were integrated using a fixed syntax: <action>; <object>; and <modifier>. The user command language was rigid to allow easier synchronization of input modalities. The synchronization process assumed modality overlapping. The lag between speech and gesture input was considered to be at most one word. Gaze input was used to provide complementary information for gesture recognition. The direction of gaze, for example, was exploited in order to disambiguate object selection. Experimental work with the above testbed concluded that multimodal interfaces allow much better interactivity and user control compared to unimodal, joystick-based input.

The relationship between speech and gesture was also exploited by Cassell et al. (1994). Their application involved animated human figures capable of conversation in a virtual environment. The underlying assumption was that gesture and speech are “communicative representations of a single mental representation.” The correlation between speech and gesture was analyzed and a set of rules to predict the location and type of gestures was given. The system provided a test bed where predictive gestures were computed during the dialogue. The implementation used the Jack virtual human toolkit, which was animated using PaT-Nets (Douville, Levison & Badler, 1996). Hand, wrist, beat (a specialized form of wrist motion), and arm motion were driven by computation modules that used information from the output of the speech synthesis module. Using this predictive approach, the VE was populated with autonomous animated conversational agents.

Another potential application area for multimodal input is military planning in which users perform very fast control tasks in a stressful and noisy environment. Such a system could possibly benefit from a multimodal input interface. Rosenblum and colleagues at the Navy Research Laboratory developed “Dragon 2,” a VE research platform for battlefield planning and control (Rosenblum, Durbin, Doyle & Tate, 1997). The multimodal input was provided by QuickSet (Cohen et al., 1997, 1999), a pen-and-voice-based system that ran on handheld PCs and communicated via a wireless Local Area Network (LAN) with the host computer running the simulation. The multimodal input for Dragon 2 consisted of voice commands and a “flight stick,” a commercial joystick modified to incorporate a Polhemus tracker. The flight stick was used for navigation, selection, and drawing on a 2-D or 3-D map. Users’ speech and gesture input were recognized, parsed, and then fused via the QuickSet multimodal integration agent.

Another military planning application—3D Mission Control—was recently developed on top of the multimodal architecture shown in Fig. 21.3 (Medl et al., 1998). The system used a commercial speech recognition engine (Microsoft WHISPER), a haptic glove (the Rutgers Master II), and a gaze tracker (ISCAN). The data fusion mechanism used the slot-filler method described earlier in this section. The user saw a 3-D map of the area where the mission was being planned (shown in Fig. 21.4 Marsic, Medl & Flanagan, 2000). The scene was composed of 3-D terrain created from a digital terrain elevation data (DTED) map file, a virtual hand, and several 3-D objects representing “assets” (base camps, jeeps, trucks, helicopters, etc.). The user could add, select, move, and delete these objects in the 3-D environment. The manipulation

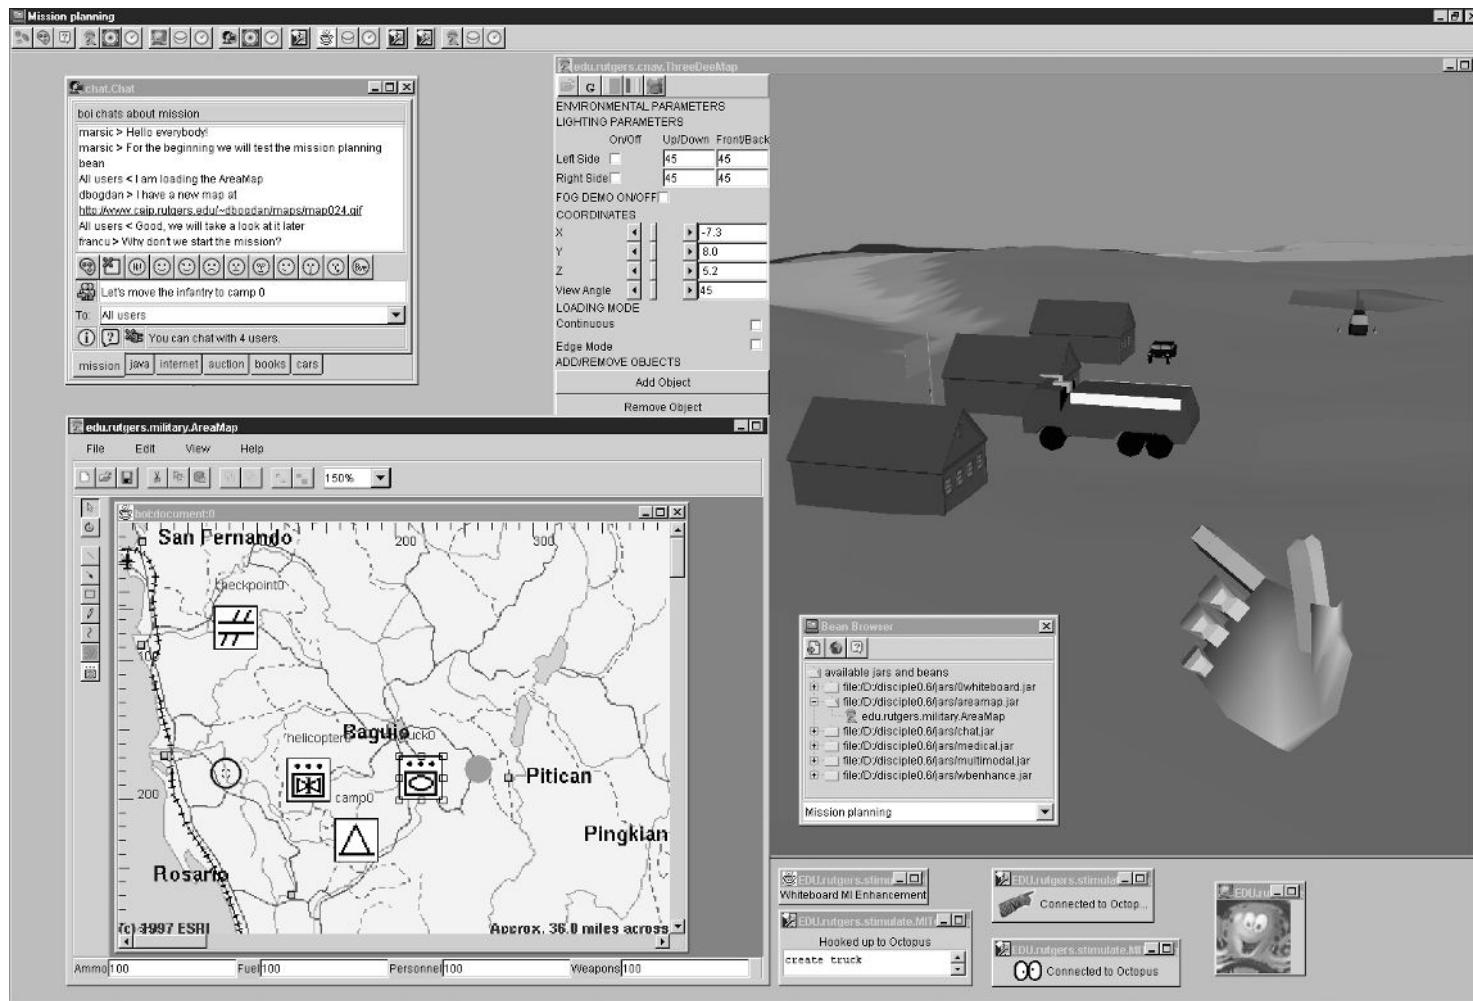

FIG. 21.4. “3-D Mission Control” (Marsic, Medl & Flanagan, 2000). © IEEE. Reprinted by permission.

of virtual objects relied on gesture input, whereas speech was most useful for object creation and deletion, and for viewpoint change. Feedback was provided to the user through visual, auditory, and haptic channels. Besides reinforcing the visual feedback, force feedback was used to map the physical properties of the objects in the virtual environment. For instance, the hardness of a transport vehicle indicated whether it was loaded or not. Synthesized voice feedback was used to confirm successful completion of a command, identify specific objects, and warn the user of errors.

2.5 Summary of Multimodal Input

Looking at the VE simulation loop from the user's perspective, multimodal input allows better control of the simulation through several communication channels. By using voice, gaze, and gesture, the simulation interactivity as well as the user's feeling of immersion (see chap. 40, this volume) into the VE may increase. Looking at the same simulation loop from the computer input perspective, multimodal input helps alleviate some very clear limitations of unimodal, voice-only input. Commands that otherwise may be difficult or impossible to understand can be disambiguated, objects can be placed in an environment more precisely, and navigation can be faster. Several approaches have been developed for the integration of the various input modalities, namely application-dependent frames, neural networks, and hierarchically organized agents. The limited data available from human factor evaluations of multimodal input suggests a clear subjective preference for multimodality versus unimodal input.

3. MULTIMODAL FEEDBACK

Multimodal feedback represents the computer response to the user's multimodal input to the simulation. Early VE systems had unimodal visual feedback through stereo or monoscopic graphics displayed on CRTs or head-mounted displays (HMDs). As research interest for other communication channels grew, bimodal VE systems (visual-auditory, visual-haptic feedback) have been developed and evaluated. Currently, the most frequently used feedback channels are visual, auditory, and haptic (force/tactile feedback). Additional channels such as olfactory feedback may significantly enhance user's immersion (see chaps. 14 and 40, this volume), but are less developed at the present time (note, however, that the technology for olfactory feedback is advancing, providing several commercially available systems including SENX Machines, iSmell Digital Scent Technology, and Aromajet).

The visual, auditory, and haptic feedback channels each use a different kind of interface. The information flow received through the visual sensorial channel is much larger than that corresponding to the haptic or auditory channels. Thus visual feedback takes the dominant role among the three primary VE feedback modalities. Stereoscopic vision allows 3-D perception of the left and right eye images rendered by the computer (see chap. 3, this volume). If the visual feedback modality is coupled with body posture (head motion) input, then the user controls the field of view to the simulation. This is thought to result in increased immersion and simulation realism (see chap. 40, this volume). Earlier HMDs were heavy and had low image resolution, problems that were compounded by low-accuracy tracking of the user's head position (Thorpe & Hodges, 1995). In recent years the problems with HMD weight and image resolution have been largely solved (Olympus, 2000). Furthermore, accurate and robust trackers are starting to immerge (InterSense, 2000).

Sounds are ubiquitous in the real world and therefore their presence in VEs should be beneficial to the simulation realism. Auditory displays can be classified as nonlocalized and localized (see chap. 4, this volume). Nonlocalized audio feedback is provided by multimedia-quality

stereo sound, meant to increase user interaction. Localized (or spatialized) sound uses head tracking and head related transfer functions (HRTF) to display 3-D soundscapes. A localized sound source remains fixed in space regardless of the user's change in head position, similar to what happens in the real world (Barfield et al., 1995). Thus 3-D sound technology has significant potential for newer large-volume simulations. A current limitation is related to the inability to customize the HRTFs to the individual user's pine (external ear) characteristics, which results in less accurate mapping of sound spatial information in VEs than in the real world. Other limitations of earlier commercial products were the high computation load required and the high hardware cost. These problems have been largely addressed in recent years, with the introduction of significantly faster hardware, at lower costs. The customization of 3-D sound remains an area of active research.

Haptic feedback is considered an important modality for VE interactions involving active virtual object manipulation (Burdea, 1996; chaps. 5 and 6, this volume). Adding haptics increases user immersion and interactivity by allowing an object's physical characteristics (weight, compliance, inertia, surface smoothness, slippage, temperature, etc.) to be displayed. Haptic feedback is also needed when the visual channel is degraded or nonexistent. Current commercial haptic feedback interfaces suffer from large weight, small workspace, and large costs. Additionally, modeling physical interactions is complex and computationally intensive, which normally requires a multiprocessor host computer. The forces applied by the computer through the haptic interface are real, which makes user's safety a concern (see chap. 41, this volume).

3.1 Multimodal Feedback Integration

Each type of feedback interface mentioned above is the subject of other chapters in this handbook (see chaps. 3–6). By contrast, the focus here is on the integration of the separate feedback modalities, including such topics as sensorial redundancy and sensorial transposition. The user's perception of the VE spans the spatiotemporal and physical domains. The spatiotemporal domain refers to the perception of 3-D space and time. The physical domain describes such virtual object properties as weight, compliance, inertia, and surface temperature. The orthogonality of these domains simplifies the analysis of multimodal feedback.

The main aspects of feedback channel interaction are complementarity and modal redundancy. *Complementarity* refers to nonoverlapping information received through separate feedback channels. This allows the VE designer to increase simulation realism by simply adding more feedback modalities. *Modal redundancy* comes from overlapping the same information in the representation domain, fed back to the user through several sensorial channels. The VE designer can use such redundancy to reinforce perception of certain features of a VE as long as coherence constraints are imposed. Maintaining spatiotemporal and physical model coherence requires that feedback modalities be synchronized. Nonsynchronized events or objects affect drastically the VE illusion and reduce the user's participation. Thus it is important to analyze the complementarity and redundancy of the visual, auditory, and haptic feedback modalities.

3.1.1 Visual-Auditory Feedback Interaction

Sound is frequently used in combination with the visual channel because it provides additional simulation cues and increased user interactivity. The acoustic characteristics of virtual objects are their spatial location, temporal properties, timbre pitch intensity, and rhythm. Sounds can be mapped to physical objects or be independent of them. The visual and auditory channels are similar and complementary, as they can both represent spatiotemporal information. However, their spatiotemporal resolution differs. Sound spatial localization of objects is

poor, whereas time accuracy associated with auditory feedback is superior to that of the visual channel. Therefore sound feedback will greatly enhance applications where the user's reaction time is critical.

The overlapping of visual and auditory information on the spatiotemporal domain results in sensorial redundancy as long as the two information flows are synchronized. This augments the perception of both modalities. For example, a graphics scene that has 3-D sound cues that are well mapped to graphical objects appears visually sharper to the user than the same scene without the associated sound. Sound can convey complementary spatial information when the object of interest is not in the field of view or when objects closer to the user occlude more distant ones. In the time domain, sound can provide very precise temporal stamps when needed. Sounds can be used to convey physical properties of objects as well, such as consistency (discriminate between an empty and a full container), weight (a heavy ball sounds different from a light ball bouncing off the floor), and elasticity (vibration of a string is correlated to its pitch). Sound can also act as a gaze direction guide by focusing the user's attention on a certain spatial event in the virtual environment. Three-dimensional sound cues can point the user to an object location (a telephone that rings) or help navigation tasks by suggesting a new direction to be explored. As a consequence of redundancy and complementarity, 3-D sound integrated with the visual display provides a more consistent spatiotemporal representation of a simulated environment.

3.1.2 Visuo-haptic Feedback Interaction

The haptic channel can represent information related to the physical properties of virtual objects in addition to their spatiotemporal ones. Haptics is rarely used for spatial discrimination by itself (except in dark environments). In most cases haptic feedback is combined with information received on the visual channel as a redundant modality. The benefits of such redundancy were mentioned earlier, but a quantitative assessment can only be based on experimental data.

Human factors experiments were conducted by Richard et al. (1994) to assess the benefits of adding haptics to a partially immersive environment in direct manipulation tasks. The experiments studied the influence of haptic feedback on dexterous manipulation of a plastically deformable ball. The performance measure was the amount of ball deformation (which had to be kept less than 10% of the ball radius). Experimental results showed increased spatial resolution (inversely proportional to ball deformation in excess of 10%) for VEs with haptic feedback. When the haptic modality was added to the visual feedback, the spatial resolution increased almost three times. Force resolution can therefore be used to increase spatial resolution when the relationship between space and force can be mentally evaluated by the user (e.g., a linear relationship—Hooke's law). This supports the idea that haptic feedback is an essential ingredient for direct manipulation tasks in virtual environments.

Coherence of spatiotemporal representation should be imposed for tactile and kinesthetic channels. For example, the "roughness" of a surface evaluated through visual inspection should be matched by the rugosity information provided by the tactile feedback interface. Large time lags between the graphics and haptic loops can confuse the user and may result in control instabilities. Information related to the physical properties of VE displayed on the haptic and visual channels needs to be coherent as well. Object surface deformation should be synchronized with force calculation to provide increased immersion in virtual environments. A "soft" ball (small forces applied to the user's finger when squeezing) should also be highly deformable. Virtual walls should resist with very high force when being pushed and should have no visual surface deformation. Plastically deformed objects should present a hysteresis behavior both in shape deformation (their surface shape remains deformed after the interaction) and in the associated force feedback profile produced by the haptic interface. When the deforming phase of such objects ends, the forces applied to the user's hand should drop immediately to zero.

Therefore, physical behavior of objects should be implemented both in graphics and haptics domains, and displayed synchronized to the user.

3.1.3 Haptic Channels Coupling

The haptic feedback channel constitutes a complex coupled system. There is a very tight coupling between its force and touch feedback components. Minsky, Ouh-young, Steele, Brooks, and Behensky (1990) demonstrated that high bandwidth (500–1000 Hz) force feedback displays could be used to render tactile information as well. Their method used the texture surface gradient and real-time physics (spring–damper model) to calculate the forces to be displayed to the user. The simulation integrated a high-bandwidth two-degree of freedom force feedback joystick that rendered various textured surfaces like sandpaper and elastic bumps. This research suggests that haptic displays can be classified as a function of bandwidth: low bandwidth corresponding to force feedback and high bandwidth to tactile feedback.

The benefits of superimposing vibratory feedback over force feedback for manipulation tasks were illustrated in Kotarinis and Howe (1995). This study identified the kind of tasks where high-frequency vibratory feedback is important (inspection, haptic exploration, direct manipulation). Additionally, it explored the use of tactile display for conveying task-related vibratory information. Their results showed that adding vibratory feedback to a force feedback system was very beneficial, resulting in increased performance in manipulation tasks, such as peg-in-hole insertion.

3.2 Sensorial Transposition

Sensorial transposition is the provision of feedback to the user through a different channel than the expected one. Sensorial transposition is typically used to substitute unavailable communication channels required by an application. For example, force feedback required in direct manipulation tasks could be substituted with visual, auditory, or tactile feedback. Sensorial transposition can be “simple,” when one modality is replaced by another, or “complex,” when one modality is substituted by multiple other types of feedback.

Sensorial transposition requires user adaptation. The level of user adaptation needed in the mappings involved in sensorial transpositions varies. Some mappings feel “natural,” whereas others require more training. For easy user adaptation, the mapping should use the strongest representation domains (visual → spatial domain, auditory → temporal, tactile → temporal, etc.) of the transposed channel. Several examples of sensorial transposition and corresponding mapping domains are shown in Table 21.2.

TABLE 21.2
Examples of Sensorial Substitution Schemes.

<i>Initial Channel</i>	<i>Input Domain</i>	<i>Transposed Channel</i>	<i>Mapping Domain</i>
Visual	Spatial	Tactile	Spatial
Auditory	Temporal (frequency)	Tactile	Sensorial intensity
Force feedback	Sensorial intensity	Auditory	Temporal (frequency)
Force feedback	Sensorial intensity	Auditory, tactile	Temporal (frequency), Sensorial intensity
Force feedback	Sensorial intensity	Auditory, tactile, visual	Temporal (frequency), Sensorial intensity, spatial
Force feedback	Sensorial intensity	Auditory, tactile	Temporal, spatial

Sensorial transposition schemes can also provide *sensorial redundancy* in virtual environments. The same feedback information is mapped through a different channel in addition to the one normally used to communicate that type of feedback. This is done in order to reinforce the original message and can be used to increase user performance in complex tasks.

When using sensorial substitution to obtain redundancy, the substitution scheme should be chosen carefully in order to avoid sensorial contradictions or sensorial overload. Otherwise, instead of reinforcing the original signal, such a method may confuse the user and induce reaction delays as the user copes with unexpected sources of information. User sensorial overload resulting from too much feedback data may also decrease human performance in virtual environments.

Research on human psychology has produced several studies describing sensorial transposition effects (Kaczmarek & Bach-y-Rita, 1995). The VE literature focuses mostly on sensorial transposition and redundant feedback effects related to the haptics channel (Fukui & Shimojo, 1992; Massimo & Sheridan, 1993; Richard et al., 1994). This was motivated by the limitations in current haptic feedback devices, which are difficult and expensive to use. The tactile channel was used in many sensorial substitution schemes to display visual and auditory feedback information. For example, tactile-auditory substitution remaps of the frequency analysis performed by the ear to intensities of electrotactile stimulation of the skin have been used and are intended to be suitable for the hearing impaired. Such a system was used to discriminate phonemes by lip reading (Kaczmarek & Bach-y-Rita, 1995). The resolution of the electrotactile stimulus was much lower than the frequency discrimination capability of the ear. Therefore the approach was not beneficial in the discrimination of connected text, making it difficult to develop high-performance systems.

Kaczmarek and Bach-y-Rita (1995) also cite another sensorial transposition scheme, namely tactile substitution of visual data. This is based on mapping to the tactile display of spatiotemporal information normally received through the visual channel. The mapping represented pixel intensity as vibrotactile and electro-tactile pulse width and amplitude. Two-dimensional images (patterns of lines) were “projected” on the skin rather than on the retina. With practice, users were able to identify more complicated objects, such as faces. However, the limited spatial resolution and narrow dynamic range of the tactile display prevented the rendering of complex scenes.

Another tactile-visual sensorial transposition is described in Fritz and Barner (1996). Here proprioceptive information was combined with the tactile feedback produced by a PHANTOM interface to substitute for visual information. Finger position information provided by the device was coupled with a haptic rendering to display textures in 3-D, as shown in Fig. 21.5. A stochastic modeling technique was used to generate random texture patterns in order to spatially display text data. High-resolution position detection, as well as the resolution of randomly generated haptic textures (256 for this application), were key in supporting a pattern discrimination task.

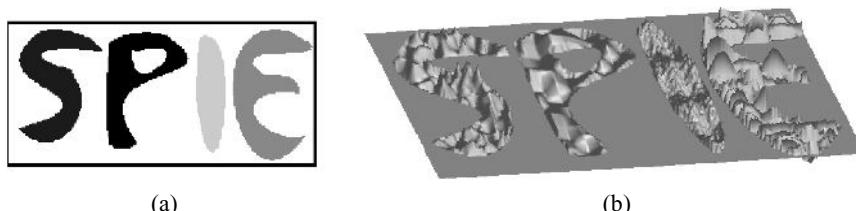

FIG. 21.5. (a) Original 2D image; (b) spatial textured pattern (Fritz & Barner, 1996). © SPIE. Reprinted by permission.

Redundant tactile feedback to reinforce the visual channel was described in Bouzit and Burdea (1998). The tactile feedback was used to increase pilot performance and reduce spatial disorientation when the visual feedback data was degraded. Airplane attitude orientation was mapped to pressure applied by pairs of air bellows on an elbow joint to resist flexion and extension movements. Tactile feedback was selected instead of force feedback due to its quicker response and unobtrusiveness of the interface. When asked to track a random attitude trajectory with degraded visual feedback, the user registered a 27.4-degree error without tactile feedback. When the tactile feedback was added to the simulation, performance increased threefold (error decreased to 8.9 degrees). This underscores the advantage of tapping into the underutilized haptic channel to convey spatial information when the visual channel is saturated. A similar example is the tactile mapping of aircraft instrumentation on pilot's torso using a tactile feedback vest under research at the Naval Aerospace Medical Research Laboratory (NAMRL, 1999).

Another area where sensorial substitution was shown to be beneficial is teleoperation with long time delays. Under such conditions the force feedback system that normally is beneficial becomes detrimental and may lead to system instabilities. Massimo and Sheridan (1993) studied the efficacy of using tactile and auditory substitution of the delayed teleoperation force feedback signal. Their experimental setup consisted of master and slave robotic manipulators, visual feedback of the remote site and additional tactile, and auditory feedback. In force-auditory feedback substitution, the intensity of the sound mapped the force magnitude. In force-vibrotactile feedback substitution, the vibration amplitude was proportional to the magnitude of force feedback. The experimental data for contact detection (taps) is illustrated in Fig. 21.6. Sensorial substitution schemes outperformed the visual display (worst) and the force feedback scheme. This experiment showed that for remote manipulation tasks the user could take advantage of the fast human response to auditory and tactile stimuli to reduce reaction time. In the second experiment, a peg-in-hole insertion task was executed with either zero or very large visual time delay. The auditory channel was used this time to convey spatial information in addition to force magnitude. Collisions with the left or right side of the hole were conveyed to the corresponding ear. Tactile mapping was similarly enhanced to display spatial information on the lower and upper part of the palm. Results showed that sensory substitution schemes allowed decreased manipulation time when no time delay was present. Auditory and vibratory substitution of forces could function independent of visual information and insure task completion for as much as 3 seconds time delay. Under such large time delay, sensorial substitution allowed teleoperation, which would otherwise have been impossible to perform.

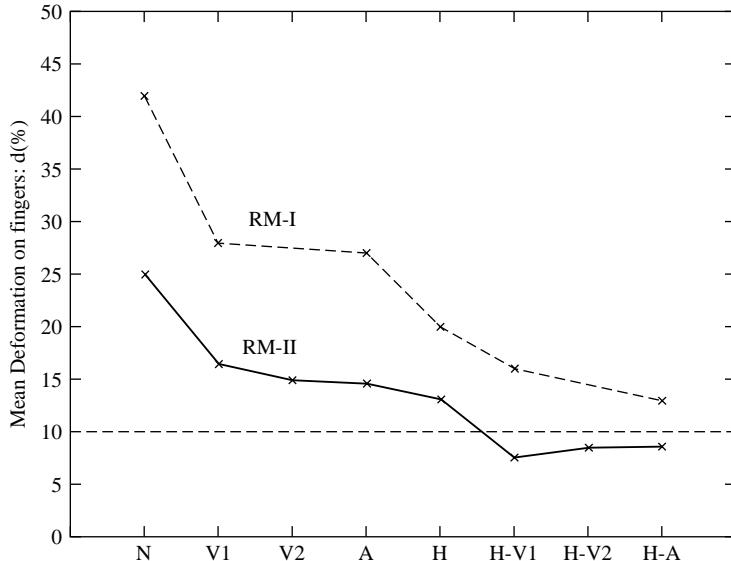

FIG. 21.7. Ball deformation for different force feedback modalities: N—graphics only; V—visual; A—auditory; H—haptic. The target was 10% deformation. Reprinted by permission from Fabiani et al. (1996). © 1996 IEEE.

Richard, Burdea, Gomez, and Coiffet (1994) and later Fabiani, Burdea, Langrana, and Gomez (1996) studied the influence of sensorial substitution and sensorial redundancy in a task involving dexterous virtual object manipulation. The experiment required the user to pick and place a plastically deformable virtual ball, as previously discussed. The substitution of force feedback through visual feedback used LED bargraphs (group V1) or bargraphs overimposed on the VE scene (V2). These were proportional with the contact forces that should have been applied to the user's fingertips by the Rutgers Master I glove. Ball deformation was also mapped on the auditory channel proportional to sound intensity (group A). Experimental results showed that redundant feedback (haptics H + another modality) provided through different mapping methods increased user performance (groups H-V and H-A; see Fig. 21.7). In the absence of sensorial redundancy, force feedback was better than methods using sensorial substitution approaches. Users were able to quickly adapt to the additional mappings available (LED and auditory) and use these successfully during the dexterous manipulation task. The overall relative performance structure remained the same in subsequent experiments with an improved haptic glove (RMII). However, absolute performance in each category improved due to the larger work envelope and dynamic range of RMII versus the older RMI.

3.3 I/O Channel Coupling

The above discussion treated multimodal input separate from multimodal feedback for ease of understanding. In reality, the human input and output systems are coupled. This was illustrated in Fig. 21.1 by the dashed line that closes the feedback loop “internally” as opposed to going through the simulator. The VE designer should not overlook this dependency.

Visuo-motor coupling is a well-known example: data from head-position trackers are used to compute the stereoscopic display images in immersive virtual environments. Gaze tracking can be used to further improve the design of visual displays. The resolution of displayed images can be decreased as pixels get further away from gaze direction because the resolution of the retina decreases toward the periphery of field of view (the so-called foveating effect). Head

orientation influences hearing, as described in the binaural model. Additional dynamic effects (acceleration, speed) should also be considered when the user moves in the virtual environment (Cohen & Wenzel, 1995).

The strongest form of integrated perception/control occurs in haptic perception. In direct manipulation tasks, tactile feedback is accompanied by muscle stimulation (force feedback). In order to increase immersion, tactile interfaces need to include force reflection devices. Otherwise the functionality of the tactual display is limited to a simple signaling mechanism (events in the VE can be associated with tactile feedback response). An example involving tactile, force feedback, and user control is grasping. An accurate model of object grasping in VE should include haptic feedback information in the hand-motion control loop. Otherwise the grasping is artificial (objects snap to the palm and force feedback is applied suddenly) and may result in control instabilities.

Hand–eye coordination is important in direct manipulation tasks. The mapping of the user's hand to a virtual hand depends on the position and orientation accuracy of the wrist tracking system. Misalignments between virtual and real hands (provided by the user's proprioceptive system) are resolved through users' adaptation mechanism (Groen & Werkhoven, 1998), but aftereffects can be observed (see chaps. 37–39, this volume). In addition to mapping, hand–eye coordination is influenced by the response time of the system. Early studies have shown that delay of hand movement in response to visual changes takes several hundred milliseconds. This limits the minimum refresh rate of the graphic scene (see chap. 3, this volume) required for preserving the same order of magnitude for the response time for hand–eye coordination in virtual environments.

Other forms of coordination are mentioned in (Burdea & Coiffet, 1994). Hand–hand coordination has three forms: coordination between hand sensing and hand force feedback; coordination between hand input and force feedback to other parts of the body; and two hand manipulation. The delay between sensing and feedback should be less than 100 msec in order to maintain coordination. Two-hand manipulation requires hand–hand coordination; one hand has a leading role while the other is playing an assisting role. Time delays between hand-relative movement, as well as hand misalignment, are important factors of two-hand coordination. The above discussion on hand–hand coordination applies to other parts of the body involving sensing and feedback.

Another important aspect of VE simulation is hand–ear coordination. This coordination depends on hand movement time delay in response to a sound event and on 3-D localization of the sound relative to hand position. Voice-ear and voice-eye are less important coordination modalities for a simulation. Voice synthesis is sometimes used to give feedback to users in response to their verbal commands. The lag between command and feedback is on the order of seconds. Changes in the visual feedback as result of a voice command have a response time of the same order of magnitude (seconds).

3.4 Summary of Multimodal Feedback

Looking again at Fig. 21.1 depicting the VE simulation loop, one realizes that multimodal feedback is key to simulation realism, and eventually to application usefulness. Multimodal feedback allows users immersed in a VE to not only see the graphics scene, but also to hear or feel virtual objects, in case such objects are manipulated. Multimodal feedback thus involves graphics, 3-D sound, and haptic (touch and force) feedback. These modalities can be used simultaneously to transmit modality-specific data independent of each other. Alternately, one feedback modality can be used to transmit data from another channel in a sensorial substitution arrangement. Such sensorial substitution may be needed when interfaces for another modality are expensive or difficult to use. Finally, several modalities can be used to convey a single event/data, such as contact between objects transmitted visually, through sound as well as haptically. Such sensorial

redundancy is beneficial in overcoming interface limitations (friction, limited dynamic range, etc.) but requires good synchronization of the redundant sensorial data. Otherwise sensorial feedback redundancy can become detrimental to the simulation. Human sensing and control are coupled such that the feedback loop has an internal component as well. This coupling involves hand–eye coordination, the proprioception component of the haptic loop, hand–hand and hand–ear coordination. Such coupling is another reason why synchronization of modalities and reduction in overall time delays are key to effective VE system design.

4. CONCLUSIONS AND FUTURE DIRECTIONS

The human–VE interface can be modeled as a bidirectional pathway containing perceptual as well as control processes. These processes are not independent, but interact with each other following complex models. These interactions manifest themselves through sensorial substitution and I/O coupling effects. Design of human–VE interfaces need not be limited to the use of a single input and/or output modality, but should exploit multimodal input and feedback.

Gesture and voice are the most popular inputs in VE, but they are typically not used together. Voice input is unreliable when using a large vocabulary. Multimodality allows erroneous speech recognition to be screened out and ambiguous gestures to be resolved, increasing application control and naturalness of human–machine dialogue. The increasing demand for interactivity and immersion (see chap. 40, this volume) will drive further development of multimodal input for human–VE interfaces. More experimental work is necessary to understand speech–gesture interaction. The studies should lead to guidelines for more efficient implementation of VE control.

Users' sensorial experience in a VE is a fusion of information received through the human perception channels (visual, auditory, somatic, etc.). While feedback in a VE is provided to users predominantly through the visual channel, additional modalities can increase the efficiency of VE simulations. Three-dimensional sound and haptic feedback increase the sense of presence in a VE with additional spatiotemporal and physical information. User immersion in a VE simulation results from rich sensorial interaction coupled with real-time simulation response. Multimodal feedback is not just the sum of visual, auditory, and somatic feedback, because there is redundancy and transposition in the human sensorial processes. Thus, to increase immersion and interactivity, VE designers can exploit sensorial redundancy and sensorial transposition effects.

Looking at the future, it is clear that the present state of multimodal interaction is rudimentary. Too few channels are tapped, and those that are are not fully utilized. Smell and taste are two feedback modalities that are currently missing. Large-volume simulations pose additional challenges to system designers, because sensing needs to be done at larger distances, and feedback interfaces need to be powerful, yet light and portable. New technologies are thus needed not only for user's multimodal input but also for multimodal feedback. The current human factors effort to quantify the usability of multimodal VEs (see chap. 34, this volume) needs to be accelerated and its scope broadened to cover the needs of large-volume virtual environments. On the theoretical front, more complex models of an intrinsically more complex system need to be developed. Such models will eventually lead to design guidelines and make system optimization efforts easier to undertake.

5. ACKNOWLEDGMENTS

1. INTRODUCTION

What are the fidelity requirements of a virtual environment (VE)? First and foremost (and sometimes neglected), the intended outcomes of the particular application ought to drive the fidelity requirements. System developers must not assume that the best possible fidelity is always needed. The particular application, overall sensory perception, and creative use of stimuli ought to drive fidelity requirements. For example, the visual fidelity of a VE intended to train surgeons in open-heart surgery probably needs to be greater than the visual fidelity of a VE intended to teach children how to read. Another consideration is that of the human sensory system: Fidelity requirements of VEs need not exceed that of the human perceptual system. Durlach and Mavor (1995) point out that any display resolution beyond the ability of human perception is wasteful. Barfield, Hendrix, Bjorneseth, Kaczmarek, and Lotens (1995) give a detailed description regarding humans' ability to detect and discriminate visual, auditory, tactile, and kinesthetic information along with corresponding technical specifications of VE equipment and emphasize the importance of using knowledge of human's sensory systems capabilities and limitations to direct the design of virtual worlds. But one must be careful not to evaluate a simulation or VE solely by the auditory, visual, and haptic technical rendering capabilities of the system. Virtual environment evaluation should be based on the degree to which auditory, visual, and haptic sensory modalities of the immersed participant, that is, an engaged human, are stimulated. Blattner and Glinert (1996) point out that we sometimes fail to appreciate the distinction between human and computer modalities. One factor in considering auditory and visual fidelity requirements is that of display resolution. In a VE, the auditory and visual resolutions ought to be properly matched. For example, Laurel (1993) mentions that designers would not want to couple simple visual displays such as cartoons with very realistic auditory displays such as environmental sounds, and likewise would not want to couple very-high-resolution visual animations with simple auditory beeps.

The National Research Council (NRC) Virtual Reality Research and Development Committee (Durlach & Mavor, 1995) recognizes that visual fidelity requirements are influenced by other modalities. They suggest that a greater understanding is needed in multimodal integration to determine how required visual display system parameters are affected by multimodal interaction, whether or not visual display system requirements can be relaxed during such interaction, and to determine the perceptual effects associated with merging multimodal display sources. Virtual environment system development must thus focus on multimodalities. This focus on the modalities need not only concentrate on the intrarelationships but also on the interrelationships. The NRC explains that study of both intrasensory and intersensory illusions is important because these illusions could help to develop more simplified and cost-effective virtual environments. Under the category of Psychological Considerations, the NRC recommends further study on visual dominance over audition and haptics (e.g. the ventriloquism effect) and how the auditory channel can be used to improve perception within visual and haptic domains. Since the technology to render very-high-quality auditory and visual displays is currently available, proper use of this technology must not neglect potential auditory and visual cross-modal perception phenomena. A goal for the VE community must be to verify and validate the existence and extent of auditory and visual cross-modal perception phenomena and its application to virtual environments. Chapter 21 (this volume) focuses on presentation of multimodal information, whereas this chapter focuses on auditory–visual cross-modal illusions.

2. INTERSENSORY RESEARCH

2.1 Theoretical Perspective

Ryan (1940) conducted a thorough literature survey on sensory interaction and concluded that certain perceptual qualities perceived by one sensory system can be influenced by the qualities of other sensory systems. Ryan also concludes that sensory systems must be considered as part of a whole unified system and not as individualized systems isolated from each other. Ryan ultimately concludes that the study of the interrelations among the senses is severely lacking.

Gilbert (1941) conducted an extensive literature review on intersensory facilitation and inhibition. He concluded that in terms of heteromodal (intersensory) stimulation, a stimulus in one modality can momentarily reduce sensitivity in another modality and after an optimal interval of about 1/2 second can then increase sensitivity in the other modality. Furthermore, a less-intense intersensory stimulation can momentarily increase sensitivity in another modality. Upon reviewing all intersensory research (through 1941), Gilbert, like Ryan, realized that the current view on the psychophysical aspect of intersensory interactions is lacking.

London (1954) presented his findings based on extensive intersensory research conducted in the Soviet Union. Upon review of numerous intersensory experiments, he concluded that the conditions that influence sensory interaction are best summarized as follows: strength, duration, and termination of accessory stimulation; excitatory state of sense organs; affectivity of stimulus; physiological state; diurnal variation; and summation, repetition, and cumulation of accessory effects. In reviewing London's research efforts, Stone and Pangborn (1968) suggested that a stimulus in one sense organ influences to a certain degree the sensitivity of other sense organs. Like Gilbert (1941) and Ryan (1940), Stone and Pangborn ultimately conclude that there is great need for intersensory studies.

Gibson (1966, 1979) suggests that within the natural environment, numerous senses respond to and interact with environmental stimulation. He believes that an organism initiates rather than reacts to certain events. As a result, intersensory perception is the rule of all perception

and not just specialized higher-order complex reactions. In other words, it is the particular surrounding environment that determines how our senses respond and interact. Thus, sensory interaction must be based on the complexity of natural life events and not on simple isolated systems.

Marks (1978) provides a more modern view of sensory interaction. From a simple to a more complex perspective, Marks describes what he calls the Five Doctrines of sensory correspondence. Briefly, these five doctrines are outlined as follows:

1. Doctrine of Equivalent Information: Different senses can inform us about the same features of the external world.
2. Doctrine of Analogous Attributes and Qualities: Despite the salience of the phenomenal differences among qualities of various sense modalities, there are a few properties held in common.
3. Doctrine that Different Senses have Corresponding Psychophysical Properties: This theory proposes that at least some of the ways the senses behave and operate on impinging stimuli are general characteristics of sensory systems, similar from vision to hearing, from touch to olfaction.
4. Doctrine that Similar or Identical Neurophysiological Mechanisms Parallel Sensory Correspondence: This doctrine states that there is a neural analogue to each of the psychological doctrines (the first three doctrines).
5. Doctrine of the Unity of the Senses: This doctrine incorporates the first four, and suggests that several senses are interpreted as modalities of a general, perhaps more primitive sensitivity.

According to various intersensory research, Marks (1978) suggests that the dimension of quality appears to show the fewest similarities from modality to modality, but that intensity displays the strongest cross-modal similarity. Marks' findings indicate that meaningful perceptual interactions occur when concurrent information enters different sensory channels, but when stimuli presented to different senses bear no meaningful relation to each other, interaction often seems to be small or nonexistent. As such, Marks concludes that sensory interaction is highly stimulus dependent. An interesting point by Marks that deserves mentioning is that intersensory similarity must necessarily be one step removed from intrasensory similarity, because if there were truly continuity between modalities then there would be only one sense. Marks concedes that the entire area of sensory quality cross-modality comparisons has hardly been explored experimentally.

Based on her research with blind and normal children, Millar (1981) concludes that the sense modalities are neither separate nor unitary, but rather a combination of both. She believes that the sense modalities complement each other where information is flexibly passed among the different modalities, and that no global generalization can be made about the interrelationships of the sense modalities.

O'Connor and Hermelin (1981), having conducted experiments with children suffering from either specific perceptual or general cognitive handicaps, describe sensory integration through the concept of *sensory capture*. O'Connor and Hermelin found that when conflicting stimuli are presented to different sense modalities, an observer tends to resolve stimuli conflict by making the weaker sense impression conform to the dominant sense impression. As such, the dominant sense captures the weaker sense impression, suggesting that similar stimulus qualities tend to be perceived across various modalities.

Overall, sensory interaction has been studied for many years by researchers in numerous disciplines such as psychoacoustics, psychology, physiology, neurology, philosophy, musicology, ecology, and human-computer interaction, and by different organizations such as the Human

Factors and Ergonomics Society, Audio Engineering Society, Acoustical Society of America, Department of Defense, artistic community, and also the film and entertainment industry. Thus, there is a large amount of intersensory research, but this knowledge is often kept within the discipline from which it was derived. Consequently, there is little cross-disciplinary transfer of intersensory knowledge. Computer science in particular, having a significantly large number of VE developers, is severely lacking in its knowledge and use of intersensory phenomena.

2.2 Neurological Perspective

Stein and Meredith (1993) argue that limited research has focused on developing an understanding of the neural phenomena that make multisensory integration possible. Nevertheless, there has been a fair amount of research confirming locations within the brain where different input modalities converge, facilitating multisensory integration. One such place in the brain where visual, auditory, and somatosensory inputs converge is in the superior colliculus. In looking at the horizontal and vertical meridians of different sensory representations in the superior colliculus, one can see a similar common coordinate system. Stein and Meredith (1993) conclude that this common coordinate system suggests a representation of *multisensory space*. By examining the neurological responses of superior colliculus in various animals, primarily the cat, considerable evidence was found that supports the principles of multisensory convergence and interaction based on single-neuron-evoked potentials. Stein and Meredith (1993) suggest that neurological studies in other animals are very important and lead to a better understanding of human perception. Thus, based primarily on neurological studies of other animals, primarily cats, Stein and Meredith (1993, p. 172) outline rules in terms of space and time governing multisensory integration based on unimodal receptive field characteristics and conclude that “the spatial register among the receptive fields of multisensory neurons and their temporal response properties provide a neural substrate for enhancing responses to stimuli that covary in space and time and for degrading responses that are not spatially and temporally related.”

Although they found considerable evidence supporting a neurological basis for sensory integration, they conclude that numerous challenges must be met before a better understanding of sensory integration is achieved.

One such challenge is gaining a better understanding of synesthesia. Cytowic (1989, p. 1) an expert in the study of synesthesia, defines synesthesia as “an involuntary joining in which the real information of one sense is accompanied by a perception in another sense. In addition to being involuntary, this additional perception is regarded by the synesthete as real, often outside the body, instead of imagined in the mind’s eye.”

The concept of synesthesia dates back over 200 years. (See Baron-Cohen and Harrison [1996] for an exhaustive survey of all classic and contemporary synesthesia literature dating back over the last 200 years.) It is estimated that synesthesia occurs in about one in 25,000 individuals (Cytowic, 1995). One of the most common forms of synesthesia is that of colored hearing. A synesthete experiences colored hearing when certain sounds (physical stimuli) evoke perceptions of various colors. For example, when listening to certain classical music, a synesthete might experience shades of blue and/or green. The validity of synesthesia, though, has suffered over the years for it is introspective in nature. However, Cytowic (1989, p. 176) has helped to validate synesthesia by examining the neural substrates of synesthesia and concludes that “The synesthetic experience may be a result of a fundamentally mammalian process in which the cortex briefly ceases to function in the modern manner, permitting the senses to fuse, or, rather, we should say, perceive fusion that may be there all along but that never arises to consciousness.”

3. AUDITORY-VISUAL SENSORY INTERACTION

3.1 Auditory Scene Analysis

In terms of auditory–visual interaction, Bregman (1990) states that there are many similarities between visual and auditory perceptual groupings. He believes that the auditory and visual modalities seem to interact in order to specify the nature of certain events within a perceiver’s environment. As opposed to the Gestalt point of view, which focuses on the similarities among modalities, Bregman presents an interesting ecological point of view focusing on differences of the modalities. One such difference between vision and audition is evidenced through the use of echoes. In audition, perceivers are mainly interested in the direct source of sound rather than its echoes, but they can also combine direct sound and indirect sound (echoes) to establish a mixed sound that still conveys information of the direct sound but with the additional properties (i.e. reverberation) of the indirect sound. However, with vision, perceivers are mainly concerned with the indirect image (echoes or reflections), and they are not able to combine direct and indirect images to establish a mixed visual image. Bregman (1990, p. 38) suggests that it is these ecological differences that might cause “apparent violations of the principle of exclusive allocation of sensory evidence.”

3.2 The Entertainment Industry

For many years, the entertainment industry has realized the important relationship between visuals and sound. Even before sound was an integral part of film, silent movies were accompanied with specific music to enhance the mood of certain scenes. As Gary Rydstrom (1994, p. 5), of Skywalker Sound, explains, “When approached creatively, the combination of sound and image can bring something to vivid life, clarify the intent of the work, and make the whole experience more memorable.”

Realizing this important relationship between visuals and sound in film, Lipscomb (1990) and Lipscomb and Kendall (1994) investigated the perceptual judgment of the relationship between musical and visual components in film. In their experiments, they took various motion picture sequences and manipulated their soundtracks. The motion picture sequence containing the original soundtrack along with the motion picture sequence containing various manipulated soundtracks were presented to participants. The task of the participants was to select the soundtrack that best fit the visuals of the film. Interestingly, the results indicated that the composer-intended musical score (the original score) was identified as the best fit by the majority of participants for all conditions. In a related experiment, they also found significant results strongly suggesting that a musical soundtrack can in fact change the perceived meaning of a film presentation.

3.3 Cross-modal Matching

Cross-modal matching is using information obtained through one sensory modality to make a judgment about an equivalent stimulus from another modality. Marks (1974, 1978, 1982, 1987, & 1989) and Marks, Szczesiul, and Ohlott (1986) have been studying auditory–visual cross-modal matching over the last 25 years. He has conducted several experiments, which suggest a strong auditory–visual cross-modal matching among brightness, pitch, and loudness. Marks (1974) had study participants match pure tones to the brightness of gray surfaces. Results indicated that most participants matched increasing auditory pitch to increasing visual brightness, and Marks concluded that the findings mimicked that of synesthesia. Marks (1982) conducted a series of four experiments in which subjects used scales of loudness, pitch, and

brightness to evaluate the meanings of various auditory–visual synesthetic metaphors such as: sound of sunset, murmur of dawn, and bright whisper, to name a few. He found that loudness and pitch expressed themselves metaphorically as greater brightness, and likewise that brightness expressed itself metaphorically as greater loudness and as higher pitch. This series of experiments led Marks (1982, p. 177) to believe that: “The ways that people evaluate synesthetic metaphors emulate the characteristics of synesthetic perception, thereby suggesting that synesthesia in perception and synesthesia in language both may emulate from the same source—from a phenomenological similarity in the makeup of sensory experiences of different modalities.”

Marks has also conducted experiments involving auditory–visual cross-modal perception of intensity (Marks et al., 1986), auditory–visual cross-modal similarities in *speeded discrimination* (Marks, 1987), and additional experiments concerning auditory–visual cross-modal similarities with pitch, loudness, and brightness (Marks, 1989). The results of these experiments are similar to his earlier ones and provide more evidence to support strong auditory–visual cross-modal matching among pitch, loudness, and brightness. In terms of cross-modal matching, one might conclude from Marks’ findings that our senses are indeed influenced by one another.

3.4 Visual Dominance

3.4.1 Ventriloquism Effect

A well-known auditory–visual intersensory phenomenon is that of the *ventriloquism effect* (see Howard & Templeton, 1966). As the name implies, this phenomenon refers to the illusion created by a skilled ventriloquist when one thinks they hear the dummy talking when in fact they are actually hearing the altered voice of the ventriloquist. Not only does one perceive the dummy as talking, but they also actually think the sounds of the dummy are emanating from the dummy’s mouth and not from the ventriloquist even though they know that the dummy cannot really talk. This effect demonstrates the strong spatial coupling that occurs between the auditory and visual senses, and as a result has been the topic of much research (see Bermant & Welch, 1976; Howard & Templeton, 1966; Pick, Warren, & Hay, 1969; Radeau & Bertelson, 1976; Ragot, Cave, & Fano, 1988; Stein & Meredith, 1993; Warren, Welch, & McCarthy, 1981). One reason why the ventriloquism effect occurs is that the visual sense is usually the dominant sense. Unless there are significant differences in the intensities of the information gathered via different modalities, visual stimuli has a greater influence on perception via other modalities as compared to the influence of other modalities on the visual sense (Stein & Meredith, 1993). Visual dominance is also explained by Wickens (1992, p. 108) who states that “if visual stimuli are appearing at the same frequency and providing information of the same general type or importance as auditory or proprioceptive stimuli, biases toward the visual source at the expense of the other two [auditory and proprioceptive] will be expected.”

3.4.2 Experimental Results Supporting the Ventriloquism Effect

Radeau and Bertelson (1976) conducted an experiment on the effect of a textured visual field on modality dominance during the ventriloquism effect and concluded that visual texture affects the degree of auditory capture of vision, but not the degree of visual capture of audition. Bermant and Welch (1976) investigated the effect of degree of separation of an audiovisual stimulus and eye position on the spatial interaction of the ventriloquism effect and found that the ventriloquism effect is not dependent on the use of a visual source typically associated with the production of sounds. The role of auditory–visual *compellingness* in the ventriloquism effect was studied by Warren et al. (1981) where it was found that given a highly compelling

stimulus situation, subjects showed a very high visual bias of audition, a significant auditory bias of vision, and a sum of bias effects indicating that subjects perceived a single perceptual event. Ragot et al. (1988) explored auditory and visual ventriloquism reciprocal effects and suggest that visual dominance appears when attention is divided between visual and auditory modalities, but seems to be absent when the subjects are asked to attend to one modality in the presence of another modality. Knudsen and Brainard (1995) present neurological evidence from studying the optic tectum (also referred to as the superior colliculus), indicating that bimodal tectal neurons are more sensitive to displacements of a visual stimulus than to displacements of an auditory stimulus. Thus, in regard to visual dominance over audition with respect to the ventriloquism effect, Knudsen and Brainard conclude that the location in the bimodal tectal map activated by visual and auditory stimuli may be more sensitive to the location of the visual stimulus than to the location of the auditory stimulus.

3.4.3 Divided Attention

During signal detection (temporal in nature and typically associated with sustained attention or vigilance), the auditory channel proves dominant over the visual channel, which is why warning signals are typically produced with auditory devices. However, in most other areas, human's visual sense dominates the hearing sense, as can be seen from the following experimental findings.

As part of a U.S. Air Force research investigation, Henneman and Long (1954, p. 13) released an extensive technical report comparing visual and auditory senses as channels for data presentation during cockpit crew coordination suggesting that "when a person is required to divide his attention or to shift back and forth between two tasks, one visually controlled, the other aurally controlled, either task can be made a "priority" task at the expense of the other. Sense channel as such does not determine this priority."

Henneman and Long (1954) indicate there has been very little experimental evidence comparing audition and vision as channels for data presentation and concludes that most auditory–visual intersensory studies have focused on sensory thresholds as opposed to suprathreshold levels that typify actual perceptual phenomena. Henneman et al. ultimately suggest that it might not be possible to make any reliable conclusions concerning perceptual phenomena from comparing auditory and visual perceptual judgments.

Colavita (1974) describes a series of experiments exploring *sensory dominance* in which participants responded to suprathreshold auditory and visual stimuli. The auditory stimuli consisted of tones, and the visual stimuli consisted of light flashes. The stimuli were randomly presented as auditory only, visual only, and combined auditory–visual. The participant's task was to identify which stimuli occurred. When participants were presented with the combined auditory–visual stimuli, the participants typically only responded that a visual light flash occurred and usually did not even notice that an auditory stimulus (tone) was present. Thus, in this task, the findings suggest visual dominance over the auditory sense.

In a study investigating the perceived duration of auditory and visual intervals, Behar and Bevan (1974) found that auditory intervals (white noise) were consistently judged to be about 20% longer than visual intervals (light from a neon glow-lamp) of the same duration. Behar and Bevan conclude that there are peripheral variables that must not be ignored when making psychophysical judgments.

Burrows and Solomon (1975) conducted an experiment investigating the ability to scan auditory and visual information in parallel. Participants were presented with pairs of letters, one being a visually presented letter and the other being an aurally presented letter. The pairs of letters were presented simultaneously or sequentially. The participants' efficiency of memory retrieval was measured in both conditions: (1) simultaneously presented letters or

(2) sequentially presented letters. The results indicated that parallel scanning is possible with a simultaneous presentation because of the continuous information from both auditory and visual stimuli, but it is not possible with sequential presentation because of the “dead time” needed to switch between modalities.

Egthe and Sager (1977) explored the locus of visual dominance over audition in which participants responded to suprathreshold stimuli consisting of an audio-only tone, a visual-only light flash, and a combined auditory-visual tone-light flash. Their findings suggest that perceptual judgment of the auditory tone is not affected by the light flash because visual dominance is nonsensory in locus and depends on the relevance of the associated visual stimulus.

Jones and Kabanoff (1975) conducted an experiment to determine if eye movements are a factor in auditory localization. They found that auditory localization accuracy is increased if participants move their eyes in the direction of the intended target. Their findings suggest that voluntary eye movement rather than a visual map is likely to provide an adequate framework for making spatial judgments (see chap. 24, this volume).

McGurk and MacDonald (1976) investigated the effect of seeing certain lip movements associated with hearing contradictory speech sounds. Participants were presented auditory-only speech sounds and mismatched auditory-visual (speech-lip movement) combinations. Their results were remarkable. During the combined auditory-visual mismatches, most participants were convinced they were hearing what they were seeing (lip movements), when in fact the lip movements were not the correct lip movements for the associated speech sound that they were hearing. Furthermore, even if one has prior knowledge of the auditory-visual mismatches, it does not preclude one from being convinced (incorrectly) they were hearing what they were seeing. The results of this experiment were so strong that it is commonly referred to as the *McGurk effect*. Interestingly, Stein and Meredith (1993) found that the visual cues of lip movement can actually modify auditory cortex activity to the extent of altering the signal-to-noise ratio of the auditory stimulus by 15 to 20 decibels.

Rosenblum and Fowler (1991) investigated if loudness judgments of speech are more closely related to the visual degree of exerted vocal effort than to the actual emitted acoustical properties of intensity. As in the McGurk effect, participants were presented conflicting audiovisual stimuli. Their findings suggest that when making loudness judgments of speech, the visual cues of vocal effort significantly outweigh the cues provided by the appropriate levels of acoustic intensity.

Hanson (1981) conducted an experiment to investigate if common processing of semantic, phonological, and physical systems were involved during reading and listening. Participants were simultaneously presented two words, one visually and one aurally, but were instructed to attend to only one modality and to make responses based on that attended modality. The results indicated that the unattended words had an influence on semantic and phonological decisions but had no influence on the physical task. (In the physical task, the visual words were presented in either small or capital letters, and the aural words were presented in either a male or female voice.) Hanson (1981, p. 99) concludes that the written and spoken words “share semantic and phonological processing but have separate modality-specific codes that operate on information prior to the convergence of information from visual and auditory inputs.”

3.4.4 Haptic Perception of Stiffness

A lesser-known area in which the visual sense can dominate is that of haptic perception. Because of technological constraints, it has not been feasible to adequately study haptic perception. However, recent technological advances have spurred significant new and exciting research into haptic perception (see chaps. 5 and 6, this volume). Srinivasan and Basdogan

(1997) outline recent advances and future challenges in haptic display technology. In terms of haptic perception of stiffness, Srinivasan, Beauregard, and Brock (1996) demonstrate the effect of visual dominance on haptic perception. In this experiment, participants had to discriminate the stiffness of two virtual springs. The two virtual springs were depicted visually on a computer monitor and force-feedback was rendered haptically via a Planar Grasper. The participants were presented randomized visual-haptic stiffness stimuli resulting in consistent (correct) and inconsistent (incorrect) visual–haptic stiffness stimuli pairings. The results indicated that the perception of stiffness is greatly influenced by visual information. Specifically, when the visual stiffness stimuli conflicted with the haptic stiffness stimuli, participants relied on the visual stimuli to make judgments about the stiffness of the virtual spring. A counter example, that of haptic dominance, was provided by Proffitt and Kaiser (1995). They asked participants to estimate the incline of a hill while viewing it. The participants were asked to make their estimates verbally, visually (using a handheld modified compass to approximate the angle) or haptically (placing their hands on a board and moving the board until its position approximated the angle). The input of the “feel” of the angle in the haptic condition supplemented viewing to achieve the best estimates. These experiments are examples of how human senses involuntarily meld together forming an overall perception of the environment.

3.5 Threshold Perception Experiments

3.5.1 Overview

The body of evidence presented thus far clearly indicates that under certain conditions, auditory–visual perceptual phenomena do exist. However, most auditory–visual research has focused on threshold levels, absolute sensitivity, or just noticeable differences. As mentioned earlier, Gilbert (1941) and Ryan (1940) independently conducted exhaustive literature surveys covering these topics. Additional evidence supporting auditory–visual perceptual phenomena from threshold level stimuli can be found in the following references: Serrat and Karwoski (1935), Pratt (1936), London (1954), Thomas, Voss, and Brogden (1958); and Loveless, Brebner, and Hamilton (1970). For a better understanding of this type of threshold-level perception research, the findings of two experiments are presented showing auditory–visual perceptual phenomena from threshold-level stimuli.

3.5.2 Experimental Results

An example of the research reviewed by Gilbert and Ryan is that of Kravkov (1936), one of the early pioneers in the area of intersensory experimentation. Kravkov’s experiment investigated the influence of sound on light and color sensitivity of the eye. In this experiment, three female participants were presented an auditory stimulus consisting of a 2100 Hz tone at 100 decibels for a duration of about 10 minutes. During these 10 minutes, measurements were made of color and light sensitivity. From the results of the experiment, Kravkov (1936, p. 351) concluded that: “The colour sensibility of the eye changes differently under the influence of sound, according to the wavelength of the stimulating light. . . whereas the colour sensibility for green rises during the acoustic stimulation the colour sensibility for orange-red decreases.”

Gregg and Brogden (1952) conducted an experiment on the effect of simultaneous visual stimulation on absolute auditory sensitivity. In their experiment, participants were presented an auditory tone along with an auxiliary light source. Their results indicate that when participants were asked to report the presence of a visual light source along with an auditory tone, the light stimulus decreased participant sensitivity to a 1000 Hz tone. However, when participants were only required to report the presence of an auditory tone, the light stimulus increased sensitivity to the auditory tone.

3.6 Suprathreshold Perception Experiments

3.6.1 Overview

When one talks about using both audio and visual displays for some kind of simulation, game, or VE, some people will say that the use of high quality sound positively influences their perception of the visual images, but that high-resolution visual images tend not to improve on the perception of sound quality (see Tierney, 1993). Stein and Meredith (1993) theorize that combinations of visual and auditory cues can indeed enhance one another and can also eliminate any ambiguity that may occur when cues are only available from one modality. Likewise, Murch (1973) suggests that under many conditions the encoding of visual-only material or auditory-only material involves the use of short-term storage of both systems. If auditory and visual displays can influence each other, then as Begault (1994) suggests, perhaps sound can be used for improving the perceived quality of visual displays. For example, Negroponte (1995) recounts a story of designing military tank simulators. The tank simulator designers were trying to make the visual display of the tank simulator very realistic by increasing the number of scan lines. As the simulator designers increased the scan lines the cost of the visual display increased. After increasing the number of scan lines resulted in a prohibitive price for the tank simulator, simulator designers decided to take an alternative approach. Instead of focusing on the visual information channel, they focused on the auditory and haptic channels of information. They introduced some tank motor and trend sounds and also added an inexpensive vibrating motion platform. As a result, Negroponte (1995) found that realism was enhanced to the point that designers were able to reduce the number of scan lines.

The empirical evidence supporting just how auditory and visual displays can influence the perception of each other is lacking. One reason for the lack of empirical evidence is that of specifying perceptually relevant dimensions for both auditory and visual modalities (Jones, 1981). Nevertheless, a few experiments have been conducted in which auditory displays influenced the perception of visual displays or visual displays influenced the perception of auditory displays.

3.6.2 Experimental Results

Neuman (1990) and Neuman, Crigler, and Bove (1991) conducted an experiment to measure the effect of changes in audio quality on visual perception on high-definition television (HDTV). The experimental design was to keep the quality of visual stimuli constant while only manipulating auditory stimuli. The auditory conditions were as follows: low fidelity (very low-quality speaker system) versus high fidelity (very-high-quality speaker system); monaural versus stereo; and three types of television programming: sports, situation comedy, and action-adventure. Participants were presented a short video clip along with one of the auditory conditions. The participants were then asked to rate: (1) their liking, (2) their level of interest, (3) their psychological involvement in the programming, (4) picture quality, (and 5) audio quality. Their results indicated that participants had difficulties distinguishing mono from stereo and low-fidelity from high-fidelity sound systems, but overall participants did prefer viewing the video clips when coupled with high-fidelity and stereo sound systems. Perhaps the most interesting finding was that a few participants perceived an increase in visual quality when coupled with better audio even though the visual quality remained constant throughout the experiment. This finding, however, was not statistically significant, and it only occurred in one of the three types of television programming presented.

Iwamiya (1992) investigated the effect of visual information on the impression of sound and the effect of auditory information on the impression of visual images when listening to music via audiovisual media. The factors used to evaluate the impression of both audio and

visual images were: tightness, evaluation, brightness, uniqueness, and cleanliness. Iwamiya suggests that these factors are considered to be the *intermodalities* between auditory and visual processing. Iwamiya found that the factors of brightness, tightness, and cleanliness of the auditory images enhanced the perception of these factors of the visual images. Iwamiya concludes that better matched auditory and visual information will result in an overall higher evaluation of combined auditory and visual impression.

Hollier and Voelcker (1997) conducted an experiment investigating the influence of video quality on audio perception. Thirty-two participants watched video clips 10 seconds in duration with supporting audio (speech) commentaries. In total there were eight video-quality variations and four audio-quality variations. The results indicated that: (1) when no video was present, the perceived audio quality was always worse than if video was present, and (2) although only small differences were noted, a decrease in video quality corresponded to a decrease in perceived audio quality. They ultimately propose an algorithmic approach for the proper development of an auditory–visual cross-modal perceptual model.

Woszczyk, Bech, and Hansen (1995) and Bech, Hansen, and Woszczyk (1995) discuss the design and results of an experimental procedure examining the interaction between the auditory and visual modalities in the context of a home theater system. With the growing interest and development of VE systems, Woszczyk et al. identifies the need for testing the interaction of audio and visual displays in order to bring about substantial improvements in the audiovisual experience of viewers. They suggest that it is important to focus on the total perceptual experience and not on the individual auditory and visual modalities. In their experiments, participants assessed audio-visual reproductions using the subjective dimensions of action, space, mood, and motion while asking specific questions focusing on quality, magnitude, degree of involvement, and audiovisual balance. Quality was defined as: distinctness, clarity, and detail of the impression. One of their findings of particular interest is that both visual- and audio-perceived quality increased with increasing screen size. To further explore auditory–visual interaction, Bech (1997) conducted two more experiments to investigate the influence of stereophonic (audio) width on the perceived quality of an audio-visual presentation using multichannel Surround Sound systems. During the experiments, participants were asked to evaluate the quality (fidelity) of spatial information contained in audiovisual reproductions. The results indicate that the quality of perceived spatial reproduction increases linearly with an increase in stereophonic width.

Recent auditory–visual suprathreshold cross-modal research has been conducted by Storms (1998). In a series of experiments conducted at the Naval Postgraduate School (NPS) in Monterey, California, he found that by varying the quality (fidelity) of both auditory and visual displays it was possible to directly measure auditory–visual cross-modal perception phenomena. The basic idea of the experiments was to manipulate visual and auditory display parameters intramodally and intermodally, and to likewise measure visual and auditory display perception intramodally and intermodally. During the experiments, which each lasted approximately 30 minutes, a single participant wore headphones and sat in front of a 20-inch display monitor. The task of the participant was to rate the perceived quality of audio-only, visual-only, and combined audio-visual displays through Likert rating scales ranging from 1 to 7. The dependent variables were the perception of visual display quality and the perception of auditory display quality. It was hoped that by carefully varying the fidelity of both auditory and visual displays it would be possible to measure auditory–visual cross-modal perception phenomena. Specifically, the goal was to answer the following question: In an audiovisual display, what affect (if any) do various audio-quality levels have on the perception of visual quality and vice versa?

The overall conclusions from Storms' research suggest that (1) whether asked to specifically attend to both auditory and visual modalities or asked to attend to only one modality, (2) whether

TABLE 22.1
Characteristics of Auditory-Visual Suprathreshold Cross-modal Perceptual Evaluation

1. When attending only to the visual modality, a high-quality visual display coupled with either a medium- or high-quality auditory display causes an increase in the perception of visual quality relative to established baseline conditions derived from visual-only quality perception evaluations.
 2. When attending only to the auditory modality, a low-quality auditory display coupled with either a medium- or high-quality visual display causes a decrease in the perception of auditory quality relative to established baseline conditions derived from auditory-only quality perception evaluations.
 3. When attending to both auditory and visual modalities, a high-quality visual display coupled with a low-, medium-, or high-quality auditory display causes an increase in the perception of visual quality relative to established baseline conditions derived from visual-only quality perception evaluations.
-

manipulating visual display pixel resolution or Gaussian noise level, (3) whether manipulating auditory display sampling frequency or Gaussian noise level, or (4) whether an auditory–visual display is tightly or loosely coupled, cross-modal auditory–visual perception phenomena exist. From Storms' (1998) findings a number of characteristics of auditory–visual suprathreshold cross-modal perceptual evaluation have been identified (see Table 22.1).

Storms' results provide the empirical evidence to support what most people in the gaming business, multimedia industry, entertainment industry, and VE community have suspected all along: that audio can influence the quality perception of video and vice versa. The results also indicate that although humans can divide their attention between audition and vision, they are not consciously aware of any potentially significant intermodality effects.

Due to the multidisciplinary nature of Storms' research effort, the impact of the overall findings is far reaching, having both theoretical and commercial implications. In terms of the theoretical impact, because the overall findings indicate that auditory quality can influence visual quality perception and vice versa, some sort of sensory interaction must be taking place. These findings support the early intersensory research conclusions of both Ryan (1940) and Gilbert (1941). Also, O'Connor and Hermelin (1981) would likely argue that these findings support the concept of *sensory capture*. But how this sensory interaction occurs is still not known. Stein et al. (1993) might conclude that this interaction could be taking place at the neurological level. However, Gibson (1966, 1979) might argue that this sensory interaction is based on the complexity of natural life events. Furthermore, one of the overall findings of this research effort suggests that when attending only to the auditory modality, a low-quality auditory display coupled with either a medium- or high-quality visual display causes a decrease in the perception of auditory quality. The reason for degrading the perception of the auditory quality might be based on the concept of visual dominance. Perhaps at some higher cognitive level, the higher quality visual display is being compared with the lower quality auditory display. This unconscious comparison might cause one to perceive that the auditory quality is worse than it actually is because of the dominating nature of the visual modality.

In terms of the commercial impact, Storms' research suggests that when attending to both auditory and visual modalities, a high-quality visual display coupled with a low-, medium-, or high-quality auditory display causes an increase in the overall visual quality perception of an auditory–visual display. Thus, suppose a VE developer has been tasked to increase the realism (and perhaps presence) of a 3-D scene depicting a typical family living room. This virtual living room contains a TV and stereo system that is rendered using high-quality visual graphics. However, the living room scene does not have any associated sounds. Instead of increasing the pixel resolution of the living room scene, causing an unwanted increase in the visual rendering

time of the scene, the VE developer adds high-quality music to the visual display of the stereo system and a motion picture expert group (MPEG) video sequence containing high-quality audio to the visual TV display. As a result, the perceptual visual quality of the scene ought to increase by simply adding the associated auditory displays without the need to manipulate any of the visual displays.

4. FUTURE NEEDS

Given that auditory–visual cross-modal perception phenomena exist, the next logical step is to incorporate these overall findings into some type of useful auditory–visual quantitative perceptual model similar to that proposed by Hollier and Voelcker (1997). This model can then be used to derive appropriate (quantitative) levels of auditory and visual fidelity for use by developers in the gaming business, multimedia industry, entertainment industry, VE community, and the Internet industry. For example, given a certain application, this auditory–visual quantitative perceptual model could help to derive the appropriate levels and specific amounts of visual display pixel resolution and auditory display sampling frequency as a function of visual-only, auditory-only, and/or combined auditory–visual media.

Illusory Self-motion in Virtual Environments

Lawrence J. Hettinger

Logicon Technical Services, Inc.

Harvard, MA 01451

lhettlinger@logicon.com

1. INTRODUCTION

Current virtual environment (VE) systems can often induce compelling illusions of self-motion in users. In many instances, the effects of visually depicted motion in a VE can be strong enough to create an overwhelming sense of actual self-motion in physically stationary observers, along with pronounced postural adjustment and/or a strong sense of disequilibrium and, occasionally, motion sickness. Indeed, the ability to generate realistic sensations of self-motion within VEs might be considered an important element in the overall sense of “presence” (see chap. 40, this volume) imparted by a given system.

In all likelihood, future VE systems will be able to produce stronger and more durable illusions of self-motion. In some cases there may be compelling reasons for doing so, particularly if the attainment of larger human–VE system objectives is thereby aided. (Note: A *human–VE system objective* is defined as the intended, often measurable outcome of the VE system with respect to its human user. For instance, the objective of a VE-based training system is to promote the acquisition of a set of general or well-defined skills in its users. The experience of illusory self-motion, or any other component of presence, may or may not assist in the attainment of overall human–VE system objectives. Indeed, it may in some cases interfere with them [cf. Hettinger & Haas, *in press*.]) In other cases, the benefits of these illusory experiences may be dramatically offset by the occurrence of negative side effects such as motion sickness (see chap. 30, this volume) and persistent perceptual–motor disruptions (see chaps. 37–39, this volume). In any event, rational design and usage decisions will need to be based on knowledge of the factors that promote (or inhibit) the occurrence of these illusions, their specific benefits with respect to the system user, and the potential risks that they entail.

The term *vection* is used to describe a broad class of illusory self-motion phenomena that are primarily induced by dynamic, large field-of-view optic flow patterns (Dichgans & Brandt, 1978; Howard, 1986a), but which have also been noted to occur with relatively small fields of

view (Andersen & Braunstein, 1985; Andersen & Dyer, 1987). Although most commonly a visual phenomenon,vection illusions have also been reported as a result of exposure to specific classes of auditory stimulation ("audiokineticvection"—e.g., Dodge, 1923; Lackner, 1977) and electrical vestibular stimulation (e.g., Cress et al., 1997; Dzendolet, 1963). Dichgans and Brandt (1978) describe a haptic form ofvection ("haptokineticvection") that produces a weak sensation of illusory self-motion induced through tactile motion stimulation of a large part of the body. Systematic examination of each of these nonvisual forms ofvection has been very limited, and they will not be described in any further detail.

This chapter will examine the implications of the considerable experimental literature in this area for the design and use of VE systems. It provides a general summary of the experimental findings from the primary areas of research in this area (e.g., optical flow pattern characteristics of effectivevection displays, neurophysiological correlates ofvection,vection-induced motion sickness and disorientation) and describes their relevance to VE design and usage issues. One of the major concerns of the chapter is to heighten the reader's sensitivity to questions of whether the user's experience ofvection in a given VE system in any way promotes its overall system objectives, under what circumstances and/or within which applications such benefits arise, and at what potential cost to the user's safety and well-being. With regard to the latter point, particular attention will be paid to the literature that has examined the negative side effects that have occasionally been associated with thevection illusion, particularly those involving motion sickness (see chap. 30, this volume) and disrupted perceptual-motor behavior or aftereffects (see chaps. 37–39, this volume).

The above questions are closely related to a major debate that has existed within the VE community almost since its inception, that centering around the potential benefits and costs of "presence" or "telepresence" in VE systems (cf. Held & Durlach, 1992; Slater & Steed, 2000; Zahorik & Jenison, 1998; Zeltzer, 1992). This debate echoes an essentially identical controversy that existed in the flight simulation community for many years, that of the role of "realism" in the design and use of these devices. Although difficult to define and even more so to measure (see chap. 40, this volume), presence and realism are too often assumed to be necessary in order for VE systems to be successful and/or accepted by users. The potential validity of this largely unexamined assumption may vary widely from one application to the next, but it is certain that it entails important cost and design implications for VE systems. In addition, in the case ofvection, it also involves important issues of user safety and well-being.

While this chapter will not examine the notion of presence in depth, we do wish to emphasize thatvection, as a key component of presence, may or may not meaningfully contribute to the system objectives of a human-VE system. It will, however, occasionally have undesired consequences for users. Therefore, it is important to understand the nature of thevection illusion and to approach its inclusion as a VE system design feature with something more than the simplistic assumption that "if it looks and feels real, then it must be good."

The strength and duration of thevection illusion, its role within and effect on the overall design goals of any given VE system, and the nature, strength, and duration of potential negative side effects are all dependent on a variety of factors to be discussed in this chapter. This chapter is intended to provide readers with a basic understanding of these phenomena, the factors that underlie their occurrence, and the degree to which they may help or hinder specific applications of VE technology.

This chapter will not provide an encyclopedic examination of all aspects of thevection illusion, nor will it be a complete and exhaustive review of the considerable experimental literature in the area. For excellent in-depth presentations of these aspects ofvection, readers are referred to Dichgans & Brandt (1978) and Howard (1982, 1986a). This chapter will deal solely with summarizing the research to date onvection phenomena and describe its relevance for the effective design and use of VE systems.

2. GENERAL CHARACTERISTICS OF VECTATION

Actual self-motion through the real world is visually specified by reliable and highly structured transformations in the pattern of optical information—the optic array—that directly correspond to the dynamics of specific forms of self-motion (e.g., running, crawling, driving in a car) through specific types of structured environments (Cutting, 1986; Gibson, 1958, 1961, 1979; Owen, 1990; Warren, 1976). Generally speaking, these patterns of optical transformations take place over a wide field of view (that corresponding to one's normal field of vision), and only occur when one is in fact moving. Therefore, when found in a situation in which large-field optical transformations of the sort that normally accompany and specify actual self-motion are made available, it is not surprising that one experiences a sense of being physically displaced even when in fact stationary.

Virtual environments, particularly those encompassing large visual fields, are particularly well suited to producevection illusions. But how are these illusions produced? What controls their onset, compellingness, and duration? Why do these illusions appear to lead to motion sickness and perceptual-motor disturbances in some individuals? And, most importantly, of what potential benefit (if any) are vection illusions to the larger objectives of individual human-VE systems, and what are their potential costs?

Experimental psychologists and neurophysiologists have studiedvection for well over a century. Mach (1875) was the first to systematically studyvection in the laboratory. Tschermak (1931, cited in Dichgans & Brandt, 1978) appears to have been the first to refer to illusory self-motion as “vection.” Although the empirical investigation of this phenomenon has primarily occurred within traditional laboratory settings using various types of specially designed devices such asvection cylinder “drums” and “moving rooms,” the advent of high-fidelity flight simulation systems in the 1970s and 1980s extended its occurrence, as well as its study, into more “applied” domains (e.g., Frigon & Delorme, 1992; Hettinger, Berbaum, Kennedy, Dunlap, & Nolan, 1990; van der Steen, 2000; More recently, the increased development and use of VE systems for entertainment (see chap. 55, this volume), vehicular simulation (see chap. 42, this volume), and many other applications has produced an even greater incidence ofvection illusions. Indeed, the tremendous popularity of “virtual reality rides” at many of the world’s most popular amusement and entertainment parks is based in large part on the reliable production ofvection in paying customers and has exposed very large segments of the population to its intended effects, and occasionally to its unintended negative side effects.

One of the earliest (and certainly most literary) accounts ofvection is found in a description by Wood (1895) of the “Haunted Swing”—a popular attraction at the 1895 San Francisco Midwinter Fair and clearly a predecessor of today’s VE-based entertainment devices. There is little doubt that the experience of illusory self-motion underlies the exhilarating and, apparently for some, slightly disturbing experience described by Wood. To experience this attraction, fairgoers entered a large room furnished in a more or less normal way, with the exception of a very large swing in the center of the room capable of holding up to 40 people and suspended from a large iron rod that passed through the center of the room. Visitors took their seats on the swing, and Wood describes what happened next as follows:

We took our seats and the swing was set in motion, the arc gradually increasing in amplitude until each oscillation carried us apparently into the upper corners of the room. Each vibration of the swing caused those peculiar ‘empty’ sensations within which one feels in an elevator; and as we rushed backwards toward the top of the room there was a distinct feeling of “leaning forward,” if I can so describe it—such as one always experiences in a backward swing, and an involuntary clutching at the seats to keep from being pitched out. We were then told to hold on tightly as the swing was going clear over, and sure enough, so it did ... (p. 277).

The Haunted Swing did not, of course, traverse a 360-degree arc. In fact, it did not move at all (with the exception of “merely being joggled a trifle”). The entire effect was based on the presence of avection illusion—the room itself (with its furnishings securely fastened to the floor and walls) moving back and forth around the astonished, yet physically stationary, observers.

Two further comments by Wood are particularly interesting in light of their relevance for the current discussion ofvection: “The curious and interesting feature ... was that even though the action was fully understood, as it was in my case, it was impossible to quench the feeling of ‘goneness within’ with each apparent rush of the swing” (p. 277). As is common of contemporaryvection illusions, even objective knowledge of the true state of affairs is insufficient to suppress the illusory sensation of motion. Finally, and somewhat more ominously: “Many persons were actually made sick by the illusion. I have met a number of gentlemen who said they could scarcely walk out of the building from dizziness and nausea” (pp. 277–278). Indeed, people are still being made dizzy and sick by similar phenomena.

Vection illusions occasionally occur in everyday life, outside of laboratories, simulators, and VE devices. One of the most frequently cited of these ordinary circumstances, perhaps more commonly experienced in Europe than in the United States, involves sitting in a stationary railroad car with another stationary train directly alongside. When the neighboring train begins to accelerate from a dead stop it is quite common for passengers in the stationary car to experience a sudden and somewhat arresting experience of self-motion, an experience that is particularly compelling when viewed in the periphery of the visual field. This experience manifests itself as a strong phenomenological sense of one’s own motion relative to the adjacent train (which is experienced as stationary), accompanied by a distinct postural control motion as the observer “adjusts” to the experienced motion. The same phenomenon occurs in stationary cars, busses, airplanes, and other vehicles. Another common setting for self-motion illusions is the cinema, particularly the wide field-of-view setting of “cinemax” and I-Max theaters. Large, hemispheric dome displays, an attraction at several of the world’s largest entertainment parks, on which compelling patterns of motion are projected, (e.g., fighter jets flying in formation) are designed to produce strongvection illusions. Wisely, railings are included for customers to hang onto and thereby avoid pitching over en masse in response to pronounced twists and turns of the motion pattern.

In most, if not all, VE applications there is a strong perceived need among designers to provide very-high-fidelity synthetic replications of the real (or, in some cases, imaginary) world. A corollary of this emphasis on design realism is the desire to provide high-fidelity representations of the multisensory consequences of users’ motor behaviors and interactions with virtual entities. In other words, there is a perceived need in the VE design community to provide a highly realistic simulation of the “response” of the perceptual world to each significant activity undertaken by the user of the system.

For example, when a user initiates optical (and other sensory) transformations specifying self-motion in a VE (either by physically walking on a treadmill or by means of some sort of intermediary device such as a DataGlove or joystick) the pattern of visual (see chap. 3, this volume), auditory (see chap. 4, this volume), and in some cases haptic (see chaps. 5–6, this volume) and vestibular (see chap. 7, this volume) information made available to the user should correspond to the intended self-motion profile. In most cases, VE users will not in fact be physically displaced. However, the entire pattern of multisensory stimulation to which they are exposed will specify self-motion, and in many of these cases users will experience strongvection illusions. As seen from Woods’ description above, this experience can be compelling and exhilarating, but also occasionally disturbing and even dangerous (depending on the activities the user engages in during exposure to the VE, and immediately upon leaving it). It is incumbent on designers of VE systems to understand the nature of this illusion in order to assure that the user’s experience is safe and accomplishes its intended goals.

Before embarking on specific discussions of how an understanding of thevection illusion can substantially impact the design and use of VE systems, the major findings invection research that are of most relevance to these applications will be reviewed. These findings are classified into the following general areas: (1) the nature of the effects experienced by observers and methods used to measure those effects; (2) the nature of the optical transformations that underlie the illusion; (3) the neurophysiological correlates ofvection; and (4) motion sickness and perceptual-motor adaptation phenomena. Prior to discussing these areas, the various types ofvection illusions that have received the most research attention will be reviewed.

2.1 Types of Vection

Vection can be induced across all six degrees of freedom of body motion (e.g., roll, pitch, yaw, and linear translations) and may be experienced as rotational motion, linear motion, or some combination of the two. In this section, the major forms ofvection that have been identified and examined as a means of describing the conditions under whichvection has traditionally been investigated and the general nature of the experimental findings that have been obtained will be discussed.

In describing these forms ofvection, the following nomenclature will be used to describe the three principal physiocentric axes of real and illusory self-motion (see Fig. 23.1):

- Z-axis—refers to the vertical, spinal, or yaw axis of the body, or an imaginary line passing directly through the head, down through the body and out the soles of the feet.
- X-axis—refers to the roll axis of the body corresponding to the forward line of sight, or an imaginary line passing through the middle of the body from front to back.
- Y-axis—refers to the pitch axis of the body, or an imaginary line passing through the body from its right side to its left side.

2.1.1 Circular Vection

Dichgans and Brandt (1978) define circularvection as illusory rotation about one or more of the three body axes. Generally speaking, however, the term *circularvection* has primarily been

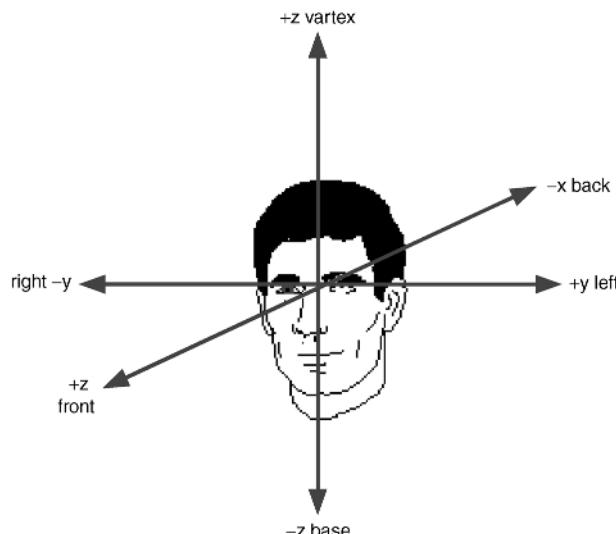

FIG. 23.1. Three body-centric axes used to classify forms ofvection.

applied to illusory rotation about the upright body's z-axis, while rotation about the body's x and y axes are more commonly referred to as roll and pitchvection, respectively. Roll and pitchvection are described separately below.

Circularvection is perhaps the most thoroughly investigated of all illusory self-motion phenomena. Ernst Mach first studied it in the 19th century, using a rotating, striped cylinder that completely surrounded his subjects (Mach, 1875). He later used a large, effectively endless belt that moved across two rollers to induce the illusion (Mach, 1922, cited in Dichgans & Brandt, 1978). The former apparatus, frequently referred to as a "vection drum," has been the most common means of inducing and examining the illusion in laboratory settings over the years.

Though certain aspects of the experience of circularvection vary somewhat from one observer to the next (notably its latency of onset), the experience itself is quite uniform across individuals. Once the motion stimulus has been initiated (i.e., the vection drum is turned on and begins rotating about the observer) the common initial impression is of object or "surround" motion—that is, the observer perceives the drum as moving, and not himself. However, shortly thereafter a distinct transformation in the observer's phenomenological experience occurs as he begins to perceive himself as moving in the direction opposite to that of drum rotation, while the drum itself appears more or less stationary. *Saturated vection* refers to the condition in which the motion stimulus is perceived as completely stationary, with all motion experienced as self-motion.

As described in more detail below, the latency and strength of the circularvection illusion are dependent on a number key optical flow parameters. These include the velocity of the motion display, spatial and temporal frequency of the visual pattern, presence of foreground and background visual information, and size of the visual field of view. As Woods noted in reference to the "Haunted Swing" illusion, it is nearly impossible to suppress the illusion of illusory rotation given an optimal combination of these parameters. Objective knowledge of one's circumstances appears to have very little influence on any aspect of the user's experience of this, or any other form ofvection. As noted by Brandt, Dichgans, and Koenig (1973), it is common for the experience of illusory circular self-motion to persist beyond termination of the optical motion, a phenomenon that may partially underlie problems with disrupted perceptual-motor behavior observed in some users of flight simulation and VE systems (Kennedy & Fowlkes, 1992).

2.1.2 Roll Vection

Rollvection is defined as illusory self-motion about the x or frontal axis of the body (Dichgans & Brandt, 1978). It has been studied using devices such as circular disks with a patterned surface that are positioned immediately in front of an observer or hollow spheres with a patterned inner surface that are set into motion around an observer (e.g., Dichgans, Held, Young, & Brandt, 1972; Held, Dichgans, & Bauer, 1975; Howard, Cheung, & Landolt, 1987). In each case the surface rotates (or in some cases oscillates) around the observer's x-axis. Recently, Allison, Howard, and Zacher (1999) examined rollvection and illusory self-tilt in a "tumbling room" very reminiscent of the "Haunted Swing," capable of a full 360-degree translation in the roll axis. When observers view such displays, they experience an illusory rotation and tilt in the direction opposite that of the motion of the display, the strength of the illusion is dependent on characteristics of the display described below.

The experience ofvection in the roll axis is often quite paradoxical. As noted by Howard (1986a), it often seems as if the body is rotating continuously, but remaining at a more or less constant and fairly limited angle of tilt. As described below, this paradoxical phenomenon appears to be due to the influence of the vestibular otoliths (see chap. 7, this volume).

The same factors that influence the latency and strength of circularvection also appear to affect rollvection. For instance, Held et al. (1975) observed that the illusory self-tilt component of rollvection increased along with the size and retinal eccentricity of the visual display. Allison et al. (1999) observed that subjects were far more likely to report experiences of “tumbling sensations” (i.e., complete 360-degree apparent self-rotation) as a function of increased field-of-view size. This effect was also greater at the faster of the two rotational velocities tested (30 deg/sec versus 15 deg/sec). For smaller fields of view, observers reported sensations of constant tilt rather than full, 360-degree roll.

2.1.3 Pitch Vection

Pitchvection occurs as a result of viewing motion patterns that rotate about the body’s y-axis (Dichgans & Brandt, 1978; Young et al., 1975) and has been studied using devices similar to those employed in the study of rollvection, such as rotating disks or hollow spheres within which observers view patterns of moving visual stimuli (e.g., Howard et al., 1987).

The general characteristics of pitchvection are very similar in most respects to those of rollvection. That is, observers can be made to experience constant illusory self-motion, but only a limited degree of displacement or self-tilt (which tends to be less than that experienced in rollvection). Unlike rollvection, however, there appears to be a body-centric asymmetry in the degree of tilt experienced in pitchvection—specifically, smaller magnitude estimates of tilt are observed for apparent pitch-up conditions as compared to apparent pitch-down conditions (Young et al., 1975). Additionally, the stimulus parameters that underlie the experience of pitchvection are very similar to those of rollvection—in particular, larger visual fields of view tend to produce more compelling pitch illusions.

2.1.4 Linear Vection

Linearvection can be produced along any of the three body axes described above (or as a vector sum of two or more of these axes), but has most often been examined as illusory self-motion along the body’s x-axis. It has been studied using a broad array of devices, including moving rooms (e.g., Lee & Lishman, 1975), devices that incorporate projection of linear optical flow patterns onto the walls of a stationary room in which an observer is standing or seated (e.g., Berthoz, Lacour, Soechting, & Vidal, 1978; Lestienne, Soechting, & Berthoz, 1977), and frontal stereoscopic presentation of motion patterns (e.g., Ohmi & Howard, 1988). Flight simulators and numerous VE devices, particularly those with wide field-of-view display capabilities, are also capable of inducing compelling sensations of linearvection.

Postural sway responses to linearvection stimuli are often quite profound. Generally, observers will make a postural adjustment toward the direction of perceived self-motion in an apparent attempt to compensate for a perceived shift in the direction of gravito-inertial force vector. However, observers tend to show greater amplitude in backward as opposed to forward postural adjustments (Lestienne et al., 1977). It is not difficult to create conditions in a linearvection study that will cause observers to fall over, a finding of clear relevance for the safe design and operation of VE devices that incorporate such a capability. Indeed, a standing, unsupported observer in any compellingvection situation is at risk of falling. In addition, linearvection can induce sensations of disequilibrium that are at least as strong as those produced in other forms of the illusion (described in more detail below). For example, Lestienne et al. (1975) reported that of the 30 subjects in their study, 3 (10%) became so disoriented that they fainted while viewing a linearvection display.

2.2 Phenomenological and Behavioral Aspects of Vection

The most common phenomenological and behavioral manifestations ofvection include: (1) a compelling illusory sense of self-motion in the absence of true inertial displacement; and (2) distinct adjustments in postural control activity that are closely coupled to the nature of the inducing stimulus. The majority of research described in this chapter employs metrics tied to these two classes of response, with particular emphasis placed on the former.

As aforementioned, when observers are first exposed to avection-inducing display or apparatus, such as a rotating cylindrical drum in a circularvection setting, they typically first perceive the drum itself as being in motion. It is not unusual for a similar first impression to occur within a VE setting—that is, users perceive themselves as immersed in a computer-generated environment within which motion is being depicted, but the motion is not experienced as being their own. Shortly thereafter, however, the perception in most laboratoryvection settings changes dramatically from one of object or surround motion to one of self-motion (assuming that conditions for inducing the experience of the illusion are appropriately configured)—the direction of self-motion being opposite in direction to that of the surround motion. Coincident with the onset of self-motion, surround motion may appear to effectively cease.

In the case of circularvection, the latency of this effect is on the order of 5 to 30 seconds (e.g., Dichgans & Brandt, 1973, 1978). This range is representative of all forms ofvection, and specific values are influenced by a host of factors described in the following section. For example, onset of thevection illusion tends to occur sooner at lower optical accelerations (Howard, 1986a; Melcher & Henn, 1981). In addition, its latency tends to decrease as a direct function of increases in the size of the visual field of view (Dichgans & Brandt, 1978). In some cases the experience ofvection may remain fairly constant once it has begun—that is, it will remain present until the motion stimulus is discontinued and may persist for a while afterward. However, in other cases the sensation ofvection may come and go, and may also increase and decrease in intensity.

In measuring the phenomenological component ofvection, two key questions that are typically addressed are: (1) Isvection present (i.e., is the subject in avection experiment or the user of a VE system currently experiencing thevection illusion?); and (2) If present, how powerful is the phenomenological experience of the illusion? A number of approaches have been used over the years in experimental studies ofvection, and they may be useful to VE system designers as they attempt to either enhance or diminish the presence and /or strength of this illusion.

As is often the case with phenomena that are largely subjective in nature (e.g., presence), the measurement of the phenomenological component ofvection is of necessity largely an indirect process. A number of approaches derived from psychophysical measurement techniques have been used, including magnitude estimation of surround and/or self-motion, magnitude estimation of degree of perceived self-tilt, and subjective scaling of the strength of the illusion (cf. Diener, Wist, Dichgans & Brandt, 1976; Kennedy, Hettinger, Harm, Ordy, & Dunlap, 1996; Ohmi & Howard, 1988). These measures are widely accepted in thevection research community and have been shown to have a high degree of psychometric reliability (Kennedy et al., 1996).

Magnitude estimation techniques often require subjects to make estimates of the velocity of apparent self-motion in the case of continuous motion (e.g., in degrees/second), displacement (e.g., in degrees) in the case of discrete motion, or in estimating the illusory tilt so commonly perceived in roll and pitchvection. Subjects have occasionally been asked to provide magnitude estimates of their own apparent motion in addition to the perceived motion of the stimulus (e.g., Wong & Frost, 1978). In the latter case, the strength of thevection illusion can be inferred by greater magnitude estimates of self-motion relative to stimulus motion.

One of the more common methods of assessing the strength of thevection illusion involves the use of comparatively simple subjective scaling techniques. Typically these scales range from zero, corresponding to a rating of no illusory self-motion, to some upper limit meant to reflect a sense of “saturated”vection (cf. Hettinger et al., 1990; Howard et al., 1987).

As noted above, postural readjustment responses are also commonly observed invection settings, and their characteristics can be used to assess the degree ofvection experienced by an observer in a given situation. These types of metrics are derived from quantitative measures of the observer’s reflexlike reactions to perceived motion in which body sway and/or other forms of postural control activity are the most common response (e.g., Bles & DeWit, 1976; Dichgans & Brandt, 1978; Stoffregen, Hettinger, Haas, Roe, & Smart, 2000). Under conditions of sufficient stimulus magnitude and/or duration it is not unusual to observe subjects losing functional postural control and eventually falling or collapsing (Lee & Aronson, 1974; Lestienne et al., 1977). As Kennedy and his colleagues (e.g., Kennedy, Drexler, Compton, Stanney, & Harm, in press) have noted, it is also not unusual for postural control disturbances to persist well beyond the cessation of the self-motion experience.

The precise, objective measurement of postural control responses during exposure to illusory self-motion stimulation is a far more complex and equipment-intensive procedure than is the use of psychophysical magnitude estimation or scaling techniques (see chap. 39, this volume). Typically, devices such as force platforms, body-mounted accelerometers, and calibrated photographic/video methods have been used to assess postural sway, and the data is then reduced to quantitative profiles of postural control activity. While this level of precision may require excessive instrumentation for most VE applications outside the laboratory, the simple observation of users’ postural control behaviors in the presence of self-motion stimuli may be a useful converging measure for assessing the presence ofvection if used in conjunction with the psychophysical techniques described above and may also provide information regarding early onset of the illusion. For example, Stoffregen (1985) found compensatory sway in a moving room to have a lower threshold than reports of motion.

One of the least understood aspects ofvection involves the nature of differences between individuals in terms of their phenomenological and postural responses. In perhaps the only study of this aspect of the illusion, Kennedy and his colleagues (Kennedy et al., 1996) examined the psychometric reliability (within individuals) and variability (between individuals) of various measures of circularvection, such as latency and magnitude estimation of perceived self-motion. Results indicated that while the classes of measures used exhibited strong intraobserver reliability (i.e., observers were quite consistent in their responses from one session to the next), there were strong and consistent differences between individuals. This finding suggests that key aspects of thevection illusion may not be as uniformly experienced across individuals as previously believed and/or that observers may respond to aspects ofvection-inducing situations differently. In addition, the authors hypothesize that those observers who exhibit greater sensitivity tovection may be among those most likely to experience occasional side effects and/or problems in readapting to normal perceptual-motor relationships once out of thevection environment. However, these hypotheses have yet to be tested.

2.3 Optical Determinants ofvection

In order to attempt to control (or perhaps, in some cases, prevent) the onset ofvection illusions in VE devices, it is important to understand the nature of the optical information that influences its onset and strength. Most of these factors have been alluded to above, but are summarized in more detail in this section. It is interesting to note that many aspects of features that appear to enhance thevection illusion are the very factors that are widely sought in current VE systems,

TABLE 23.1
Visual Display Factors Affecting Vection

1. Size of the visual field of view.
 2. Optical velocity (or temporal frequency) of the visual stimulus.
 3. Spatial frequency of the stimulus pattern.
 4. Presence of background and foreground information.
-

and which are generally thought to support the experience of presence. In other words, the visual display features that enhancevection, such as the size of the field of view, spatial and temporal frequency of the optical pattern (i.e., “scene detail”), and others described below are widely emphasized in the design of contemporary VE systems. Therefore,vection in VEs should become increasingly common as systems continue to more closely attain the engineering and display parameters that promote its occurrence.

Vection is strongly influenced by a number of visual display factors (see Table 23.1). The influence of most of these is summarized in Dichgans and Brandt (1978) and Howard (1986a). The vast majority of thevection literature is characterized by studies that focus on one form ofvection at a time, and little work has been done to attempt to generalize findings across the various forms of the illusion. Recognizing that the critical elements underlying specific forms ofvection may vary according to the form of the illusion under examination, it is nevertheless possible to make a number of general statements concerning visual display factors.

Despite several findings indicating that it is possible to induce sensations ofvection with relatively small (less than 10 degrees of visual angle), centrally presented motion patterns (e.g., Andersen & Braunstein, 1986), there appears to be little doubt that peripheral visual stimulation is far more effective in inducing the illusion (and corresponding postural adjustments) than central visual stimulation. Simply put, wide fields of view are more effective for inducingvection than are comparatively narrow fields of view. This is almost certainly due to the greater connectivity between the vestibular system and peripheral retina in comparison to the central retina (see later discussion of neurophysiological correlates ofvection).

Many studies have examined field of view effects onvection. The findings of Lestienne, Soechting, and Berthoz (1977) and Brandt, Dichgans, and Koenig (1973) are illustrative of this work in general. In their examination of linearvection, Lestienne and his colleagues observed that the amplitude of the postural sway response observed in their subjects depended primarily on the size of the motion pattern. Specifically, increases in postural sway amplitude were linearly related to field-of-view size—the larger the field of view, the more pronounced the postural sway response to the linearvection stimulus. This is consistent with the findings of Brandt et al. (1973), that the intensity (i.e., strength of the illusion) and velocity of illusory self-rotation in circularvection are strongly dependent on the size of the available field of view, with intensity being more adversely affected than apparent velocity at smaller field-of-view sizes. A centrally located field of view of 30 degrees (the lowest value tested) produced very low estimates of intensity compared to full-field stimulation. In a compelling illustration of the impact of the visual periphery onvection, Brandt et al. (1973) masked the central 120 degrees of the visual field so that subjects could only view the rotating motion stimulus in the far periphery. The intensity of thevection illusion was scarcely affected by this manipulation.

The relevance of these findings for VE system design is very clear. Larger fields of view will generally be more effective for elicitingvection illusions than will smaller fields of view. In some cases this may be advantageous (e.g., in helping to make a VE-based entertainment

ride more exhilarating) but in other cases may result in excessive problems with motion sickness and/or postural disturbances. The addition of accurate representation of motion-in-depth information (e.g., radially expanding optical flow patterns characteristic of forward, linear self-motion), which Andersen and Braunstein (1985) assert to be the critical factor in supporting illusions of self-motion with small, centralized displays, should serve to enhance the field of view effects.

Optical velocity is another key visual display factor, influencing both the intensity and velocity of illusory self-motion. Howard (1986a) reports the general finding that the apparent velocity of illusory self-rotation in circularvection is directly proportional to optical velocity up to values of approximately 90 deg/sec, although this relationship is influenced by the spatial frequency (optical texture density) of the stimulus pattern. Similarly, Brandt et al. (1973) and Dichgans and Brandt (1974) observed that perceived velocity of illusory self-motion in circularvection is linearly related to stimulus velocity up to about 90 to 120 deg/sec, beyond which perceived illusory self-motion velocity lags behind stimulus velocity.

The spatial frequency of the visual stimulus, or what can generally be considered to be equivalent to the amount of "detail" presented in the display, also affects the perception of illusory self-motion. Diener, Wist, Dichgans, and Brandt (1976) observed that subjects' perceptions of the velocity of illusory self-rotation more closely matched the true velocity of the stimulus with increases in the spatial frequency of the visual display. These findings correspond to those obtained by Owen and his colleagues (e.g., Owen, Wolpert, & Warren, 1983; Warren, Owen, & Hettinger, 1982) who observed that "edge rate" information was more salient than global optical flow in affecting observers' judgments of self-motion.

One of the earliest and most common findings in thevection literature is that the perception of illusory self-motion is greatly enhanced when observers fixate a stationary target located in front of the visual motion pattern (e.g., Mach, 1875). By implication, this finding suggests that the inclusion of foreground visual information in VEs that requires sustained attention by the user will result in more pronounced sensations ofvection, if a wide field-of-view pattern of motion is made available.

When there are multiple displays in view, each depicting patterns of motion and each at different distances from the observer, the most distant display has been observed to control the direction of illusory self-motion (Brandt, Wist, & Dichgans, 1975). Additionally,vection is suppressed by stationary objects seen beyond the moving display but not by stationary objects in the foreground (Howard & Howard, 1994).

2.4 Neurophysiological Correlates of Vection

Significant research attention has been devoted to the identification and description of the neurophysiological correlates ofvection—that is, the nature of the activity that occurs in the central nervous system (CNS) in conjunction with exposure tovection-inducing displays. This work strongly suggests that the neurophysiological basis of the illusion lies in the activity of the vestibular nuclei (Daunton & Thomsen, 1978; Dichgans & Brandt, 1978; Waespe & Henn, 1977a), a CNS site whose activity is also strongly tied to actual self-motion. Such a convergence makes sense not only becausevection and actual self-motion are very similar in a phenomenological sense, but also because they share many observable behavioral similarities (e.g., postural sway, motion sickness) and physiological similarities, such as the occurrence of optokinetic afternystagmus (the tendency of the eyes to exhibit a pattern of nystagmic motion following exposure to real or illusory self-motion), a phenomenon known to be directly affected by activity of the vestibular system (e.g., Waespe & Henn, 1977b, 1978).

Interactions between the visual and vestibular system are central to thevection illusion. Research in visual–vestibular interactions has its own long history (see Henn, Cohen, & Young,

1980; Howard, 1982, 1986b, 1993, for reviews of this literature), and much of the work either overlaps with research onvection or has direct relevance for it. Indeed, the desire to understand and explain the neurophysiology of the visual–vestibular system has always been a prime motivator ofvection research (e.g., Dichgans & Brandt, 1978; Straube & Brandt, 1987).

One method used to examine the nature of visual–vestibular interactions invection involved attempts to isolate components of this ordinarily highly interactive system. For instance, Howard et al. (1987) demonstrated that the paradoxical combination of continuous illusory self-rotation with limited, constant tilt in upright observers is a function of activity from the vestibular otoliths. Specifically, when observers lying on their back (effectively nulling inputs from the otoliths) view a rollvection stimulus, the experience is simply one of continuous self-rotation. This clearly suggests a strong role of the vestibular system invection illusions.

A different approach for isolating visual and vestibular inputs from one another involves the examination ofvection and other visual–vestibular phenomena in microgravity, where vestibular inputs are greatly reduced. For example, Young et al. (1986) studied rollvection in four crew members under microgravity conditions during a Space Shuttle mission, as well as during the microgravity phases of parabolic flight. Their findings indicated that perception of rollvection was enhanced in the early phases of weightlessness (i.e., early in the mission), possibly due to sharply reduced functionality of nonvisual cues for gravity and orientation. Results obtained during later phases of the mission were somewhat more variable, perhaps due to effective incorporation of nonvestibular cues for orientation.

As noted by Howard (1986a), it was originally thought thatvection could be ascribed to the effects of optokinetic nystagmus (OKN)—the eye’s reflexive tendency to alternative slow pursuit motions with rapid, saccadic return movements when viewing a scene or object (such as a train) moving in one direction (see chap. 3, this volume). However, Brandt et al. (1973) demonstrated that the phenomenological,vection-inducing effects of a large moving field are unaltered even upon adding a small central display of motion in the opposite direction. Whereas the latter changes the direction of OKN as long as the subject fixates on it, it has no effect on thevection experience. On the other hand, the duration of positive and negative aftereffects of illusory self-motion appear to be directly related to the time course of optokinetic afternystagmus, the tendency of the eye to show nystagmic patterns of motion following the cessation of a motion stimulus. (Note: *Positive aftereffects* are illusory motion sensations experienced as being in the same direction as the immediately preceding, stimulus-driven illusion. *Negative aftereffects* are illusory sensations experienced as being in the opposite direction.)

2.5 Motion Sickness and Adaptation Phenomena

One of the most widely studied areas invection research, and one with tremendous relevance to VE design and usage issues, concerns the relation betweenvection, motion sickness, postural disturbances, and other negative perceptual–motor side effects. Circularvection has been shown to induce symptoms of motion sickness in approximately 60% of healthy human subjects (Stern et al., 1985; Stern, Koch, Stewart, & Lindblad, 1987), and, as previously noted, Lestienne et al. (1977) observed that 3 of the 30 subjects in their linearvection study were disoriented by the experience to the extent that they lost consciousness. Anyone who has been around flight simulators or vehicular simulators for very long is familiar with “simulator sickness” (Kennedy, Hettinger, & Lilienthal, 1990; see chap. 30, this volume), a phenomenon that appears to be spreading to the larger domain of VE systems in general.

Motion sickness resulting fromvection has been discussed as a type of “visually induced motion sickness” (Hettinger & Riccio, 1992; McCauley & Sharkey, 1992). The underlying cause of sickness in these circumstances has traditionally been attributed to the existence of

conflict between sources of sensory information specifying self-motion and orientation. The “sensory conflict theory” (Reason & Brand, 1975) is the most widely accepted theoretical explanation of motion sickness in real and virtual environments. However, over the years many concerns have been raised with the theory, including why only certain types of conflicts appear to be nauseogenic, why the same conflict might not reliably produce sickness across different individuals (or, indeed, even within the same individual across time), and how to attempt to quantify the amount of conflict present in a given situation and relate it to the frequency and severity of motion sickness. Stoffregen, Riccio, and their colleagues have proposed an alternative explanation, arguing that motion sickness, whether it occurs in virtual or real environments, results from prolonged disruptions in normal postural control activities (Riccio & Stoffregen, 1991; Stoffregen & Riccio; 1991; chap. 39, this volume). Results to date suggest that this is a promising theoretical approach (Smart, Pagulayan, & Stoffregen, 1998; Stoffregen & Smart, 1998; Stoffregen et al., 2000). However, the notion of sensory conflict still seems to be of value in explaining many of the situations that lead to prolonged postural disruptions and/or motion sickness. It may be that both views are to some extent correct, and that motion sickness, including that induced byvection stimuli, ultimately results from unusually provocative disruptions in the normal cycle of perceiving and acting.

One of the most vivid similarities between motion sickness observed in real and illusory motion conditions involves the presence of *Coriolis effects* in the former, and *pseudo–Coriolis effects* in the latter. Coriolis effects are powerful and well-known stimuli for motion sickness, and occur as a result of the cross-coupled angular accelerations that are produced within the vestibular system when the head is tilted out of the body’s axis of rotation (cf. Benson, 1990). This is often done by placing subjects in a rotating “Barany chair”—a device that rotates the body about its z-axis like a barber chair might, and then asking the participant to tilt the head slightly out of the axis of that rotation. Intense nausea is quickly produced (cf. Melville-Jones, 1970) and vomiting will nearly always follow shortly afterward if the motion and/or cross-coupled stimulation are not ceased. Dichgans and Brandt (1973) demonstrated the existence of a pseudo–Coriolis effect through what one might today refer to as a virtual simulation of the Coriolis situation. By exposing subjects to a circularvection stimulus (a rotating cylindrical drum) and then asking them to tilt the head outside the axis of apparent rotation, they were able to produce the same sort of motion sickness symptomatology observed in actual Coriolis situations.

Stern, Koch, and their colleagues have pioneered the study ofvection-induced motion sickness. In much of their research (e.g., Stern, Hu, Vasey, & Koch 1989; Stern et al., 1985) they have studied sickness by recording subjects’ gastric myoelectric activity using an electro-gastrogam (EGG). The EGG provides a very sensitive and reliable index of gastric motility associated with subjective symptoms of nausea and is often reflected by a shift from the normal gastric rhythm of 3 cpm to 4 to 9 cpm, referred to as *tachygastria* (Stern et al., 1985; see also chap. 32, this volume). The work of Stern, Koch, and their colleagues has demonstrated that motion sickness is a common side effect of the experience ofvection, which appears to diminish in severity as a result of adaptation to repeated exposures (Hu, Grant, Stern, & Koch, 1991), concentrated focus on deep breathing (Jokerst, Gatto, Fazio, Stern, & Koch, 1999), and treatment with acupressure techniques (Hu, Stritzel, Chandler, & Stern, 1995).

There is nearly unanimous agreement among VE system designers, and especially users, that motion sickness is a distinctly unpleasant experience, the occurrence of which should be minimized to the greatest degree possible. (Note: An interesting exception is the NASA Preflight Adaptation Trainer, a VE-based system whose intent was to preadapt astronauts to conditions considered to be highly evocative of space motion sickness. This unique system’s objective was, in fact, to induce feelings of queasiness and disorientation in its users, thereby inoculating them to such conditions in the microgravity environment of space [cf. Harm,

Zogofros, Skinner, & Parker, 1993; Parker, 1991]). However, the most urgent risk to users might not involve the feelings of discomfort that occasionally accompany use of the system. Rather the greatest risk might involve the disrupted perceptual-motor control that is often observed after use of the system (see chaps. 37–39, this volume). A point made repeatedly by Kennedy and his colleagues in their discussions of sickness in flight simulators and VE systems is that negative side effects experienced after exposure to a VE are of greater safety concern than those that occur during exposure (e.g., Kennedy & Fowlkes, 1992; Kennedy et al., 1990).

Aftereffects of exposure tovection-inducing events have been frequently noted in the experimental literature. For example, in his review ofvection phenomena, Howard (1986a) notes that aftereffects can be readily demonstrated to occur in circularvection settings: “If the lights are put out after a moving scene has been observed for some time, the illusory self rotation continues as a *positive aftereffect* followed by a *negative aftereffect* in the opposite direction” (p. 28). Some form of adaptation tovection-inducing events may underlie these aftereffect phenomena, suggesting that on leaving avection-inducing situation such as a VE system, flight simulator, or laboratory device, observers may need to undergo a process of readaptation and recalibration, during which time their normally effective perceptual-motor control might be disrupted.

3. RELEVANCE OF VECTON FOR VE SYSTEM DESIGN AND USE

An understanding ofvection phenomena is important for the design of safe and effective VE technology for a number of reasons:

- Vection appears to be one of the key elements underlying the broader illusion of “presence” (see chap. 40, this volume) in a virtual environment. To the extent that presence is a desirable design feature of a particular VE device, then a proper understanding of the design elements that underlievection is an important engineering issue.
- Vection may or may not contribute to the achievement of a VE device’s “behavioral goals.” To the extent thatvection in fact facilitates the achievement of various desired outcomes with respect to the user of a device, it is important to understand the factors that promote its occurrence.
- Vection has frequently been identified as a correlate of, and perhaps a causal element in, the phenomenon of motion sickness in VEs—or *cybersickness*. Additionally, exposure to a compellingvection stimulus may be a crucial factor in a larger process of perceptual-motor adaptation (see chap. 31, this volume) to virtual environments. To the extent that adaptation does occur, a period of readaptation upon return to the normal spatiotemporal constraints of the actual world is necessarily required. These periods of adaptation and readaptation may expose users to a number of risks. To control these risks, it is necessary to understand the factors that createvection.

All of these concerns are directly related and cannot be considered in isolation from one another. There is little doubt thatvection can play a key role in helping to produce a sense of presence in a VE system. An illusion of “being in” a computer-generated environment is clearly enhanced by a sense of illusory self-motion so compelling that it can hardly be distinguished from actual self-motion. Furthermore, the research literature provides relatively firm guidance, summarized in the preceding sections, concerning system design and usage guidelines for producing the illusion and enhancing its strength. However, much of this literature also describes the risks that system users may face as a result of exposure to self-motion illusions, most notably motion sickness and perceptual-motor disturbances.

The fundamental questions that VE system designers must address with respect tovection are as follows:

- In light of the potential risks to system users posed byvection, does the presence of illusory self-motion meaningfully contribute to the overall objectives of the human–VE system? In other words, are the overarching goals that the system is intended to accomplish being supported by producing compelling sensations of self-motion in users, are they being interfered with, or does the experience ofvection have little or no impact on them?
- If a reasonable case can be made thatvection is a key factor in promoting the overall objectives of the human–VE system, then the question becomes one of how to safeguard users from the risks associated with its negative side effects.

With regard to the first of these two points, there is little evidence to date thatvection plays a critical role in the attainment of human–VE system objectives. However, there are situations when it is likely to play a key role, notably in the successful application of VE-based entertainment devices (see chap. 55, this volume) and potentially in certain VE-based training applications (see chaps. 43–44, this volume) in which skill in the perception and control of self-motion is critical. A major potential problem exists in the former application area, however, in that VE-based entertainment devices are intended to expose as many people as possible to the illusory perceptual features characteristic of this technology. This, of course, raises the risks of significant numbers of users being made ill and/or suffering postexposure side effects.

In many cases the occurrence ofvection may actually interfere with the objectives of VE systems. “Self-motion artifacts” might arise in situations where no perception of self-motion is desired, but where the stimulus information is such that momentary (or longer)vection illusions arise. For instance, this could occasionally occur if motion of virtual objects in the periphery of the visual field gives rise to transientvection illusions, causing disruptions in both the phenomenological experience of the VE as well as psychomotor disturbances associated with postural readjustments.

Certainly the occurrence ofvection-induced motion sickness and perceptual–motor disturbances can be expected to interfere dramatically with the objectives of most human–VE systems. Any benefit to be derived from the inclusion ofvection-inducing stimuli in a VE system has to be carefully weighed against such potential risks. And if there is no benefit to be gained from the presence of self-motion (or, indeed, if there is significant risk associated with the occurrence of its side effects), then design and usage guidelines to minimize its occurrence should be adhered to. Familiarity with the stimulus factors that underlie the illusion, summarized above and described in detail in the literature cited in this chapter, can help to promote effective and safe system design. In addition, simulator and VE system usage guidelines developed by Kennedy and his colleagues (e.g., Kennedy et al., 1990) should be used to further protect users from the occasional negative side effects of exposure to simulated self-motion.

4. RESEARCH ISSUES

This section addresses research issues that may be of potential value in further illuminating our understanding of the relation betweenvection and virtual environments. These issues fall into two broad categories: research onvection and related phenomena that would be useful in enhancing the future safe and effective design and use of VE systems; and research onvection using VE systems as research tools.

As anyone who has ever experienced or worked with VEs knows, they are fascinating systems from many perspectives. As this chapter has discussed, they raise many important

psychological, physiological, and behavioral issues as developers attempt to maximize their safe and effective use. However, they not only raise important research issues, they also provide new means for examining these issues. In other words, because of their compelling multisensory, interactive nature, and because they are programmable and permit the acquisition of very detailed information about user behavior (based, for instance, on data retrievable from body motion sensors—see chap. 8, this volume), they afford the means to examine important psychological and physiological issues in ways that have not been possible to date (cf. Durlach & Mavor, 1995). Even in restricting the present discussion to matters concerned withvection and self-motion perception, it is clear that VE technology offers many exciting possibilities for enhancing our knowledge.

For example, Oman, Howard, and their colleagues have been engaged in research on circular and linearvection in the microgravity environment of outer space (Oman et al., 2000) using a helmet-mounted display and computer-generated VE as a motion stimulus. As described previously, the microgravity environment is useful for the study of visual–vestibular interactions because it allows researchers to isolate the influence of the two systems. However, until the introduction of VE technology it was very difficult to examinevection phenomena in microgravity because of the severe weight and size limitations of the equipment involved. Oman’s and Howard’s work has provided important information on the relative roles of visual and proprioceptive sources of information for orientation in microgravity. Their results, indicating dramatically increased circular and linearvection after several days of exposure to microgravity, also provide a very useful source of converging information to those found by Young et al. (1986) for rollvection.

4.1 Effect of Complex Motion Patterns on Vection

Research conducted to date onvection has concentrated almost exclusively on relatively simple patterns of motion; specifically motion along or around a single axis. However, many current and future VE applications will require the depiction of far more complex patterns of self-motion, such as that involved in depicting the intricate and aggressive motion patterns of aircraft engaged in air combat (for training such skills) and any number of possible complex motion profiles for entertainment purposes.

Very little is known about illusory self-motion under such conditions, primarily because until very recently the technology for examining such issues has not existed. This is clearly an example of a research area that stands to benefit from the application of VE technology, and future applications of the technology will in turn benefit from the results of that research.

4.2 Multisensory Patterns of Information Specifying Self-motion

Virtual environments are fundamentally multisensory devices. Their intent is to take advantage of the information acquisition capabilities of as many of the sensory systems as possible to replicate the perceptual experience of the real world (or create compelling multisensory experiences of imagined or synthetic worlds). Research to date on thevection illusion has concentrated almost exclusively on the visual modality, with limited research attention having been devoted to audition (e.g., Lackner, 1977). In addition, several studies on electrical stimulation of the vestibular system have shown that it is possible to produce compellingvection illusions (primarily of roll) using such an approach (e.g., Cress et al., 1997; Dzendolet, 1963). However, there has been very little research to date examining the effects of multisensory information onvection. Cress and his colleagues (1997) contrasted the effects of visually specified rollvection, electrical stimulation of the vestibular (producing illusions of roll motion), and combined visual and electrical vestibular stimulation and found that the latter condition produced

sensations of motion that were rated as significantly more realistic by observers than either of the two former conditions alone. However, no other formal work that we are aware of has been conducted in the area of multisensory effects onvection.

Research of this type would not only help to provide design and usage guidance for VE systems, but may even help to illuminate the role that sensory conflict plays (or does not play) in creatingvection-induced motion sickness.

4.3 Adaptation, Readaptation, Transfer of Adaptation, and Virtual Environments

The problems that users occasionally experience when adapting to the rearranged perceptual-motor relationships of VEs and/or when readapting to normal actual environment spatiotemporal constraints after having spent time immersed in a VE have been described above and in chapter 31 (this volume). Not all of these problems are due tovection illusions of course, but motion sickness and adverse postexposure symptomatology have been repeatedly observed invection studies and related settings with sufficient frequency to identify it as a probable key contributor to this problem.

As VE systems become more widely distributed and more commonly used in everyday work and entertainment settings, these problems can be expected to increase in frequency. In addition to being more widely available, the fidelity and resulting strength ofvection illusions (indeed, the overall sense of presence) afforded by VE systems will almost certainly continue to increase for the foreseeable future. Each of these factors will combine to increase problems with undesired side effects unless research on their cause and amelioration is aggressively pursued.

One avenue of research that may help to alleviate the severity of these problems involves the examination of factors that promote functional adaptation across environments (actual and virtual) that vary in their spatiotemporal characteristics (cf. Hu, Stern, & Koch, 1991; Welch, in press). The identification of system design and usage features that promote the safe transition of users between the differing spatiotemporal arrangements of actual and virtual environments should remain a high priority in order to assure a safe and successful future for this technology.

4.4 Effect of Visual Frames of Reference on Vection and Orientation

Many sources of information interact to produce one's sense of static and dynamic orientation in the world, including the potentially powerful effect of "visual frames of reference." "Visual frames," as described by Howard and his colleagues, are sets of distinct horizontal lines and surfaces (e.g., elements of the optic array corresponding to walls, ceilings, pillars, etc.) whose orientation is highly linked to that of the gravito-inertial force vector (Allison et al., 1999; Howard & Childerson, 1994). Familiar objects (e.g., trees, furniture) within these frames of reference also exhibit an "intrinsic visual polarity" (Allison et al., 1999, p. 299). When the visual frame of reference and all objects contained within it are tilted with respect to gravity, the result is a compelling experience of self-tilt. Prothero and Parker (in press), in examining their "rest frame hypothesis," have identified strong interactive effects between observers' visual frames of reference, the perception ofvection, and subsequent occurrences of motion sickness and disorientation.

As described above, Allison et al. (1999) studied the effect of field size, stimulus velocity, and visual fixation on rollvection and illusory self-tilt in a specially designed moving room reminiscent of the "Haunted Swing." While the results were clearly informative of the role of these visual factors on the strength and other characteristics of the illusion, there would seem to be distinct advantages in conducting such research in a virtual as opposed to an

actual environment. The principal advantage may lie in the relative ease with which the key parameters of visual stimulation can be manipulated in the virtual environment. For instance, the relative effect of the visual polarity of familiar objects versus the effect of a more global frame of reference would seem to be much easier to manipulate. However, the problem at this stage in the development of the technology involves the relatively restricted field of view and limited resolution of most current VE systems compared to actual environments.

5. CONCLUSIONS

The purpose of this chapter has been to provide a summary of research performed to date on thevection illusion, and in so doing demonstrate its relevance, and the relevance ofvection phenomena in general, to the design and use of effective VE systems. The illusion of self-motion is an increasingly ubiquitous aspect of modern VE systems, and it is likely to become even more characteristic of future systems. While there is little doubt that a compelling sense ofvection can be a powerful contributor to an overall sense of presence in a VE system, it is by no means clear that it will always be of benefit in achieving the overall system objectives of a given device. Given the “cost” of thevection illusion—occasional, and occasionally severe, problems with motion sickness and perceptual-motor aftereffects—there is a clear need to understand the nature of this phenomenon and to incorporate knowledge of its stimulus characteristics and human performance implications into the design and use of VE systems.

6. ACKNOWLEDGMENTS

The very helpful comments of Robert S. Kennedy and Dean H. Owen on an earlier version of this chapter are gratefully acknowledged.

1. INTRODUCTION

Everyone has been disoriented at one time or another. It is an uncomfortable, unsettling feeling to be unfamiliar with your immediate surroundings and unable to determine how to correct the situation. Accordingly, one might think that the goal of navigation research in virtual environments (VEs) is to create a situation where everyone is oriented properly all the time and knows exactly where everything is and how to get there. This, however, may not be absolutely correct. Much is gained from the navigation process beyond just spatial knowledge. The path of discovery rarely lies on a known road. The experience of serendipitous discovery is an important part of human navigation and should be preserved. But how does one resolve the conflicts between this and the not-so-pleasant experience of “lostness”?

Navigation tasks are essential to any environment that demands movement over large spaces. However, navigation is rarely, if ever, the primary task. It just tends to get in the way of what you really want to do. The goal is to make the execution of navigation tasks as transparent and trivial as possible, but not to preclude the elements of exploration and discovery. Disoriented people are anxious, uncomfortable, and generally unhappy. If these conditions can be avoided, exploration and discovery can take place.

This chapter is about navigation in virtual environments—understanding how people navigate and how this affects the design of VE applications. The chapter begins with a clarification of terms and some theoretical background on navigation, primarily in the real world. A discussion of methods for navigation performance enhancement will follow. This is about how to improve performance in a virtual environment and differs from the next topic concerning the use of VEs as training tools, where the interest is in performance in the real world. The chapter concludes with a summary of principles for the design of navigable virtual environments.

1.1 Definition of Terms

One of the problems found in the literature is confusion over terms involving navigation. It is difficult to compare two studies that use different terms in different ways without unknowingly comparing apples to oranges. In this chapter specific terms with specific definitions are used and the research community is encouraged to adopt these.

Wayfinding is the cognitive element of navigation. It does not involve movement of any kind, but only the tactical and strategic parts that guide movement. As seen later in the chapter, wayfinding is not merely a planning stage that precedes motion. Wayfinding and motion are intimately tied together in a complex negotiation that is navigation. An essential part of wayfinding is the development and use of a *cognitive map*, also referred to as a *mental map*. Still poorly understood, a cognitive map is a mental representation of an environment. It has been called a “picture in the head,” although there is significant evidence that it is not purely based on imagery but rather has a symbolic quality. The representation of spatial knowledge in human memory that constitutes a cognitive map will be an important part of this chapter.

Motion is the motoric element of navigation. A reasonable synonym for motion is *travel*, as used by Bowman et al. (1997; also see chap. 13, this volume). Durlach and Mavor (1995) subdivide this further into *passive transport*, such as a “point-and-fly” interface or other abstraction, and *active transport*, such as the Omni-Directional Treadmill (see chap. 11, this volume) or other literal motion interface (Darken, Cockayne, & Carmein, 1997). Active transport interfaces are often referred to as *locomotion interfaces*. *Maneuvering* is a subset of motion involving smaller movements that may not necessarily be a part of getting from “here” to “there,” but rather adjusting the orientation of perspective, as in rotating the body, or sidestepping. This is an important distinction to make for the development of active transport interfaces for locomotion such as Gaiter (Templeman, Denbrook, & Sibert, 2000; also see chap. 11, this volume).

Navigation is the aggregate task of wayfinding and motion. It inherently must have both the cognitive element (wayfinding) and the motoric element (motion). Consequently, this term is used only when implying the aggregate task and not merely a part. The literature is replete with references to “navigation” that are only interested in novel motion techniques. This can be confusing and counterproductive to discussion and thus is avoided here.

It should also mention what is implied by *navigation performance*, as this is the metric used to determine the relative effectiveness of specific navigation tools and techniques. This is entirely dependent on the navigation task in question. Is the ability of a person to find an unknown object in a complex space being studied? If so, then search time might be an appropriate measure. Is the focus on the ability to find a known location in a complex space? Route following might then be appropriate. Or is the interest in determining a person’s overall knowledge of the configuration of a space? A map drawing exercise might be appropriate. These issues will be discussed in more detail below.

1.2 Training Transfer or Performance Enhancement?

There are two primary classes of applications having to do with navigation in virtual environments. All VEs that simulate a large volume of space will have navigation problems of one sort or another. Typically, any space that cannot be viewed from a single vantage point will exhibit these problems as users move from one location to another. The need to maintain a concept of the space and the relative locations between objects and places is essential to navigation. This is called *spatial comprehension*, and like verbal comprehension, involves the ability to perceive, understand, remember, and recall for future use.

In applications where users tend to become disoriented or are unable to relocate previously visited points of interest, it is desirable to either redesign these applications so these problems

do not appear or provide tools or mediators to help alleviate these problems. This class of application involves a need to enhance performance within the virtual environment. This distinction differentiates these applications from those where improved performance is required outside of the virtual environment, in the real world. These are training transfer applications which are discussed next.

The second class of applications that involves navigation has to do with the use of VEs as training aids for real-world navigation tasks. The fact that virtual representations of real environments can be constructed has led many to consider the use of VEs for much the same purposes that a conventional paper map might be used. While there are certainly similarities between these two classes of applications, the validation process is entirely different. If one wants to show that a visualization scheme in a virtual building walk-through, for example, can be used to lessen cases of disorientation, they need only show that users of the VE with this visualization scheme perform better on navigation tasks than users of an identical VE without the visualization scheme. However, if one wants to show that this same VE can be used as a training aid for navigation tasks in the actual building, navigation performance within the virtual environment, whereas interesting, does not prove this point. A training transfer study must be completed to show that users who trained in the VE navigate the building better than users who received some other form of training or possibly no training at all. This is an example of the use of a VE as a training aid for specific environments. Navigation performance is expected to improve in one specific real environment, and nowhere else.

Another interesting issue is the use of a VE as a training aid for general navigation tasks. If it could be shown that a VE could help people use paper maps more efficiently, or to select landmarks in an environment effectively, that performance increase would be expected to exist across physical spaces, possibly assuming some spatial similarities with that of the training environments (e.g., a VE that could be used to train a person to effectively navigate in a generic city would probably have little impact on that person's ability to navigate in a generic forest). This is beyond the scope of the current discussion but is an important use of VEs that has not yet been explored.

Whether or not a VE attempts to simulate the real world, one has to consider the fact that people are accustomed to navigation in physical spaces. Certainly, there are differences between regions of physical space that alter how navigation works, such as navigating in a forest versus navigating in a city, but there are assumptions that can be made based on past experience in real environments that are useful in any real space. While this is not a satisfactory reason to blindly copy the real world in every way possible, it is important to learn everything possible about how people relate to the physical world so designers can understand how to build better virtual environments.

1.3 Spatial Knowledge Acquisition

There are many ways to acquire spatial knowledge of any environment. The fundamental distinction between sources of spatial knowledge is whether the information comes directly from the environment (primary) or from some other source (secondary), such as a map. An issue specific to secondary sources has to do with whether or not the source is used inside or outside of the actual environment.

1.3.1 *Direct Environmental Exposure*

When you navigate in an environment, you extract information both for use on whatever navigation task currently is being executed and for any subsequent navigation task. Exactly what information is useful for navigation? A person can't possibly attend to every stimulus and

make use of it. Much of it is irrelevant or at least of lesser importance. If designers knew what information was the most important, this could be useful in designing virtual environments. Designers would know what to put where to help people find their way around. While there is no clear answer to this question, Kevin Lynch presents the most compelling, environment independent answer to date (Lynch, 1960).

In studying urban environments (Lynch was an urban planner), he found that there are certain similarities across cities. There are in fact “elements” of urban environments, or building blocks, that can be used to construct or decompose any city. He starts with landmarks, which are the most salient cues in any environment. They are also directional, meaning that a particular building might be a landmark from one side but not another. Then there are routes or paths that connect the landmarks. They don’t necessarily connect them directly, but they move you through the city such that the spatial relationships between landmarks become known. A route isn’t necessarily a road. It could also be a bike path or railroad. Cities tend to have complex road and rail structures. Interchanges or junctions between routes are called *nodes*. These are important because they are fundamental to the structure of the routes. This structure must be understood before proficient navigation can take place. Most cities have specific regions that are explicitly or implicitly separated from the rest of the city. These are *districts*. Landmarks and nodes typically are found within districts. Routes pass through districts and connect them. Finally, regions of the city, and in fact the city itself, are bounded by *edges*. Edges prevent or deter travel. A typical edge is a river or lake.

An interesting fact is that classifying some city object as one element or another does not preclude it being classified as something else in another context. To a pedestrian, a walking path is a route, whereas highways and railroads are edges. To a driver, the roads are routes and everything else is an edge. Classification depends on the mode of travel. Furthermore, the mode of travel also affects what gets encoded, not just how it gets encoded (Goldin & Thorndyke, 1982).

1.3.2 Map Usage

There are a number of secondary sources that have been used for spatial knowledge acquisition. These include maps, photographs, videotape, verbal directions, and recently virtual environments. The most common of these is the map. For any map used in any environment, virtual or real, designers need to know when the map is used, or more appropriately, what tasks the map is to be used for. The critical issue is in whether or not the map is to be used preceding navigation or concurrent with navigation. This is important because maps that are used concurrently with navigation involve the placement of oneself on the map. The first part of any task of this nature is: Where am I? What direction am I facing? A transformation is required from the egocentric perspective to the geocentric perspective. If the map is used as a precursor to navigation, it is used only for planning and familiarization. No perspective transformation is required. Planning a trip is one example of such a geocentric navigation task. The planning is done outside of the environment so there is no perspective transformation needed. However, when such a transformation is required, as in using a map during navigation, the problem is more complicated.

When a perspective transformation must be performed, the rotation of the map can have a great effect on performance. Aretz and Wickens (1992) showed that maps used during navigation tasks (egocentric tasks) should be oriented “forward-up” (the top of the map shows the environment in front of the viewer), whereas maps used for planning or other geocentric tasks should be “north-up.” Rossano and Warren (1989) reinforced this concept by demonstrating that judgments of direction are adversely affected by misaligned maps. Levine, Marchon, and Hanley (1984) go on to provide basic principles of map presentation, including aligning the

map with the environment, always showing two concurrent points on the map so the viewer can triangulate position, and avoiding symmetry. Péruch, Pailhous, and Deutsch (1986) showed that redundancy of information is crucial to resolve conflicts between different frames of reference.

The key to map use for navigation is resolving the egocentric to geocentric perspective transformation. This certainly isn't the entire problem, but it is the biggest part of it. This involves the ability to perform a mental rotation. The easier this rotation is, the easier the task. Unfortunately, mental rotation is not a level playing field. Some of us are better at it than others, so much so that it affects the way individuals perform navigation tasks (McGee, 1979; Thorndyke & Stasz, 1980). Everyone knows individuals who maintain a high level of proficiency in navigating environments, including environments that they have never been in before. Alternatively, there are individuals who will get lost on the way home from work if they can't follow their usual route for some reason.

One way to simplify the transformation is to show the viewpoint position and orientation directly on a map. Until recent improvements in global positioning system (GPS) technologies, this was not possible to do in the real world. As of May 1, 2000, the United States no longer jams GPS signals for private use, so GPS is now 10 times more accurate than it was previously. While "dithered" GPS could only place a receiver in an area the size of a football field, it is now accurate to within the area of a tennis court. However, there are no commercially available databases available that make use of spatial data at this resolution. Even if there were, it is still not known what the best uses are for this data in the real world, so it will be some time before a payoff is realized from the declassification of GPS. Automobile navigation systems with moving maps are already commonplace. However, the interfaces to these systems are generally poor. One of the issues looked at later is the use of virtual maps and how they should be presented.

1.4 Representations of Spatial Knowledge

Arguably the most important part of this puzzle is the part understood the least. Once spatial knowledge is acquired, how is it organized in the mind for future use? Spatial knowledge must be organized in some way such that it can be used during navigation tasks. The term "cognitive map" was first used by Tolman (1948) to describe a mental representation of spatial information used for navigation. However, 50 years later, there are still no hard answers about the structure of spatial knowledge.

The representation of spatial knowledge is affected by the method used to acquire it. Knowledge acquired from direct navigation is different from knowledge acquired from maps. After studying a map of San Francisco before an initial visit there, information gleaned from the map is in a north-up orientation, just like the map. Consequently, when entering the city from the north, the mental representation of the city that has been acquired is upside down from what is being seen. This requires a 180-degree mental rotation before the cognitive map can be in line with the real environment. Spatial knowledge acquired from maps tends to be orientation specific (McNamara, Ratcliff & McKoon, 1984; Presson, DeLange & Hazelrigg, 1989; Presson & Hazelrigg, 1984). This implies that accessing information from a misaligned cognitive map is more difficult and error prone than if it were aligned (Boer, 1991; Rieser, 1989).

The longest standing model of spatial knowledge representation is the Landmark, Route, Survey (or LRS) model described by Siegel and White (1975) and Thorndyke and Goldin (1983). This model not only addresses spatial knowledge but also the development process. The theory states that first landmarks are extracted from an environment. These are salient cues but are static, orientation dependent, and disconnected from one another. Landmark knowledge is like viewing a series of photographs. Later, route knowledge develops as landmarks are connected by paths. These need not be optimal paths. At this point, an individual may know

how to get from A to B and from B to C but probably won't know a direct route from A to C. Route knowledge can be thought of as a graph of nodes and edges that is constantly growing as more nodes and edges are added. Finally, survey knowledge (or configurational knowledge) develops as the graph becomes complete. At this point, even if an individual has not traversed every path through their environment, they can generate a path on the fly because they have the ability to estimate relative distances and directions between any two points. This model directly fits the elements of urban environments described by Lynch (1960).

The most important caveat to this development process has to do with the use of maps. Maps allow jumping over the route knowledge level and proceeding directly to survey knowledge because they afford a picture of the completed graph all at one time. However, survey knowledge attained from maps is inferior to survey knowledge developed from route knowledge and direct navigation because of the orientation specificity issue described earlier.

A second model of spatial knowledge is similar to the LRS model, but it is hierarchical (Colle & Reid, 1998; Stevens & Coupe, 1978). In some cases, direct exposure to an environment for extremely long durations never results in survey knowledge (Chase, 1983). In other cases, survey knowledge develops almost immediately. The model proposed by Colle and Reid suggests a dual-mode whereby survey knowledge can be acquired quickly for local regions and slowly for remote regions. The "room effect" comes from the ability to develop survey knowledge of a room rather quickly but survey knowledge of a series of rooms develops relatively slowly and with more errors.

1.5 Models of Navigation

Understanding how navigation tasks are constructed is useful in determining how best to improve performance. If it were possible to decompose navigation tasks in a general way, one might be able to determine where assistance is needed or where training can occur. Several attempts have been made at such a model (Chen & Stanney, 2000; Darken, 1996; Downs & Stea, 1977; Neisser, 1976; Passini, 1984; Spence, 1998), but most are either too specific to one type of environment or another or they do not capture the intricacies of the entire task.

The model proposed by Jul and Furnas (1997) is relatively complete in that it incorporates the motion component into the process in a way not attempted before (see Fig. 24.1). The model works as follows. I am at the shopping mall and decide I need a pair of shoes. I have just formulated a goal. Now, how should I go about finding shoes? I decide to try the department stores. Department stores are typically on the far points of the mall. I have just formulated a strategy. The next step is to gather information so I don't walk off in a random direction. I decide to seek out a map of the mall. I am acquiring information and scanning (perceiving) my environment. This is the tight wayfinding/motion loop referred to earlier. I view my surroundings, assess my progress toward my goal, and make judgments as to how to guide my movement. At any time in this loop, I may decide to stop looking for shoes and look for books instead. This is a change in goal. I could also decide to look for a small shoe store instead of a department store. This is a change of strategy. In any case, the task continues, shifting focus and process as necessary.

An important point is that navigation is a situated action (Suchman, 1987). Planning and task execution are not serial events but rather are intertwined in the context of the situation. It is neither possible nor practical to consider the task, the environment, and the navigator as separate from each other. Observable and measurable behavior is a product of these factors, yet the relationships between them are, as yet, poorly understood.

In the real world, this process is performed so often that it is typically automatic. When one knows where they want to go, they go there. When they don't know where to go, they ask someone or look for some other source of assistance. Virtual environments are entirely different.

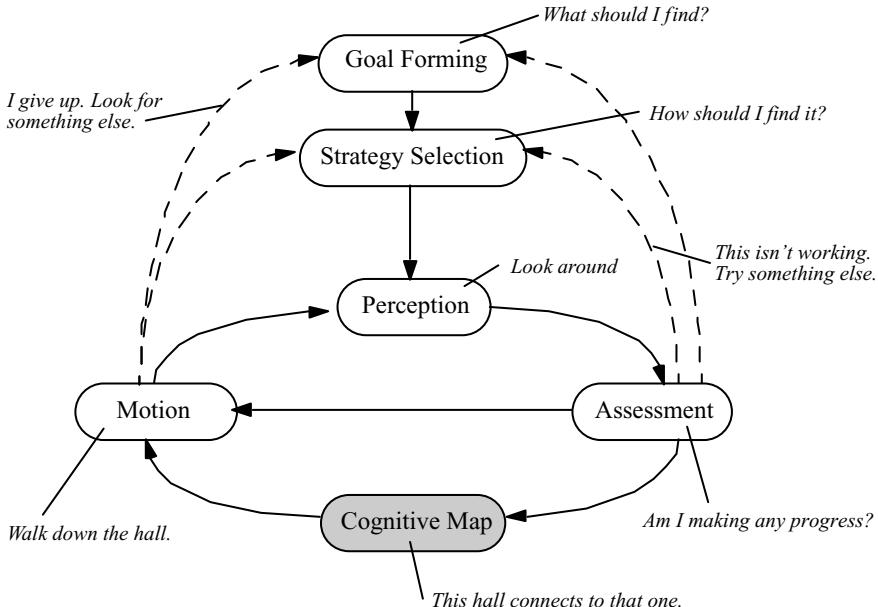

FIG. 24.1. A model of navigation adapted from Jul and Furnas (1997).

Movement is not typically so easy. It requires thought. Knowing where to go is problematic. Who can be asked for help? How can one get unlost? These are the issues discussed next.

2. NAVIGATION PERFORMANCE ENHANCEMENT

The ease with which one can navigate depends on the environment traversed. For example, many of the physical environments that the navy must operate in are inherently sparse and consequently difficult to navigate. Literal virtual representations of these environments are even harder to navigate considering that the number of cues available is diminished even further. Early prototypes provided valuable lessons in how difficult navigation can be. Whereas open-ocean naval applications might be on the more difficult end of the complexity scale, problems can arise in any application. This section will look at ways to help people navigate a virtual space without regard to whether or not their improved performance transfers outside of the virtual environment.

The most obvious way to address navigation problems in complex VEs is to provide some sort of tool or mediator that can be used directly on the task at hand. This, of course, is the history of the map, the compass, the sextant, and the chronometer, to name a few real-world tools. Used together, these tools are able to help their users determine their position in the environment, their direction of travel, and the relative position of other objects or places in the environment.

An alternative to mediators is the actual organization of the space itself. There are a few real-world vocations related to this including architectural design and urban planning, each of which has extensively studied the relationship between people and their environment. They are interested in much more than just navigation, of course, but there is much to learn from these disciplines about how to construct space in a meaningful way in which people can comprehend and operate effectively. In VEs where the contents of the environment cannot be changed, such as in a flight simulator, there is not much that can be done in the way of spatial organization.

However, in other applications, such as many scientific visualizations, it is possible to organize the data expressly for the purpose of navigability.

2.1 Navigation Tools and Mediators

This section discusses a number of navigation tools and mediators that have been investigated in our laboratory. Although they are similar to others in the literature, it should be noted that our intent is to investigate principles for the design of navigable virtual environments, not merely new techniques. It is unlikely that one of these tools as described here will perfectly match the needs of a real application, but by explaining how certain types of information affect behavior and its related performance, designers can mix and match the techniques described here and elsewhere to construct custom built tools specifically for the demands of their application.

2.1.1 *Maps*

The navigation mediator people are most familiar with is the map. Maps are extremely powerful tools for navigation because of the wealth of information they can provide and the rate at which people can digest this information. However, their use in any VE application is not to be taken lightly. There are right ways and wrong ways to use maps. Maps come in a variety of forms, the differences usually being in terms of symbology or projection. However, VEs have certain qualities the real world does not have that make the use of maps in VEs different.

It is possible to navigate directly on a map in a virtual environment. Rather than use the map to determine where to go in the virtual environment, why not just point on the map to where you want to go? This has been attempted several times. The Worlds-in-Miniature (Stoakley, Conway, & Pausch, 1995) metaphor was one such implementation. In this case, a scaled-down version of the world, a virtual map, was held in the hand. Movement could be specified directly on the virtual map. This same behavior is possible in some video games. DOOM (Id Software, Inc.) allows movement to take place while viewing a map. The environment cannot be seen during this interaction. Similarly, the use of maps can be a moded or unmoded task in a virtual environment, meaning that its use can be in lieu of, or concurrent with, motion. In the real world, it is typically unmoded. Under certain conditions one might want to stop moving to read a map, but it is not required. Some games and VEs mode maps so that map use precludes motion.

For maps of very large virtual environments, there is a scaling problem. How do I view the map such that I can see the detail I need to navigate but still maintain a sense of the overall space? This is a classic problem of navigation in any problem domain (e.g., Donelson, 1978; Furnas, 1986). There are ways to zoom into a map or otherwise scale it to a usable level. One advantage of VEs is that often the problem only concerns maintaining one perspective—your own. In applications where I might need to not only know where I am but also where other people are as well, the problem gets considerably harder. Street Atlas USA (DeLorme, Inc.) is an excellent example of an application addressing this issue. As one zooms into the atlas to the street level, context is lost. Consequently, there is always an overview window available.

The last issue discussed about maps, and the primary focus of this section, has to do with the orientation of the map. As discussed earlier, the orientation of a map with respect to the viewer has a strong effect on the viewer's ability to perform the mental rotation required to use a map during navigation. However, if it is already known that forward-up maps are best for egocentric tasks and north-up maps are best for geocentric tasks, isn't this a moot point? The fact that most video games continue to use north-up maps is enough to warrant investigation.

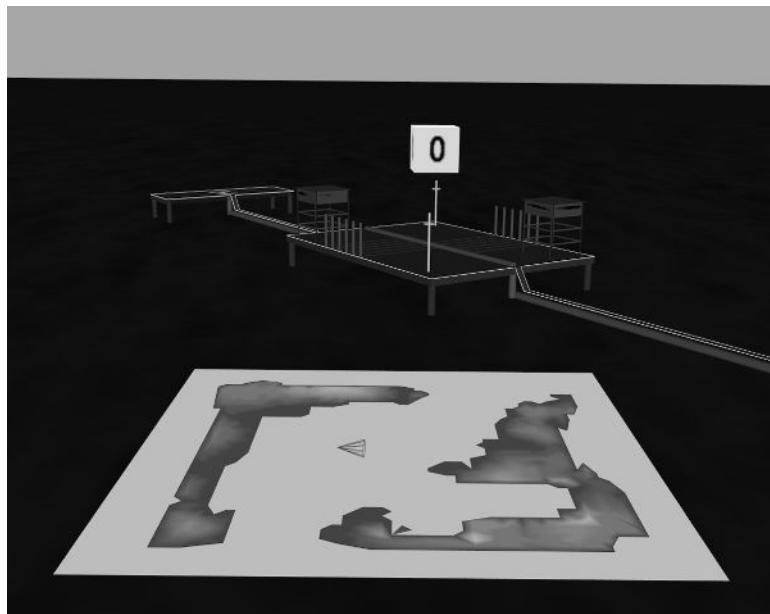

FIG. 24.2. The north-up map configuration has a directional cone for the you-are-here indicator. The top of the map always stays at the top. It is aligned with the viewer, not with the environment.

Is it possible to put enough redundant information on a north-up map to make it equivalent to a forward-up map?

To investigate this issue, we created two very large virtual environments. One was a sparse open-ocean environment and the other was an urban environment (Darken & Cevik, 1999). Both a head-mounted display and a Fakespace PUSH display were used with similar results. The results reported here are using the PUSH display. Participants were asked to locate objects in the spaces. Sometimes they were shown the targets on the map (a targeted search), sometimes they had to return to known targets that were not shown on the map (a primed search), and other times they had to locate a target not shown on the map and not seen before (a naive search). Performance was timed, and wrong turns where participants clearly moved away from a target rather than toward it were marked. At the conclusion of each trial, participants were asked to sketch a map of the environment from memory.

We created two virtual maps; one was in a north-up configuration (see Fig. 24.2), the other was in a forward-up configuration (see Fig. 24.3). Both maps had a “you-are-here” marker that dynamically moved across the map as the user moved through the environment. The only difference on the maps, besides their orientation, was that the you-are-here indicator on the north-up map was a cone, whereas the you-are-here indicator on the forward-up map was a small sphere. This was necessary because a north-up map does not indicate direction implicitly while the forward-up map does.

What we found was comparable to the results of Aretz and Wickens (1992) but to a lesser degree. The forward-up configuration seems to indeed be best for egocentric navigation tasks, whereas the north-up map is best for geocentric tasks. The results also indicated that individuals with high spatial abilities (as measured with the Guilford-Zimmerman standardized tests) are able to use either type of map better than participants with low spatial abilities on similar tasks (see also chap. 50, this volume). Furthermore, these principles were found to apply across different types of environments with vastly different spatial characteristics, but sparse

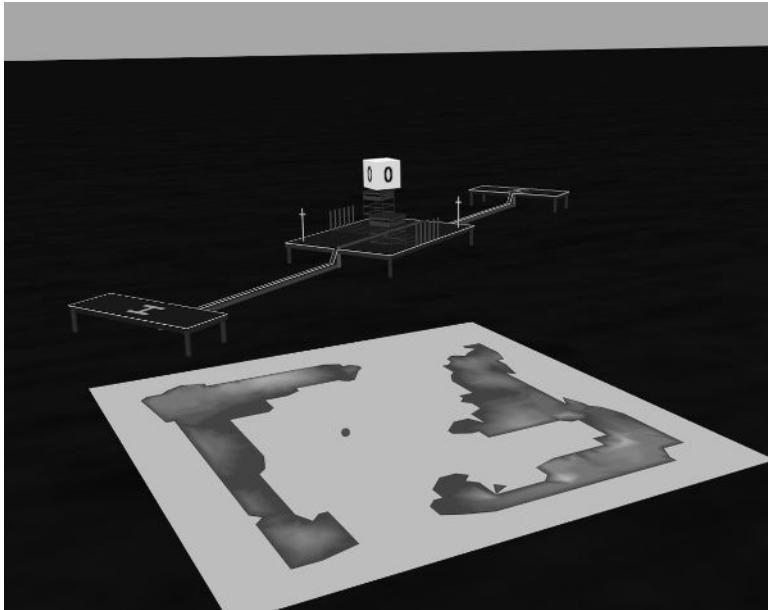

FIG. 24.3. The forward-up map configuration has a small sphere in place of the cone for a you-are-here indicator. This map rotates with respect to the viewer as the viewpoint is rotated in the environment. It is aligned to the environment, not the viewer.

environments seem to exhibit less of a performance difference than dense environments. Virtual environment designers should make virtual map decisions by carefully weighing the priorities of navigation tasks versus the spatial ability of their users.

Interestingly, in asking participant's subjective assessment, most preferred the north-up configuration even if their performance did not correlate. In postevaluation debriefing, most of these people reported maintaining a strong bias based on video game play. Regardless of how they perform, they like what they are comfortable with. This complicates the problem. This study seemed to indicate that while the forward-up map was better for egocentric tasks, it was not so much better that we would advise ignoring the preferences of users. It will be imperative in the future to examine the effects of exposure to video games on performance of navigation tasks in virtual environments.

2.1.2 *Landmarks*

Landmarks are extremely important to spatial knowledge acquisition and representation. As such, it might be useful to allow users to affect the placement of landmarks themselves. If landmarks are useful as "anchors" on which to relatively place other objects, what would happen if the locations of the objects remained constant but users were allowed to insert highly salient landmarks on which to anchor their locations?

Using the open-ocean environment as before, participants were given a set of ten different colored markers to place on the surface of the environment at any position. These markers were visible from a far greater distance than the objects themselves. Where might the markers be placed and how would this might affect performance?

Markers tended to be placed in-between objects such that as one marker would disappear from view, another would appear on the horizon. Moving between markers and objects, the participant could always have something to "hold on to" much like a "handrail" is used in

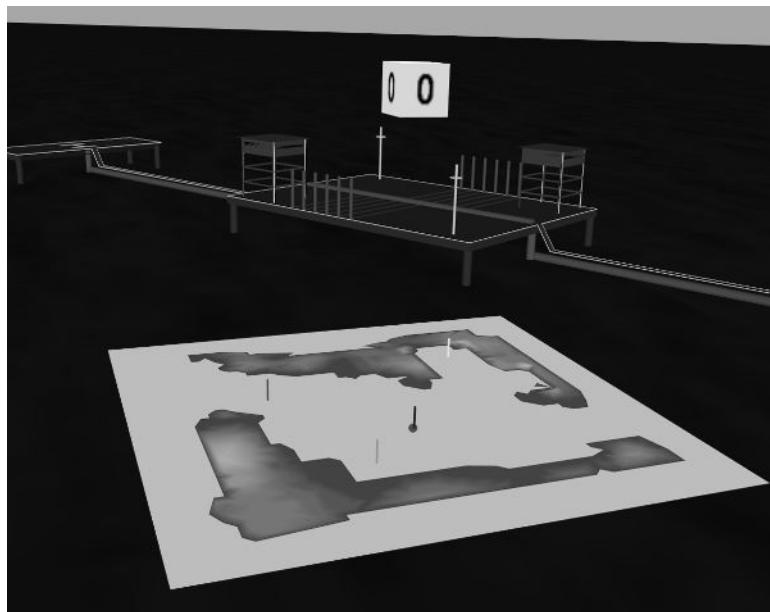

FIG. 24.4. This map shows a user returning from finding a number of objects. The markers are used like pushpins to show where targets were located. Before leaving the virtual world and beginning the map drawing task, the participant would simply remember the configuration of markers on the map.

sport orienteering. (Note: A *handrail* is a linear feature, such as a stream or road, that land navigators use to guide movement. They typically use it to constrain movement, keeping it to one side and traveling along it for some distance.) For most individuals, being in a void, even a partial void like sometimes occurred in this environment, is very uncomfortable. Most people need regular reassurance that they are not lost. Only the most advanced navigators do not seem to need this kind of assurance.

The same condition was studied in combination with a forward-up map (see Fig. 24.4). As participants would place a marker, it would appear both in the environment and on the map. Would the strategy remain the same or would the map override the utility of the markers?

This turned out to be unquestioningly the preferred condition of every approach explored to date. The reason is simple. Participants still were not given any help in locating target objects. As they found them, however, they no longer had to remember anything about them. They simply placed a marker at each object. The markers in the environment were not used at all, but the markers on the map were like colored pushpins. They simply had to remember what color coincided with the corresponding target, making the posttrial map drawing exercise trivial.

Certainly one might devise other techniques that may fare better than this condition, but it is our intent to study methods that can generalize to many navigation tasks in any type of environment rather than only to specific tasks and environments. The objective is to determine design principles so that application designers have a starting point from which to develop specific mediators for their specific tasks in their specific environments.

2.1.3 *Trails*

Since participants used the markers to create a sort of “trail” connecting objects with markers and other objects, it brought to mind an old idea. If a trail was left behind such that it specified

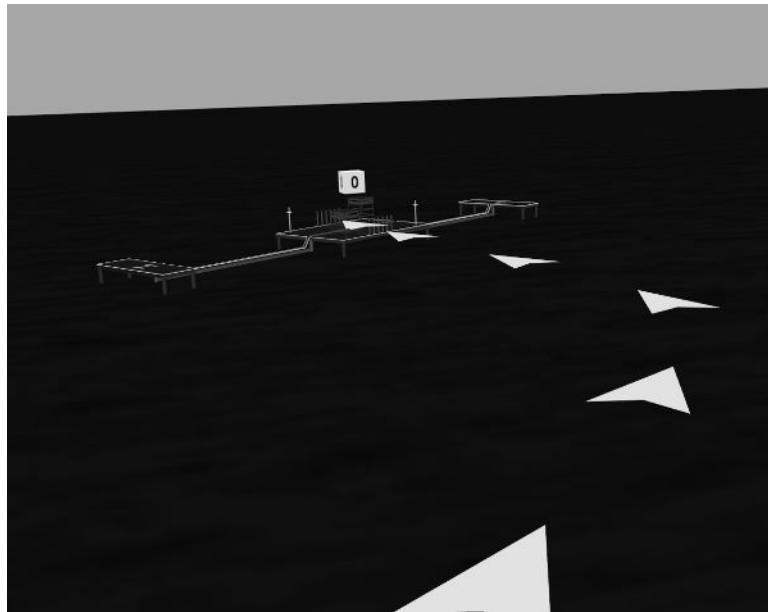

FIG. 24.5. In this example, the participant has moved backward and is looking toward the start object location. The footprints show the direction the user was looking at that point in time.

not only where the participant had been but what direction they were going at that time, this might be an even better tool than the markers (see Fig. 24.5). This was called the “Hansel and Gretel” technique (Darken & Sibert, 1993). A better analogy is that of footprints since footprints are directional and breadcrumbs are not.

This technique is useful for scanning space in an exhaustive search (e.g., a naive search). One of the problems in an exhaustive search is knowing if you have been in some place before. An optimal exhaustive search never revisits the same place twice, assuming the targets are not moving (ours weren’t). However, it might be useful to retrace steps if disorientation occurred. This was not, however, found to be the case. As navigation proceeds, the environment becomes cluttered with footprints, so much so that the directional component is ignored. Also, when the user crosses paths, how does the user disambiguate which ingress route goes with which egress route?

As with the markers, this was tried with a forward-up map (see Fig. 24.6). Similarly, it was found that participants ignored the footprints in the environment, only using the trail left on the map to help direct the search.

2.1.4 Direction Finding

So far, a number of tools and mediators have been discussed that deal with absolute position information. Maps show exactly where the user is at all times. Markers specify an exact location in an environment. Each footprint designates an exact location as well. What about orientation? How important is it to know absolute direction versus absolute position?

To study this, two simple tools were derived, both of which show nothing more than direction. Even though our environments did not have a “north,” it was decided to make the initial view direction be north. It did not matter what was designated as north as long as it was done consistently. The compass in Fig. 24.7 always points to virtual north; it floats out in front of the viewpoint similarly to the maps discussed earlier.

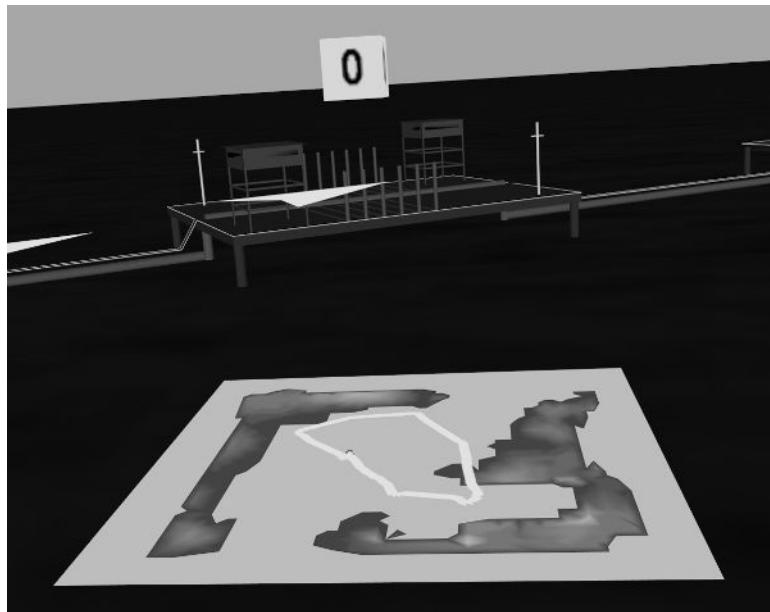

FIG. 24.6. This participant has made a cycle through the environment. The actual positions of the target objects are not shown on the map. The participant must remember where along the path they were located.

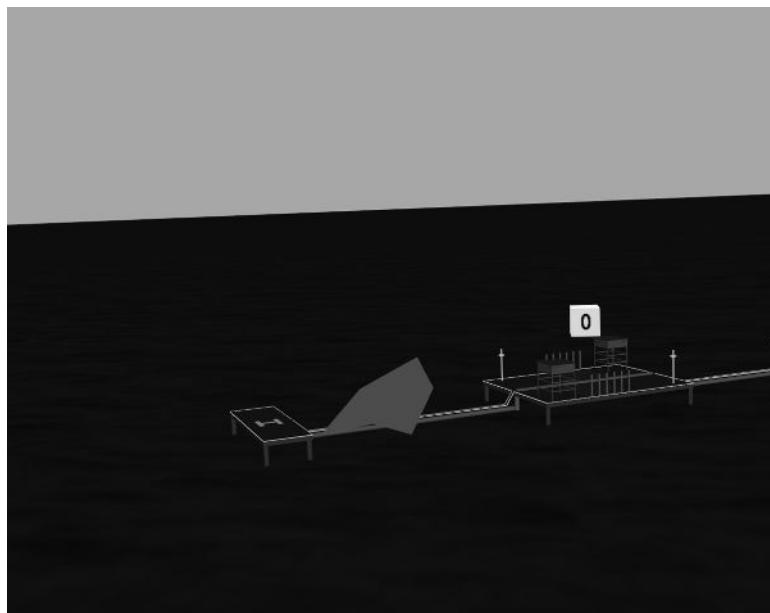

FIG. 24.7. The compass simply shows the direction that the participant was facing at the onset of the trial.

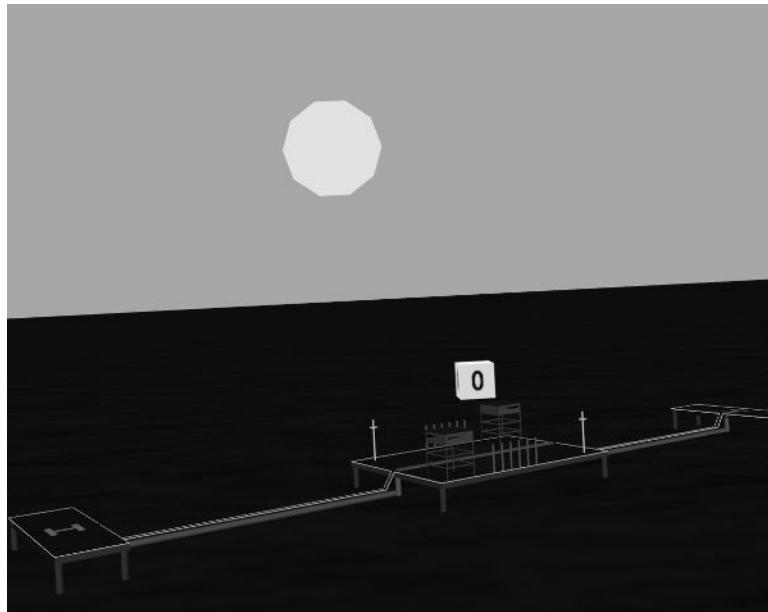

FIG. 24.8. The sun is positioned low on the horizon so directional information will be clear and unambiguous.

The second tool implemented was a virtual sun. This was placed on the horizon such that it would identify one direction only (see Fig. 24.8). It was up to the participant to call it east or west. This never seemed problematic.

The task was the same as it was for every other condition. The results indicated that the compass was preferable to the sun because it was in view all the time, versus the sun that required the participant to turn toward it. However, performance using both of these tools was very low as compared to the other conditions studied. In fact, performance on both of these conditions was not significantly better than the control condition where no assistance was given whatsoever. The reason for this is that while maintaining spatial orientation is essential to all navigation tasks, orientation without position information is not useful. Similarly, position information without orientation information is equally limited in utility as shown by the “coordinate feedback” tool described by Darken and Sibert (1993).

2.2 Organizational Remedies

It could be said that the tools and mediators described in the previous section should be the last recourse of the designer if all else fails. That is, if the constraints of your application are such that you simply cannot develop a navigable VE that does not need tools or mediators for usability, then you need to determine what tools are most appropriate to allow any user to navigate effectively. However, there are many applications where it is not appropriate or even possible to organize a space because the positions of objects in the space are constrained in some way. For example, if a VE driving simulation of metropolitan Los Angeles is being constructed, designers have no control over the positions and orientations of buildings and streets. If, alternatively, a VE visualization of the stock market is being constructed, designers would have control over how objects looked, where they were located, and how they were organized.

This section will discuss two primary methods for organizing spaces for navigability. The first relies heavily on Lynch's "elements" of urban landscape where the environment is implicitly organized (Lynch, 1960). The other involves a more explicit organizational technique where a specific pattern is forced on the space itself.

2.2.1 Implicit Sectioning

Passini (1984) talks about the use of an "organizational principle" in architectural design. If a space has an understandable structure and that structure can be made known to the navigator, it will have a great influence on the strategies employed and resulting performance on navigation tasks. For example, knowing that Manhattan is generally a rectangular grid is of great benefit to any navigator. Given the knowledge of the grid and its orientation, words like "uptown" and "downtown" instantly have meaning. But while there is great power in using such an organizational principle, there is a danger that goes along with it. Violations to that principle will have a much greater negative effect than they might otherwise have. For example, Manhattan is generally a grid, but Broadway cuts through on an angle, thus violating the grid principle. A naive tourist thinking that the grid principle held throughout will probably be misled at some point. It is important to develop a clear organizational principle and stick to it throughout the environment. If it must be violated, it should be made clear where the violation occurs and that it is a violation; otherwise, the navigator may attempt to erroneously fit it into a cognitive representation.

Organizational principles can also add meaning to cues that might be seen during navigation. Again using the Manhattan example, if a tourist is looking for 57th St., street signs for 44th St., 45th St., and so forth not only tell which is the correct direction but also give a rough estimate of distance as well.

There have been attempts to apply Lynch's elements of the urban landscape to virtual environments (Darken, 1996; Ingram & Benford, 1995). In principle, this will work, but implementations can seem contrived as if an inappropriate structure is being forced on abstract data. It may be that the very generic nature of VEs might demand a different set of elements similar to Lynch's but not necessarily identical.

Darken and Sibert (1996) commented that people inherently dislike a lack of structure. A person who is in an environment that is nearly void of useful cues and that does not suggest ways to move through it is generally uncomfortable. Users will grasp at anything they can view as structure whether or not the designer intended it to be that way. In our earlier experiments, participants were observed using coastlines and the edges of the world as paths even though this was not a particularly effective strategy toward completion of tasks. People adopted these cues because they were all they had to work with. If even a simple bit of structure is added such as a rectangular or radial grid (described in the next section), performance immediately improves. A path should suggest to the navigator that it leads to somewhere interesting and useful.

It is common to see urban metaphors applied to unstructured environments such as Web sites because the structure of a city can add meaning to information that may otherwise be viewed as amorphous. This works in many cases even when there is no obvious semantic connection between the information presented and the city metaphor. In other cases, this fails because the constraints implied by an urban landscape do not coincide with the constraints of the information presented. This should be used judiciously. Using a metaphor to simplify navigation may unknowingly inhibit some other piece of functionality. Therefore, it is important when studying user performance in these types of applications to study the whole task, not just the navigation component. Again, navigation is not an isolated action but is situated in some other higher order task.

2.2.2 *Explicit Sectioning*

In some cases, like our open-ocean environment, there are simply too few objects in the environment to organize into a navigable environment. In these cases, the space can be explicitly organized using explicit cues. We experimented with two sectioning schemes based on Lynch's ideas of "districts" and "edges" and also using a simple organizational principle as described by Passini.

The first scheme tried was a radial grid. A radial grid was placed over the open ocean environment. There were highly salient landmarks in each cardinal direction and a single landmark in the center. The second scheme used was basically the same idea but was a rectangular grid rather than radial. Again, highly salient landmarks were placed in the cardinal directions and the center.

The results indicated that search strategies for these two schemes were quite different but that performance between the two was not significantly different. The radial grid tended to elicit strategies having to do with "pie slices" or similar ideas (i.e., strategies within the radial grid condition tended to focus on the center landmark, moving through each "pie slice" sequentially until targets were found), whereas the rectangular grid produced more "back and forth" motions within bounded regions. The nature of the task or environment would probably dictate which was better in a particular situation. In our case, the difficulty of the task without any aids caused performance to increase for both grids. Observed strategies were clearly related to the type of grid presented. In a given situation, if a particular strategy is clearly preferable over alternatives, structure such as this can be used to guide the user toward the preferred method. As observed in our experiments, there will almost always be room for unexpected behavior. It is possible, given a well-defined task, to design in a desired tendency.

We then experimented with combining the grid overlays with the map tools previously described (see Fig. 24.9). This was found to be highly effective, particularly with the forward-up map because the map provided directional information and survey knowledge, whereas the

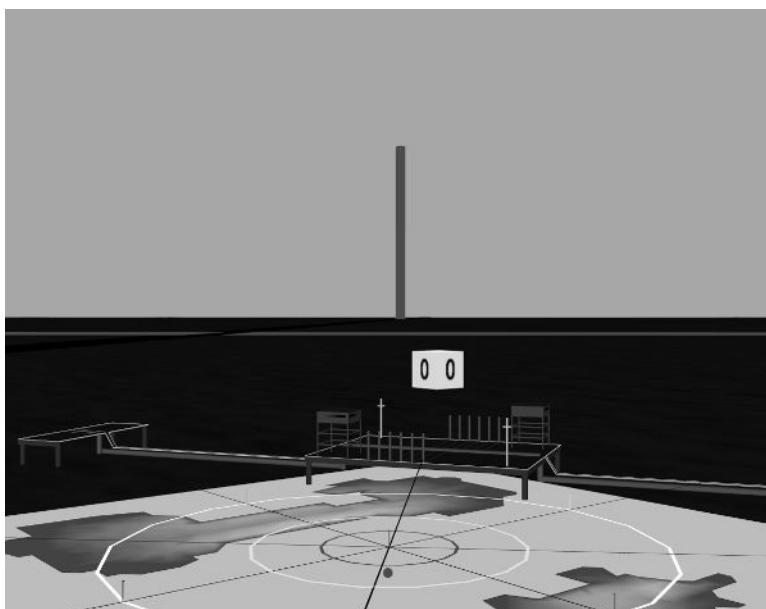

FIG. 24.9. The radial grid superimposed on a forward-up map. There is a wealth of information in this environment to help in navigation.

grid provided directional cues and landmark knowledge. Some participants tended to focus more on the map than the grid or vice versa but, in general, the two were used in combination as intended.

3. ENVIRONMENTAL FAMILIARIZATION

Imagine that you could visit places using a VE before you actually got there. If it were a vacation spot or resort, you might want to see if you like the views, beaches, or anything else that might catch your interest. If you were planning to drive into a city you have never been to before, you might plan a route using a conventional map and then drive your route in the VE to become familiar with distances and key landmarks. If you were a soldier about to enter a hostile environment, you might use a VE to rehearse a planned route and familiarize yourself with the area.

In each of these examples, the VE in question is not a mere abstraction but is a representation of a real environment. In each case, the interest is not in how well the user navigates the VE but rather in how they navigate the real world after exposure to the virtual environment. This section will examine several empirical studies involving the use of VEs for environmental familiarization. Studies of this kind are central to the topic of this chapter for two primary reasons:

1. Such investigations highlight the differences between navigation in the real world and in virtual environments, whereas studying VE navigation alone does not. Studying behavioral differences between virtual and real world navigation may provide insights to help us better understand and model human navigation, virtual or real. People know how to navigate in the real world. They bring this knowledge with them into virtual environments. While this does not mean that VE navigation must replicate real world navigation in every way, it makes sense that one needs to understand how humans navigate in the real world before they can optimize methods for navigation in the virtual environment.

2. Although the potential use of VEs to enhance training for real-world performance of many tasks has been touted from the inception of the technology, few application domains have clearly demonstrated a significant enhancement. Environmental familiarization (or mission rehearsal) is among these applications. In fact, a close inspection of the literature will lead to the conclusion that there is much confusion over whether or not VEs offer a significant enhancement over traditional methods of spatial knowledge acquisition. Furthermore, even if they were known to be useful, it is still not known exactly how they should be used to optimize the positive effects desired while minimizing negative effects (e.g., reverse training). Transfer of spatial information might be a near-term training domain that is within the reach of current technology. Environmental familiarization may represent a microcosm of the issues involved in virtual training of any knowledge domain.

A key aspect of the studies presented in this section is that performance measures are made in the real world to evaluate how much spatial information was acquired in the VE or how the VE may have affected behavior. This is not to say that measurements are never made in the virtual environment, only that without real-world measurements, one cannot know what affect, positive or negative, the VE tool may have had on participants.

3.1 Spatial Knowledge Transfer Studies

To ground this investigation, four actual studies are compared. There are many more studies of this type in the literature but a subset have been selected for presentation here. Each of these

is a transfer study implying that there is a training phase involving a VE of some type and a testing phase involving transfer to the real environment. The focus here is only on studies about environmental familiarization rather than skill development so the VE must replicate a specific real environment rather than some generic real environment such as learning to navigate in a generic city.

The purpose of this comparison is to systematically point out the similarities and differences in the studies so that some statement can be made about what is currently known about the use of VEs for environmental familiarization. An issue that will become very clear is that there is little consistency in the literature about what to study or how to study it. Consequently, one sees a variety of experiments controlling a variety of parameters but in a way that it is difficult, if not impossible, to leverage what was done previously.

Four experiments will be briefly discussed, concluding with a discussion of environmental familiarization and how VEs might be used for these tasks. The experiments are:

- Witmer, Bailey, and Knerr (1996), *Virtual Spaces and Real World Places: Transfer of Route Knowledge*
- Darken and Bunker (1998), *Navigating in Natural Environments: A Virtual Environment Training Transfer Study*
- Koh, von Wiegand, Garnett, Durlach, and Shinn-Cunningham (2000), *Use of Virtual Environments for Acquiring Configurational Knowledge About Specific Real-World Spaces: Preliminary Experiment*
- Waller, Hunt, and Knapp (1998), *The Transfer of Spatial Knowledge in Virtual Environment Training*

3.2 A Basis for Comparison

In an attempt to make a meaningful comparison between these experiments, each is looked at in terms of a structured set of parameters. The key elements for this comparison are: (1) the characteristics of the human participants; (2) the characteristics of the environment; (3) the characteristics of the tasks to be performed; (4) the characteristics of the human-computer interface; and (5) the characteristics of the experimental design to include dependent measures. Table 24.1 is a summary of the four experiments in terms of these elements.

Each experiment investigated human navigation performance, and the characteristics of the participant sample must be taken into account. Traditionally, important issues such as the quantity, age, and gender of the participants are considered. However, navigation is a specialized task, so two specific differences may be quite critical. First, some of the experiments situated the navigation task within a higher level task context. In those cases, participants' experience in the respective domain could be expected to influence both motivation to participate and task competence level. Second, individuals enter the experiment with a given level of innate spatial ability (see chap. 50, this volume). Although measures of individual spatial and navigation ability may provide ambiguous results, attempts to quantify and categorize participants based upon individual ability can help to explain differences in performance.

The real-world environment that is modeled in the VE influences navigation behavior. Just as individuals possess differing navigation ability, so do various environments afford different navigation experiences. Some real-world environments simply provide more navigation cues than others do. Furthermore, some environments lend themselves to a higher model fidelity level than others. How closely a VE matches its real counterpart is referred to as "environmental fidelity" (Waller et al., 1998). However, do not assume that higher environmental fidelity must correlate with higher performance. There are other issues that are equally important.

With so many varieties of VEs and their associated interfaces, it is necessary to be more descriptive in terms of the specific differences between them. The devices and interaction styles

TABLE 24.1
A Comparison of Training Transfer Studies

<i>Experiment</i>	<i>Participants</i>	<i>Environment</i>	<i>Tasks</i>	<i>Interface</i>	<i>Measures</i>
Witmer, Bailey, & Knerr	No domain expertise	Architectural, structured	No maps used, 15-minute repeated exposure, route replication	Immersive display, buttons	Wrong turns, bearing/range estimation, time
Darken & Bunker	Domain expertise	Natural, unstructured	Maps used, 60-minute exposure, route planning and execution	Keyboard, mouse, desktop display	Deviation from route
Koh, Durlach, & von Wiegand	No domain expertise	Architectural, structured	No maps used, 10-minute exposure, survey knowledge	Both immersive and desktop displays, joystick	Bearing/range estimation
Waller, Hunt, & Knapp	No domain expertise	Structured	No maps used, 2 or 5 minutes exposure, route replication, path integration	Both immersive and desktop displays, joystick	Time, bumps into walls

used by the system provide differing levels of sensory stimulation to the user. How closely a VE interface matches the interface to the real world (e.g., walking, driving, etc.) is referred to as “interface fidelity” (Waller et al., 1998). Again, do not assume that higher interface fidelity equates to higher performance or training transfer. This has not yet been established, and it is unclear if this will eventually be found to be the case.

Desktop VEs channel visual output to a computer monitor that rests on the desktop (see chap. 12, this volume). Immersive VEs use a head-mounted unit or projection system to display the world to the user. Still, within both desktop and immersive categories, the mix of input and output devices requires a more detailed description. The power of the system to deliver high-fidelity multimodal output and monitor user input commands in real-time is a critical discriminator. The primary issue with interface fidelity in the studies concerned with here has to do with the motion technique, specifically, what interaction method is used to control speed and direction of travel (see chap. 11 and 13, this volume). Finally, some interfaces provide the user with special abilities and computer-generated tools that further differentiate one from another.

Experimental tasks, conditions, and standards differ across experiments. Since transfer studies consider both the training task and the testing task, both cases must be considered. The experimenter’s instructions to the participant will constrain task performance. Two items of interest are the procedures and the dependent measures. Other items of consideration include the use of maps and exposure duration to the virtual environment.

Although the experiments investigate a wide range of issues related to knowledge transfer, the central issue is what is learned and how it is applied to the real environment. The level of spatial knowledge acquired is of particular interest. A study that develops route knowledge but then tests survey knowledge may mislead the reader to believe that some other factor was the cause of low performance. Even if a system had the right interface and the right level of fidelity for a given rehearsal task, it can be used incorrectly resulting in poor performance on the transfer task in the real world.

3.3 The Experiments

Witmer et al. (1995) were among the first to show that a VE could be useful for spatial knowledge acquisition. They compared a VE to the real world in an architectural walk-through application. They used an immersive display, and their population was a random sampling without any expertise on the task. Gaze-directed movement using buttons on the display controlled motion.

The experimental protocol divided the session into four stages: individual assessment, study, rehearsal, and testing. During the individual assessment stage, participants responded to numerous questionnaires, some of which probed their sense of direction and navigation experience level. Next, regardless of experimental treatment condition, every participant was given 15 minutes to study written step-by-step route directions and color photographs of landmarks. Half of the participants in each treatment condition were also provided a map of the building as a third study aid. Following the 15-minute study stage, each participant rehearsed the route three times, either in the VE or the real world depending on their group. All participants were required to identify six landmarks on the route, and researchers provided immediate correction if a participant made a wrong turn or misidentified a landmark. Finally, participants were tested in the real building, and were asked to replicate the route they had learned and to identify the six landmarks. The route replication measures included attempted wrong turns, route traversal time, route traversal distance, and misidentified landmarks. Configurational knowledge was tested by requiring participants to draw a line on a map from their known location to an unseen target.

This study effectively showed how landmark knowledge could become route knowledge, but survey knowledge was not given the opportunity to develop. Survey knowledge takes time to develop by primary exposure to an environment. Exposure times for this experiment were not long enough for this to occur. Nevertheless, this study effectively provided optimism that the technology could work for this purpose, but not how well or under what conditions.

Darken and Bunker (1998) studied how a VE might be used as an augmentation to traditional familiarization methods. They compared performance of three groups: a map-only group; a VE group that also had the use of the map; and a real-world group that also had the use of the map. The interface to the VE was a desktop display controlled with a keyboard. The environment used was a natural region of central California with a few man-made structures but largely vegetation and rough paths (see Fig. 24.10). They used a participant population with specialized knowledge of the task, specifically sport orienteers and experienced military land navigators.

The experimental session was comprised of two phases, planning/rehearsal and testing. During the planning/rehearsal portion of the session, which lasted 60 minutes, participants studied and created a personal route from the starting point to nine successive control points. By the end of the planning phase, participants were required to draw their planned route on the map. Testing involved execution of the planned route in the real environment without the aid of the map or compass. As the participant navigated the real-world course, the researcher followed, videotaping participant behavior with a head-mounted camera. A differential GPS unit worn by the participant recorded their position every two seconds. This information was used to measure the quantity of unplanned deviations from the route and total distance traveled. In addition, the frequency of map-and-compass checks was recorded as a dependent measure.

This study is unique in many respects. It required the participants to plan their own routes rather than practice a given one. This serves to develop survey knowledge since alternative routes must be explored. They also attempted to introduce individual experience as a factor in addition to spatial ability. Since the task was specific to a particular domain, experience on these types of tasks should have an effect.

FIG. 24.10. The top image is a photograph from the testing area in the former Ft. Ord, California. The bottom image is a snapshot from virtual Ft. Ord at that exact location.

The results show that only intermediate participants seem to improve with the use of the virtual environment. Beginners have not yet developed enough skill at the task to be able to make use of the added information the VE offers, and advanced participants are so highly proficient at map usage that the VE simply does not add much information they cannot gain in other ways. In a complex environment such as the one studied here, even the hour of exposure provided did not seem to be enough. Given very short train-up times, maps still seem to be the best alternative for spatial knowledge acquisition.

Koh et al. (2000) expanded previous work by specifically looking toward the development of configurational knowledge in architectural environments. In their experiment, they compared a real-world group, an immersive VE group, a desktop VE group, and what they call a “virtual model” group that is similar to a noninteractive World-in-Miniature, which is held in the hand. They used a general population sample and varied the interface to the VE, as described by the group (immersive or desktop). In the two VE conditions, participants controlled their motion direction and speed with a joystick. The desktop group viewed a typical computer monitor. The immersive group members wore a head-mounted display. Their heads were tracked, and head rotation updated the visual scene, although gaze direction was not linked to the direction of travel.

The experimental sessions were split into three phases: administration, training, and testing. During the administrative phase, the participants were informed about bearing and distance estimation tasks, although the specific stations and targets were not disclosed. Participants in the three non-real-world groups then were provided a period of time to familiarize themselves with the interface. Training consisted of 10 minutes of free exploration under the assigned treatment conditions. The members of the real-world group explored the real building and members of the VE groups explored the synthetic building. Testing was specific to configurational knowledge.

Participants were asked to estimate distances and bearings to unseen targets in the real world while being transported from place to place while blindfolded in a wheelchair.

The purpose of this study was to specifically focus on the development of configurational knowledge. The experimenters were not interested in landmark or route knowledge, although they do reference the hierarchical landmark, route, and survey model. Furthermore, the researchers pronounced a bias that higher fidelity experiences may not necessarily lead to better transfer of knowledge, hence the use of three different fidelities in different configurations. Their results show that the VE conditions developed configurational knowledge at a comparable level to the real world.

Waller et al. (1998) used six different conditions based on the practice method. The conditions were real world, map, no-study, and three different virtual groups (desktop, short-duration immersive, and long-duration immersive). The environment was a maze constructed of full-length curtains with targets placed at selected locations. They also used a general population sample with no specific experience in these tasks.

All participants in VE conditions controlled their motion using a joystick, and the immersive groups both used a head-mounted display. The short-duration immersive group spent a total of 12 minutes in practice, while the long-duration immersive group spent a total of 30 minutes in practice over repeated trials.

The experimental protocol was comprised of four phases. The first was administrative and included proctoring of the Guilford-Zimmerman spatial abilities test. The second phase tested route knowledge by interleaving practice and testing six times. The participant would make a practice run followed immediately by a testing run. The third phase tested survey knowledge. The experimenter altered the configuration of the maze so that portions of the learned route were now blocked. The blindfolded participant then had to find a new route from one location to another. Dependent measures for both phases two and three included time to traverse the route and quantity of times the participant bumped into a wall. Finally, in the last phase, participants completed a pencil-and-paper test of their configurational knowledge.

This study showed that maps were just as effective as short durations of training but that if enough time was given, the VE did prove to be more effective, to the point of surpassing the real-world condition.

The graph in Fig. 24.11 attempts to explain these results. Note that these curves are hypothetical, because all the training transfer studies in the literature cannot be directly compared, and even if they could, there are far too few data points to establish the shape of the curves. Based on this research, however, it is suggested that given a short exposure duration, maps are better than any VE alternative simply because they do not overload the user with information that cannot be absorbed. However, the map is only useful to a point. Given enough

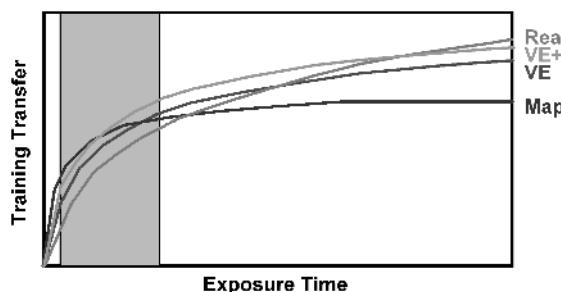

FIG. 24.11. This graph shows a hypothetical picture of how spatial knowledge might be acquired over time depending on the apparatus used. Maps are best for short term events, but the real world or virtual environments with training interventions (VE+) are best over time.

time, the added information a VE may provide may increase performance. The dark vertical bar represents the time slice that encompasses most of the studies in the literature. Very rarely are participants given enough time to develop survey knowledge in any meaningful way. The figure also differentiates a general virtual environment (VE) that is assumed to be only a virtual replication of the real space, from a specialized virtual environment (VE+) which might have added training features such as aerial views, transparent walls, or other features that may enhance the training effect. However, it is important to note that current research in this area is attempting to determine those features. In order to create VE systems for environmental familiarization that compare or even surpass the real world, an understanding of what tools to use under what conditions is eventually needed.

4. PRINCIPLES FOR THE DESIGN OF NAVIGABLE VIRTUAL ENVIRONMENTS

This final section will serve to summarize the chapter into a series of principles discussed in earlier sections. This is not to be interpreted as a design “cookbook” where designers can look to see how to select navigation aids for their application. Navigation is a highly aggregate task involving people, tasks, and environments. It is not possible to develop a design solution without addressing all three elements as a whole system and not as a set of parts. What is provided here is a set of guidelines based on the literature and on our experiments as a starting point for designers to address the important issues they may face. In some cases, one of these techniques may fit perfectly; in others, an adaptation may be needed. The key is in providing enough spatial information so that users can execute navigation tasks as demanded by the application without overconstraining the interface, thereby eliminating exploration and discovery.

4.1 Performance Enhancement

4.1.1 Tools and Mediators

4.1.1.1 Map Usage.

1. Maintain orientation but match map orientation to the task. Predominantly egocentric tasks like searching should use a forward-up map, whereas geocentric tasks such as exploration should use a north-up map.
2. Always show the user’s position and view direction on the map and update dynamically.
3. The orientation problem will be more severe with a user population that includes individuals with low spatial abilities, such as mental rotation ability. Be aware of who your users are.
4. Video game play may have an effect on the selection of an appropriate map for a virtual environment. If the user population is largely a gaming community, their spatial abilities are likely to be high.
5. Use modded maps (e.g., where the use of the map precludes motion) only where appropriate. The default method should be unmodded.

4.1.1.2 Landmarks.

1. Allowing users to annotate the environment in some way to “personalize” the spatial cues they wish to use can be effective for complex spaces and is easily adaptable to a wide variety of navigation tasks.

2. Beware of giving the user the ability to clutter the space with excessive information. What they think will be helpful can become distracting noise.
3. Provide enough obvious landmarks (typically dependent on the context of the application and the task) so that the navigator has “reassurance” cues along a route to know that they are on the right path.
4. Make sure that landmarks are directional as well as salient. They should help provide orientation information to the navigator as well as position information.

4.1.1.3 Trails or Footprints.

1. Simply leaving a trail is marginally useful since it tends to clutter the space. Making the trail such that it disappears over time is better but can be confusing because it no longer tells the navigator that this place has been visited before, only that it has not been visited lately.
2. Trails can be particularly effective for exhaustive searches. It may be appropriate to use them in the context of a specific exhaustive search but then turn them off afterward.

4.1.1.4 Directional Cues.

1. Directional cues (e.g., sun, compass) alone will not be satisfactory as a navigation aid. They should be used with other techniques since they do not provide positional information.
2. Directional cues can be effective when moded.
3. Directional cues, when used with directional landmarks, are highly effective because they place landmarks in a global coordinate system.

4.1.2 Organizational Remedies

4.1.2.1 Implicit Sectioning.

1. Use an organizational principle wherever possible and do not violate it.
2. If the organizational principle must be violated, make it obvious where and why the violation occurred so the navigator does not attempt to resolve the violation into the organization principle.
3. Match landmarks to the organizational principle whenever possible. They can be used to reinforce the shape of the space.
4. Do not blindly try to use the elements of urban design in any virtual environment. They might not be appropriate. Keep in mind the key concepts: provide useful paths, observable edges, and usable landmarks; and divide big, complex spaces into a number of smaller navigable spaces that are connected in some clear, understandable way.
5. Use an urban metaphor for abstract data judiciously. Make it clear where the metaphor fits and where it does not.

4.1.2.2 Explicit Sectioning.

1. Use explicit sectioning, particularly when implicit reorganization does not work for a particular environment.
2. Again, use an organizational principle and make it obvious.
3. Select a scheme for organizing your space based on which tasks people are likely to do there. If they are doing a lot of naive searches, for example, make sure there is a way for them to easily and systematically explore the entire space without repetition.

4.2 Environmental Familiarization

1. Do not assume that because someone can efficiently navigate a VE that they can navigate the real world as well. This is simply not the case.
2. Beware of creating performance “crutches” by adding features in the VE that enhance performance there but that are not available in the real world.
3. Given a short amount of time with which to familiarize someone with an environment, use a map and perhaps photos if they are available.
4. Beware of developing orientation-specific survey knowledge if only maps are used. Given enough time, a VE can be used to develop orientation-independent spatial knowledge, but it takes time.
5. Be careful when deciding how to use a VE for environmental familiarization because it is extremely difficult to compare studies in the literature. Make a decision based on the whole problem—the people you are training, the tasks they are doing, and the environment they are navigating in.

1. INTRODUCTION

Content development is the design and construction of the objects and environment that create a virtual experience. This includes the visual, auditory, interaction, and narrative aspects of the virtual environment (VE). While this new medium of expression has much in common with other media (e.g., computer animation and games), it has its own peculiar aspects and distinctive features. These include real-time network communications, interactive spaces, multiuser interaction, avatars, and multimodal interfaces.

Virtual environments have the revolutionary capability in human communication akin to that of the moving image in the last century. They may constitute the principal communications media of this century. We are just beginning to learn what it means to create a full sensory experience with control of view and narrative development. Exploring and expanding the limits of the technology requires a background in technical aspects of world creation. It also requires a background in aesthetic (perception of beauty) and metaphysical (nature of being) issues so as to best stimulate and hold a user's attention and effectively communicate ideas.

Discovery of proper aesthetics of a medium requires artistic experimentation: learning the technology; finding its limitations and unique aspects; and then turning those aspects into assets. Davies' (2001) Osmose and Ephemerale and Laurel's Placeholder (Laurel, Strickland, & Tow, 1994) are early examples of artistic exploration of virtual environments. This chapter goes

beyond the tools and techniques of content creation to outline aesthetics and design patterns that capture the distinguishing features of virtual environments.

2. TECHNICAL PRAGMATICS

Many of the pragmatic technical issues of content development for VEs are also found in computer animation and game development. Three-dimensional (3-D) modelers, textures, sound effects, and behavioral simulators are part of the common toolbox. Craftsmen skilled in their use can easily cross over between these disciplines. Technical and popular how-to handbooks for these tools are quite plentiful. Discussion of most of the pragmatics is left to those resources.

The development process for these media parallels standard engineering processes and benefits from the same techniques (e.g., planning, configuration management, usability testing). Several aspects of this development process are discussed in other chapters of this handbook (see chaps. 3–13, 17, 26, 28, and 34, this volume). Rollings and Morris (1999) argue convincingly for the use of these techniques in computer game development. Developers are however cautioned that a strictly engineering approach often shortchanges the content design and development aspects of a virtual environment. It is common for technically oriented developers to underestimate the importance or complexity of modeling and other content development tasks.

One pragmatic issue that does bear mentioning is the fidelity with which an environment is modeled. There are major tradeoffs in object and behavior complexity, development effort, rendering time and purpose (see chaps. 3 and 12, this volume). Photorealistic rendering, modeling of minute details, and exact physical simulation may be unnecessary for many purposes. Developers of the early military VE training system SIMNET (see chap. 43, this volume), faced with major budget restrictions, came up with the concept of “selective fidelity.” They conducted a detailed analysis of the tasks of tank crews and carefully chose which parts of the physical interface and computer models would be recreated in high fidelity and which could be low fidelity or eliminated entirely. Many of the controls in these simulators are simply painted on, and multiple levels of detail are used throughout the computer models. Selective fidelity proved to be highly successful in reducing cost while preserving simulator effectiveness. This is an important lesson for VE designers.

3. LEARNING FROM OTHER MEDIA

Effective design of content for a medium comes from understanding something of its aesthetics. A new medium such as VE will have aesthetic properties that distinguish it from more established media. However, these aesthetic particulars are not readily knowable and designers often start with techniques from prior forms (Oren, 1990). The first film cameras were propped up immobile before a proscenium to record theater plays. Then filmmakers discovered the “camera eye” that could be moved around to pan, dolly, and so forth. There is now a large body of experience and accumulated theory for filmmaking. A number of authors (Clarke & Mitchell, 2000; Laurel, 1991; Lindley, 2000) have written on the applicability of film and theater theory to the design of virtual environments. However, a virtual world is not a broadcast medium like film, TV, or radio, where a story unfolds, told by one person to many. Virtual environments are at their heart an interactive medium, one in which the viewer has unprecedented control. The free-ranging participant, able to move and modify objects in the world, plays havoc with traditional narrative forms. Even the interactive techniques of multiform narrative

(i.e., showing multiple points of view) and branching plotlines fail when the user can wander away from the scripted actions.

Interactivity and narration may be more or less important for a VE, depending on its purpose. Commerce and design review environments' need interaction for manipulation of viewpoint and the object under review. Narrative control is reduced to predefined viewpoints, collaborative baton passing, and perhaps modification of simulation parameters. A training and educational environment uses narrative control to lead the student to particular places of interest and induce them to undertake tasks. Community environments exist to foster the development and sustainability of virtual communities. They need to hold the attention and encourage participation of their residents. The architecture or composition of space within the VE plays a part in these more subtle narrative controls. This is an area where we may pick up some lessons from computer game design and architecture.

3.1 Computer Game Design

Computer games are a closer media relative of VE than film. Computer games are thus a fruitful area of study for those interested in understanding VE as a communications medium. Indeed, the line between a VE and a highly interactive computer game may be simply a difference in interface devices. Three-dimensional computer games are almost certainly the largest and most complex VEs in existence at the moment. Such games are designed to run using standard desktop environments, thus providing low levels of technological immersion (see chap. 40, this volume). This means games rely on content for their success and not technological sophistication.

The commercial nature of the computer games industry has led to a large body of knowledge being built up concerning what captures and retains player's attention. There is, however, little traditional experimental research on computer games. Johnson (1999) is one exception to this, though he is not a games developer. Most of the available material is in the form of accounts of the design process from specific companies and individuals. Saltzman (1999) devotes a chapter to accounts of the game design process from luminaries of the games world. There appear to be a number of common themes addressed by these and other writers on games design. Some of the most common are:

- A clear sense of purpose, mood and genre, to include setting emotional objectives for player's experience
- Verisimilitude or perceptual realism, for internal consistency of the game world is more important than adherence to real life
- Deep controls, an intuitive interface, easy to learn but with a steep learning curve before becoming an expert
- Multiple solution paths
- Flow, to include:

Challenges appropriate to player's skill levels

A balance of anxiety and reward

An almost unconscious flow of interaction

While not all application domains for VE will share all these themes, it is clear that computer game designers have a large and, probably, most critical audience, thus their insights should be of great benefit to the wider VE community.

A particularly rich resource on game design is the *Game Developer's Magazine* and its companion Web-site Gamasutra.com. The magazine has a regular design feature series with highly informative articles.

The computer games industry also has its own jargon, which clashes with that of the traditional VE community. For instance, immersion refers to what the VE industry calls presence (see chap. 40, this volume). Virtual reality in the games community refers to the technology of immersion (eg., headsets, gloves, and so on), which is what the VE community understands as immersion or the embodying interface (Biocca, 1997).

3.2 Architectural Design

Architects deal with freely moving visitors as they strive to create an experience in their design of spaces. Benedikt (1992) was an early exploration of the architectural aesthetics of virtual environments. Beckmann (1998) and Anders (1999) are more recent works relating architecture, aesthetics, and virtual environments. Anders presents VE as a space for perception and cognition, which spans physical presence (i.e., material artifacts, tools for symbolic work), perceivable representation (i.e., symbolic presence), and cognitive presence. Anders uses this scale of abstraction to characterize concrete and abstract attributes of artifacts, spaces, and motion. He suggests that on this scale, VEs are a cross between perceivable representations that provide symbolic presence and tools for symbolic work that provide physical presence. They present many kinds of perceived and cognitive movement and action, and their choreography should “be determined by an overarching unity—an art of aesthetics” (Anders, 1999, p. 101). Designers must thus construct VE experiences for consistency and grace, maintaining coherence between transitioning states and spaces. They may have to (Anders, 1999, p. 108) “think like the director of a film, unifying content, movement and transition through careful design.”

Theme park designers are especially tasked with telling a story through the experience of a physical space. The colors, architecture, and sounds of a space can strongly affect an audience’s emotions. One technique of designers is to infuse story into all elements of the environment, from the textures of walls to the scripts of theme park guides. The rules by which the imagined universe exists are very broad, and violating them will destroy a visitor’s experience. Carson (2000a, 2000b) discussed the application of lessons from theme park design to computer games. Some of these lessons can be summarized as follows:

- Have a story, which provides the all encompassing idea of the world and/or rules that guide the design and project team to a common goal.
- Never break these rules.
- Provide localization—Where am I?
- Provide purpose—What is my relationship to this place?
- Use cause-and-effect vignettes to lead people to their own conclusions on previous events or suggest potential ahead.
- Use the familiar as anchors to draw people into the story.
- Less is more—don’t clutter an environment with too much detail or too many choices.
- Use subintuitive design elements—underlying structure draws audience helplessly to a desired conclusion.
- Use “arrows” and “pathways” in visual design to guide the eye.
- Use physical archetypes to invoke desired mental and emotional responses.
- Use contrasting elements (light/dark, small/large).
- Give illusion of complexity—multiple paths to same goal, etc.
- Provide repeated gentle reminders of “The Story” (past, present, and future events/places).
- Use forced perspective.
- Frame it—guide audience with well framed glimpses of places to come.
- Observe “Past Art”—learn what worked and what did not work.

The convergence of theme park and VE design is evident in the work of the OZ Entertainment Company. They are developing both an international tourist destination and a Web-based virtual world based on “The Wonderful World of OZ” (<http://www.worldofoz.com>; E3D, 2000).

4. CHURCH–MURRAY AESTHETICS OF VE

The previous section discussed lessons from some other media. An emerging aesthetic particular to VEs is now discussed, which might be called the Church–Murray Aesthetics of virtual environments. It started as a combination of Murray’s (1998) aesthetics for interactive media and Church’s (1999) “Formal Abstract Design Tools” (FADTs) for games. It also draws from Slater’s and Usoh’s (1993) concept of copresence and Heim’s (1999) “Transmogrification.” The Church–Murray aesthetics of VE are characterized as agency, narrative potential, presence and copresence, and transformation.

4.1 Agency

The term *agency* is used by Murray (1998) to describe the pleasure of being, or appearing to be, in control through interacting with a medium as opposed to being a passive recipient. Church (1999) gives agency two components:

- Intention: Making an implementable plan in response to the current situation and an understanding of the available options.
- Perceivable Consequence: A clear reaction from the VE to the actions of the user.

Agency is a lot more than just firing a gun or opening a door. Agency is about users constructing links between cognitive responses to VE content and the way in which the consequences of their virtual actions match their mental model of what they thought would happen.

4.2 Narrative Potential

Traditional media designers invariably underestimate the way agency subverts traditional narrative forms. Agency gives a user the freedom to ignore some or all of the wonderful things the designer has so painstakingly built into the world. There are design tricks that entice users to follow the paths set for them and undertake the activities planned for them. If this is done well, users will come away from the VE able to tell appropriate stories that show the experiences they gained in the VE were more or less the ones designed in for them. This narrative potential is the glue that binds together the set of experiences offered through agency.

4.3 Presence and Copresence

Presence is the mental state of a VE user not noticing or choosing not to notice that the world, which they perceive, is artificially generated (see chap. 40, this volume). It is thus the sense of being mentally transported to the “place” of the virtual environment. Presence is thus an aesthetic pleasure of oral storytelling, painting, novels, television, and film, as well as virtual environments. Presence cannot be directly coded into a VE but arises from appropriately designed agency and narrative potential.

The related concept of copresence, being present with others, is also of interest (Slater & Usoh, 1993). By others, we mean animals and alien races, as well as humans, some or all of whom may be intelligent agents (see chap. 15, this volume). Copresence has been shown to

be one of the primary aesthetic pleasures of digital media from e-mail to MUDs (multiuser domains), MOOs (MUD Object Oriented), and networked computer games.

4.4 Transformation

Heim's (1999) positions avatar design at the heart of VE design and relates this strongly to the pleasures of transmogrification (i.e., to change shape or form, particularly into one that is bizarre or fantastic). We use Murray's (1998) related term "transformation" as the change is often mundane. Transformation is a further by-product of agency, narrative potential, and the ability of the VE to allow players to feel themselves as part of the mediated environment. As a result of interacting with a VE, users may temporarily become someone else or even another species, either terrestrial or alien. But transformation is not just about taking on another character. It is about being able to do things one cannot normally do, having skills, power, and authority not normally possessed, and so on. This is very apparent in game and chat worlds. Participants normally do not want to look like themselves in these fantasy worlds—they choose nonrealistic avatars that project idealized self-images.

The Hubble VTE (Loftin & Kenney, 1994) is a good example of a less fantastical transformation experience. The flight team could become astronauts for a while even though none of them, except the person that communicates directly with the flight crew, were likely to go into space themselves. Even grown up boys and girls might want to pretend to be astronauts.

5. PERCEPTUAL OPPORTUNITIES

This discussion of Church–Murray aesthetics has demonstrated that content for VEs is not just scene graphs nodes, objects, or audio assets. Content is about stimulating perceptions, which gives rise to meanings in the mind of the user and stimulates action, which in turn leads to further meaningful insights.

Perceptual opportunities (POs) offer a generic means of talking about VE content (Fencott, 1999b). They can also be used to look at the relationship between objects' various meanings and the way these affect users' behavior. Some objects seem to attract attention to the possibility of danger, reward, and so on. Identifying such objects offers opportunities to establish goals to further users' progress through a virtual environment. Other objects, or combinations of objects, are useful in helping users plan and achieve goals. Intense patterns of such objects form mini-missions and retain users' focus of activity in the cause of larger objectives. The keyword here is opportunity. Part of the art of VE design is providing users with carefully structured opportunities to allow them to explore, strategize, formulate and solve problems, and plan for and attain goals. This in turn allows users to feel some degree of control over what they are doing, allows them to creatively unfold the plot, feel present, and maybe become transformed in terms of skills and/or persona.

The PO model is a characterization of the roles objects are intended to play in establishing purposive experience. Figure 25.1 shows how POs may be broken down into three principal forms, each of which focuses on different kinds of meaning that objects may offer. Sureties deliver denotative meaning and collectively try to establish basic believability. Surprises seek to deliver connotative meaning and thus collectively seek to deliver purpose. Shocks are perceptual bugs that tend to negate the other two forms by breaking the illusion. Shocks will not be pursued here.

The relationships between POs can be documented using perceptual maps, which are a sort of grammatical structuring that seeks to ensure that users construct an appropriate temporal ordering over their attentions and activities within the virtual environment.

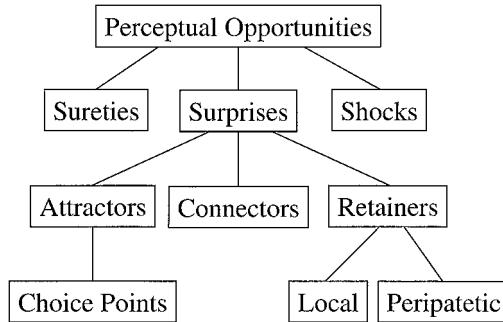

FIG. 25.1. Characterizing perceptual opportunities.

5.1 Sureties

Surities provide certain kinds of basic information that support the main purpose of a virtual environment. They are mundane details that are somehow highly predictable—their attraction is their predictability. They should appear to arise quite naturally and are concerned with the logic of the environment unconsciously accepted. Sureties deliver denotative meaning and thus help users to accept the fundamental nature of the world or level. Recent research shows that much of what we know about the world we know unconsciously and that it is this knowledge that allows us to function from second to second.

Surities should inform a user of such things as: How big am I? How fast am I moving? What do I look like? Have I been here before? Sureties also provide other reassuring information to do with such things as the physics of the world and the believability of other beings in terms of their avatars and behaviors. Furthermore, people are used to the real world being complex and cluttered, so it helps if the virtual world is as well. This is called redundant complexity or perceptual noise. A useful aphorism is that in interacting with the real world we are trying to make sense of too much information, whereas in a VE we are trying to make sense of too little.

Surities succeed by not being noticed when they are there but being missed if they are not present. They are thus the basis on which a designer seeks to achieve the willful suspension of disbelief in the mind of users. If sureties are the basis of belief, then surprises are what really deliver the goods.

5.2 Surprises

Surprises are nonmundane details that are not always predictable but they do arise, however surprisingly, from the consciously accepted logic of a space. Surprises therefore are intended to deliver the memorable pleasures of the world by allowing users to accumulate conscious experience. Surprises are concerned with the connotative meaning of VE content. Surprises can be implausible but beneficial or totally plausible but unexpected, and there are three basic types: attractors, connectors, and retainers.

Perceptual opportunities can be both sureties and surprises, depending on the context in which they are offered—there is no mutual exclusivity between them. A fire escape can be both a surety—familiar objects that provide sureties for scale—and also a surprise—access to rooftops. Some things will be more or less surprising than others.

5.2.1 Attractors

Attractors are POs that seek to draw users' attention directly to areas of interest or to situations that require action. Attractors are the means by which users are stimulated into

setting goals for themselves. It is thus important that major attractors are associated with retainers, which reward users with things to do, remember, excite, and puzzle over, and which will allow them to feel they have attained the goal they set for themselves as a result of the attractor.

Attractors may be characterized according to the reasons they draw attention to themselves in several ways. First of all, there is the way they stimulate natural curiosity through mystery, movement, strangeness, and so on. An attractor may exhibit a combination of such characteristics. However, although attractors rely on peoples' natural curiosity they are also directly related to users' emotional involvement with the world. A second and very useful characterization concerns the connotative meaning users attach to attractors. Two of these that are important for computer games, for instance, are:

- Objects of desire: have some benign significance to users and to the task at hand.
- Objects of fear: have some malign significance to users and to the task at hand.

The purpose of attractors is to stimulate goal formation. Very often an attractor might have several possible goals associated with it and thus becomes a choice point—a source of great dramatic potential. When attractors are discussed, suggested goals will always be associated with them. Attractors are thus the means by which users are coaxed into following a particular course, choosing between possible courses, or changing course.

5.2.2 Connectors

Connectors are POs that help users by supporting the planning used to achieve goals stimulated by attractors. Connectors are thus the means by which users make connections, both mental and “physical,” between attractors and associated retainers, which allow users to achieve their goals and deliver objectives specific to the purpose of the world. The actual objective of a retainer might well be hidden or not clear from the point of view of its attractor(s), but lower level goal formation should lead users into situations where objectives can be realized.

5.2.3 Retainers

Retainers are activities that seek to deliver specific objectives and rewards of the world and collectively, therefore, its purpose. The activity might be simply walking over some treasure to collect it, or it might be a whole mini-mission, such as a firefight. Retainers come in three forms: local, dynamic, and peripatetic. Local retainers seek to keep users in a particular place in a game. Users encounter dynamic retainers unexpectedly within the world. Peripatetic retainers are offered wherever users are in the world.

5.3 Perceptual Maps

Attractors, connectors, and retainers function together to deliver the aesthetics pleasures of a virtual experience. Surprises should work together in patterns to form possible temporal orders on retainers and thus the coherent set of purposive experiences that are intended to deliver the purpose of the world. These patterns are called *perceptual maps*, and they can be seen as a sort of invisible but comprehensible labyrinth that users will want to discover through their own agency (Murray, 1996). Perceptual maps have much in common with the way painters arrange the composition of a work so as to catch viewers' attention and lead them around the canvas in a particular way. This leads to the purposive accumulation of experience. A perceptual map is the framework within which narrative potential can be designed.

TABLE 25.1
Perceptual Map for a Hypothetical Game

Attractors	Connectors	Retainers
Ricochets (Dynamic objects of fear) Goal is to find cover.	Plan is to make for cover. Uses doorways, walls, alleyway, etc.	Activity is to take cover. (Local) Reward is time to think, plan, etc.
Movement of opponent(s) (Dynamic object[s] of fear and desire—your opponent can fight back) Goal is to find cover.	Plan is to make for cover. Uses doorways, walls, alleyway, etc.	Activity is to take cover. (Local) Reward is time to think, plan, etc.
Movement of opponent(s) (Dynamic object[s] of fear and desire—your opponent can fight back) Goal is to frag opponent.	Plan is to take opponent by surprise. Uses guns and ammo and maybe cover.	Activity is to firefight (dynamic, peripatetic) Reward is fun and increase frag count.

The simplest way of documenting a perceptual map is by way of a table with three columns, which relate attractor, connector, and retainer triples. Rows indicate suggested relationships left to right and cells give brief descriptions. For a hypothetical game, a partial table—just three of many entries—of surprises would look something like that shown in Table 25.1.

Of course, users might have a number of goals at any one time and will take notice of a host of attractors as they execute one or more of their current plans. Notice that the second two attractors are the same except for the goal. This is what Murray (1998) refers to as a choice point, which is identified as one of the most important dramatics structures in virtual environments. Comparative content analysis between various VE designs can be conducted by contrasting their perceptual maps (Fencott, 2000). This work is still the subject of research but involves comparing properties of these maps. For example:

- Complexity in terms of the number of rows in the table and resulting number of choice points, which gives an indication of the complexity of the decision making processes involved.
- The nature of the attractors, for example, their perceptual and emotional characteristics (e.g., shoot-em-ups will be largely composed of objects of desire and fear, whereas a virtual tourist site may be composed of objects of desire and curiosity).
- Goal stacking, which is the number of goals users work with at any one time; interestingly, shoot-em-ups seem to demand concurrent stacking of a large number of goals, whereas more contemplative VEs might only require one or two at a time.

Perceptual opportunities and maps have also been studied as part of a suggested VE development methodology (Fencott, 1999b), which looks, for instance, at the relationship between aesthetic design and engineering design.

Attractors should draw attention to sites of retainers and, if properly designed, lead users around a world in a meaningful way using connectors. Attractors may also themselves be retainers. Seen from a distance an animated object may act as an attractor but when experienced close up the object may be some sort of vehicle to ride in and control thus becoming a retainer.

Retainers are actually localized patterns of attractors and connectors. Early computer games, such as Viper and Breakout, can be viewed as retainers in this sense.

Some general rules govern the relationships between surprises:

- Users should be rewarded if they follow attractors.
- Retainers do not have to have attractors.
- Retainers can be their own attractors.
- Retainers can have multiple attractors.
- Connectors should lead to an attractor or directly to a retainer.

Thus connectors, like attractors, should be rewarded if followed.

Sureties and surprises should be designed to work together. If a perceptual map constitutes Murray's (1998) comprehensible labyrinth, then sureties are the means by which this is grounded, virtually, in a believable world.

In this section, the aesthetics of VE have been shown to be significantly different from the conventional aesthetics of media such as film and television. This stems largely from agency through which users and intelligent agents are empowered. The way VE content development is approached must take this into account. However, VE, perhaps more than any other media, offers the possibility to investigate the very nature of being.

6. DEEPER MOTIVATION OF DESIGN

Metaphysics is the systematic investigation of the nature of being or reality. It can inform and motivate a designer's aesthetic. Virtual environments expose the nature of reality to direct observation and experimentation. It is perhaps the first medium to do so and opens up a whole realm of exploration (Lauria, 1997, 2000).

6.1 The Nature of Being in a VE

Metaphysical questions do not immediately come to mind for someone looking at a medium for the first time. Yet such higher level questions allow us to experiment outside the box of previous media that rely heavily upon narrative story telling, one-way broadcasting, and the manipulation of attention (as opposed to interaction). Metaphysics takes us beyond conventional aesthetics, where one might hope to avoid the pitfalls of the early history of photography, film, and television. Those media remained stunted for decades by trying to reproduce the legacy content media of still painting, tripod cameras, and formally staged theater productions. "Content" is not something that can be simply dumped from one medium into another. The artistry in any medium lies in finding a harmony of content and form, something appropriate to the specific medium.

Plunging into the depths of metaphysics frees the imagination, but it does not take a big leap to get metaphysical about virtual environments. If metaphysics deals with the nature of being itself, then the virtual worlds designer faces that question head-on when first confronting virtual space. What does it take to make something "real" or to make it "be"? This is not an airy question when you design a virtual environment. It is a pressing decision. Designers have to decide what counts as a real thing or entity, and they need to also rank its level of reality (e.g., permanence, vivacity, porosity, intelligence, efficacy, agency) relative to other beings. Take "backgrounds," for instance. Is there to be a single, persistent texture that serves as the permanent backdrop for action, movement, and relations? Or should background textures change constantly and flow? If flow is chosen, then at what rate? How much permanence, if any, is needed for a particular world's background?

When William Bricken (Bricken & Coco, 1993) first conceived the Virtual Environment Operating System (VEOS), he drew on two main sources: the notion of Sunyata (emptiness) in Zen Buddhism, and the “Laws of Form,” by George Spencer-Brown, who authored a book by that title. The Buddhist “void,” or emptiness, offers a metaphysics of virtual space. This space can be understood as a fundamentally nondirectional, nonfixed emptiness, rife with fertile possibilities. From the void evoked by VEOS emerges any set of entities, their attributes, and the relationships among those entities. No substance precedes the void. Historically, Spencer-Brown’s (1979) Laws of Form interpreted the *Principia Mathematica* written by Bertrand Russell and Albert North Whitehead (1910, 1912, 1913) at the beginning of the 20th century. The *Principia* did to logic theory what Newton’s *Principia* did to physics. *Principia Mathematica* laid new foundations for mathematical logic, making possible the later information/noise theory of Claude Shannon (Shannon & Weaver, 1963). Spencer-Brown (1979) interpreted the *Principia* from a Zen point of view. The initial logical distinctions of the *Principia* became themselves grounded in void space. “Draw a distinction in empty space” became the first act of creativity. The drawing of a distinction between any X and non-X sprung from a timeless act, from emptiness or openness to all possibilities. By unifying these two intellectual foundations, Zen and the *Principia*, Bricken’s VEOS applied general metaphysics to cyberspace, a synthesis which came to Bricken in the late 1960s. Today, virtual worlds designers still return to the void and the act of creating distinctions from the void as the primal principles of design.

The metaphysics of void space “grounds” cyberspace design because conceiving virtual space and creating virtual space are nearly identical. As a phenomenon of human perception, cyberspace requires no material substrate. As a software phenomenon, cyberspace of course requires algorithms, and its software requires a hardware base. For the designer, however, the thought of a distinction becomes the first act of creation. There is no material element to shape or take into consideration outside function and ergonomics, psychology, and the perceptions of the human user. While limitless on a conceptual level, there are the stubborn facts of software engineering and hardware input/output devices. These stubborn facts are less insistent than stone and are yielding to the social confluence between virtual world engineers and virtual world designers.

If a designer accepts the challenge of metaphysical design (i.e., designing from the void and Spencer-Brown’s basic laws of form), then the designer must also take responsibility for communicating with software engineers. The basic ontology—the types and ranks of beings that can exist—must be designed at the most fundamental level of software design:

- How should a self be represented?
- Should avatars be anthropomorphic?
- How many degrees of freedom should movement have?
- What kinds of entities (models) should exist, and should they exist as independent entities or as arrays, ephemerals, or more substantive types?
- Should a world have multiple portals or a single ground zero?
- How much participation (editing) should be under the control of world participants (users)?

All these questions, and many more, will arise if the designer accepts the metaphysical responsibility of working with the software engineer to determine the world’s ontology. In previous forms of technology—probably because of the substrate of expensive, resistant materials—the engineer maintained a certain distance from the art designer, and vice versa. When the conditions of cyberspace design are considered, however, this role separation becomes a

distinction rather than a separation. The two will work together to mine the rich possibilities of the void.

6.2 Transmogrification

To “transmogrify” means to change into a different shape or form, especially one that is fantastic or bizarre. Transmogrification might prove to be a valuable style for designing VEs and avatar worlds. Virtual environments might succeed not as a replication of the physical world, nor as a direct representation of our personalities. Instead, avatar worlds might inject a touch of fantasy and a sense of fun into conventional activities like business meetings and instructional classes. The “disguise” quality of online virtual worlds suggests a playful attitude that adds a distinct quality to everyday activities.

Avatar in its Hindu origin means the incarnation of a deity, as in Vishnu taking the identity of Krishna in the Sanskrit poem the Bhagavad Gita. (The Sanskrit *avatārah* derives from *ava*, “down,” and *tarati*, “he crosses,” meaning “the crossing down.”) The avatars of virtual worlds are placeholders for real-time human presence (see chaps. 14–15, 45 this volume). They are not—with the possible exception of “bots” or semi-intelligent surrogates—empty media receptors like answering machines or phone pagers. They are animistic spirit vessels in a vast system of digitally encoded events. As such, avatars maintain a remnant of fresh humanistic issues in an age of technical systems. If, as some smart observers suggest, these systems are “not really about people at all,” then avatar presence can still be used to pervert the basic trajectory of systems whose teleology is immanent and whose tangential implications are antihumanistic, or at least hostile to humans insofar as human life becomes yet another artificial life form to assimilate. Avatars are more than subservient system input or maintenance attendants for the auto-poetic network.

Avatars tap into the age-old magic of transformation. Humans can, under the right conditions, take what lies immediately in front of them and transform it into something of cosmic significance. This transformative power is at the heart of ritual. The transformative power of the spirit animates avatars and confers on them presence at a distance (telepresence).

Likewise, when users put “on” their avatar, they also put “off” the habitual self. They accept a moment of transformation, shifting their shape in order to be who they are in different forms. They shed their form like a changeling. They lay aside the illusory fixity of being a hard ego encapsulated in a shell of flesh. Avatars allow users to engage a playful self, a self that does not let it be defined in narrow technical terms. This avatar self is a changeling, a joker-prankster who revives the human capacity to laugh and to laugh at oneself.

One day, the Chinese sage Chuang-Tzu had a dream, and he dreamt he was a butterfly. When he awoke, he was not so sure: Was he Chuang-Tzu dreaming he was a butterfly? Or was he a butterfly now dreaming he was Chuang-Tzu? The dreams people have show the expansive, tenuous quality of human’s deep self-identity. A related Taoist practice is to go through an entire day nurturing a feeling of inner softness, blurring the outer events of life into a diaphanous, dreamlike pattern. In such a state, one’s usually strongly invested attachment to the outcome of events recedes, and harsh reaction toward events fades. With the edgy ego momentarily disengaged, newly rewarding ways of responding to life events are often discovered. The diffuse ego flies free of being identified fully with either Chuang-Tzu or with the butterfly. Avatars can become the toys of Chuang-Tzu if designers use them rightly.

7. CONCLUSIONS

Art is often about diffusing the rigid ego so that we can move more freely through time and space. We should not let our pride in the new networks we have built override the inherent

powers we have always enjoyed as natural teleoperatives. The challenges of world and avatar design remind us of the need for art to maintain our proper relationship to technology.

Technology Management and User Acceptance of Virtual Environment Technology

David Gross

499 Boeing Blvd.

Huntsville, AL 35824

David.C.Gross@Boeing.Com

1. INTRODUCTION

Technology deployment, or transitioning innovation into use, is the natural objective of any technologist who develops an innovation. Despite the old saw that “build a better mousetrap, and the world will beat a path to your door,” the particular power, or utility, of a technological innovation is just one of the criteria for successful technology deployment. Technology deployment takes places within a human society, which may (or may not) adopt the innovation. The economic circumstances of that society, as well as its mores (formal or informal moral attitudes), also play important roles in the success (or failure) of a technological deployment. Furthermore, the ongoing advance of technology, independent of the technology in question, as well as evolving demands from consumers in society, create forces that affect a society’s adoption choice. Figure 26.1 illustrates the many forces affecting the success (or failure) of deploying a technological innovation.

Some of these forces tend to encourage technology deployment, but some discourage it because many of these forces create societal inertia. This resistance to change is a phenomenon so pervasive and widely recognized that it scarcely requires documentation (Mackie & Wylie, 1988). The forces resisting change can slow and stunt the adoption of new technologies, a classic example being the deployment of nuclear power technology.

Virtual environment (VE) technology, like other innovations before it, has vast potential for improving the way people work and live; therefore VE technologists seek to deploy it. However, fulfilling this potential will certainly require equally vast changes in the way these things are done now. Every significant technology deployment has changed the adopting society’s way of life. Consider for example the deployment of automobile technology and the wide-ranging impact it has had on every aspect of modern life. Some of those changes were anticipated and appreciated; some were not. Whether desirable or not, change is a certainty with a new technology. The resistance to deploying VE technology can be reduced by

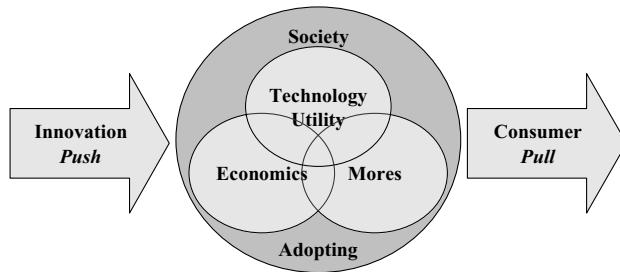

FIG. 26.1. Multiple effects on a technology's diffusion in society.

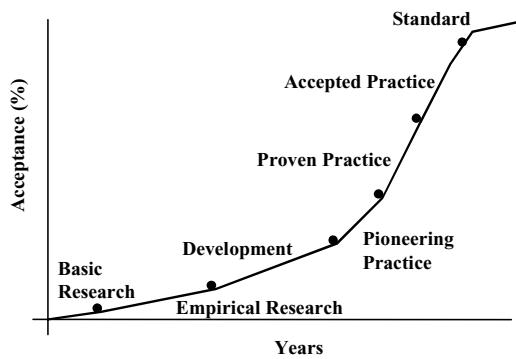

FIG. 26.2. Typical technology transition cycle.

understanding how organizations within a society come to understand and adopt technological innovations.

1.1 Technology Deployment and Adoption

Technologists can increase the rate of adoption if they understand the obstacles and concerns an adopting organization faces. Figure 26.2 suggests an expected timeframe for technology innovation adoption on the order of a decade or more (Utz & Water, 1992).

If technology deployment is the natural objective of a technology developer, then technology adoption is the choice of a technology user. Technology deployment can be very frustrating to the technology developer, who feels that the relative advantage of this technological innovation over present approaches is so overwhelming that only the naive would not immediately adopt it. However, potential adopters frequently see the technological innovation differently than developers. Adopters are concerned with issues such as an innovation's compatibility with the rest of an organization and with the complexity of using and maintaining the innovation. The reluctance of adopters to easily adopt innovation has led to what Rogers (1994) calls the *Innovativeness-Needs Paradox*, in which individuals or other units in a system who most need the benefits of an innovation are generally the last to adopt it.

1.2 Toward an Understanding of Technology Adoption

One approach to understanding technology adoption is Innovation Diffusion Theory, especially as described by Rogers (1995). Technology adoption cannot occur unless the innovation is distributed or diffused through a society. The essence of the technology diffusion process

is human interaction in which one person communicates a new idea to another person. Thus, at the most elemental level of conceptualization, the diffusion process consists of: (1) a new idea; (2) individual "A" who knows about the innovation; and (3) individual "B" who does not yet know about the innovation. The innovation diffusion model suggests a four-step process for technology diffusion: innovation, uncertainty, diffusion, and adoption/rejection. Although the technology itself plays an important role in this process, social relationships have a great deal to say about the conditions under which A will tell B about the innovation, and the results of this telling (Rogers, 1995). In this light, the factors that most affect a particular organization's decision to adopt a particular technology are internal to the organization, that is factors describing the social relationships in the organization. These factors can be grouped into three categories: (1) an organization's past experience with technology; (2) the organization's characteristics; and (3) the organization's pursued strategy (Lefebvre & Lefebvre, 1996).

While innovation diffusion theory has much explanatory power, the complaint has been made that it focuses too much on internal factors. Innovation diffusion theory models technology adoption based on a company's communication patterns in which prior adopters inform potential adopters and persuade them. One alternative is the theory of network externality, which argues that adopter behavior is strongly influenced by relevant parties outside the company (e.g., vendors, consultants, standards bodies). These external factors can be grouped into the following categories: (1) the industry level; (2) the macroeconomic environment; and (3) national policies (Lefebvre & Lefebvre, 1996).

If classical innovation diffusion theory focuses on internal factors, and network externality theory focuses on external factors, perhaps an approach that balances these factors is needed. Bhattacherjee and Gerlach (1998) suggest that while these approaches have explanatory power for relatively simply technology adoptions, they fail to explain more complicated pervasive technology adoptions such as software's object-oriented technology (OOT). The potential of VE technology certainly is as pervasive as the introduction of OOT was, so it is worth considering a more holistic approach. An emerging approach that balances the internal and external influences on adoption decisions is *Organizational Learning Theory*. Organizational Learning Theory suggests that organizations learn by a collective process very similar to how individuals learn; that is, organizational learning occurs when we learn collectively, when we act and reflect with others. Shibley (1998) divides an organization's learning into two parts, observation and reflection. Observation involves collection of the raw information of daily events and the discovery of patterns in those events. Reflection involves the attempt by organizations to place their observations in a useful context, either system structures, mental models, or corporate vision. Most often, observations are forced into preexisting structures, but valuable learning takes place when the raw data forces a change in these structures (Senge, 1990). An Organization Learning Theory approach to understanding technology adoption depicts an organization as attempting to integrate both the internal and external factors into a corporate view of a technological innovation, which dictates an adoption decision.

2. MANAGEMENT CHALLENGES

Managers of organizations considering adoption face real challenges in realizing the opportunities that the technological innovations afford them, while avoiding their pitfalls. This has led to difficulty in explaining experiences in technology adoption. For example, despite the widespread awareness of OOT's benefits for software development, and the commercial availability of reusable libraries, databases, methodologies, programming languages, and packaged applications, many businesses remain cautious about deploying OOT for major system

development (Bhattacherjee & Gerlach, 1998). This experience may prove instructive for technologist concerned about deploying VE technologies in many of the same businesses that have been slow to adopt OOT.

2.1 Integrating Into Corporate Culture

Chief among management's concerns of about VE technological innovations is the difficulty of integrating new technologies into existing corporate culture. At companies like Boeing for example, introduction of personal computers capable of supporting technical documentation maintenance was slowed by concerns about what would happen to existing central word processing organizations. Of course, all adopting organizations are not the same; some will express innovation rapidly and easily, and some will not. Table 26.1 shows Roger's classification of different kinds of adopter organizations.

Even within these classifications, an organization may choose to have a more or less aggressive stance toward a particular technology, choosing, for example, to lead the market in one technology but simply defending its competitive position in another. Table 26.2 illustrates some objective organization characteristics, and whether or not they were significant factors affecting the adoption of a particular technology, namely Integrated Services Digital Network (ISDN). The data is an analysis of formal corporate surveys.

Understanding what kind of organization is considering adoption can help the technology developer plan for and accommodate the particular problems of an organization, thereby increasing the likelihood of success. For example, a VE technologist proposing a first VE project should realize from Tables 26.1 and 26.2 that organizations that commit significant resources toward a VE project and are at or near the forefront of their industrial domain are more likely to experience success. In contrast, the VE technologist should probably not be as concerned about the impact of the organization's degree of formality (rank, office, titles, etc.) or complexity (layers or styles of management) on success. In addition, a VE project proposal for a laggard organization will need plenty of support in the form of experience by other similar organizations.

TABLE 26.1
Classification of Innovation Adopters*

<i>Adopter Categories</i>	<i>Share of Whole</i>	<i>Description</i>
Innovators	2.5%	Venturesome, cosmopolite, networked with other innovators, financial resources, understand complex technical knowledge, cope with uncertainty
Early adopters	13.5%	Respectable, more local than innovators, strong opinion leadership
Early majority	34%	Interact frequently with peers, seldom hold positions of opinion leadership, interconnectedness to system's interpersonal networks, long period of deliberation before making an adoption decision
Late majority	34%	Adoption might result from economic or social necessity due to the diffusion effect, skeptical and cautious, relatively scarce resources
Laggards	16%	Most localized, point of reference is the past, suspicious of change agents and innovations, few resources

* Adopted from Rogers (1994).

TABLE 26.2
Significance of Organization Factors in the Adoption of ISDN*

<i>Organization Characteristic</i>	<i>Significant</i>	<i>Not Significant</i>
Adoption encouragement	X	
Open vs. closed organizations	X	
Slack (uncommitted) resources	X	
Large vs. small organization	X	
Norms encouraging change		X
Organization centralization		X
Organization formalization		X
Organization complexity		X

* Adopted from Lai and Guynes (1997).

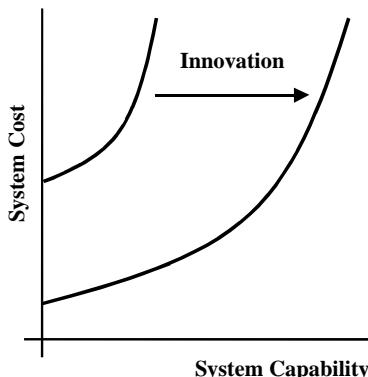

FIG. 26.3. Innovation increasing process productivity.

2.2 Need for Credible Productivity Gains

The second major challenge facing VE technology adopters' management is the need to address the "bottom line." Sometimes simplified as just showing a profit, the more accurate concern is to increase the process' productivity (return for resources invested). Figure 26.3 illustrates this desire in terms of moving an example process capability curve to a greater capability at a lower cost.

A legitimate claim that a VE project will improve productivity makes it easier for an organization to adopt the innovation. Can VE technology make this claim? The capability of business processes is a function of the knowledge, techniques, and tools that their employees apply. Human actions determine whether production is done efficiently and whether new and improved methods of production are introduced (Ostberg & Chapman, 1988). Virtual environment technology, integrating visualization and artificial intelligence, can legitimately claim to impact the productivity of business processes because it offers powerful opportunities for improvements in the way humans perceive and utilize knowledge (see Fig. 26.4).

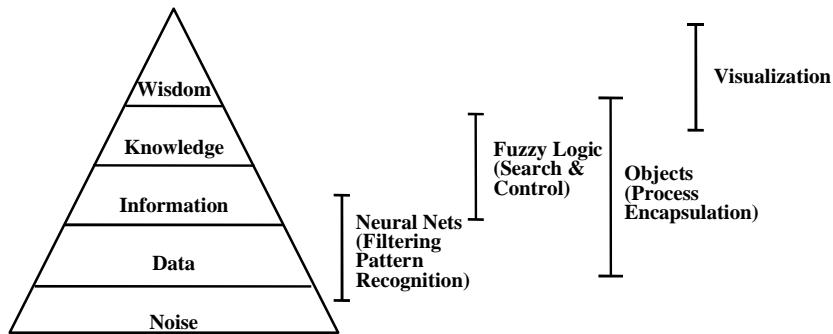

FIG. 26.4. Relevant merits of technologies to perceive and utilize knowledge (Hoffman & Wright, 1997).

2.3 Fear of the Operations and Sustainability Tail

The second major challenge facing VE technology adopters' management is the potential operations and sustainability tail. Major manufacturers such as Boeing have seen operations expense resulting from introduction of the personal computer far outstrip their acquisition cost as well as their productivity gain, particularly from earlier installations. Management has legitimate concerns about VE technology becoming another logistics nightmare, particularly considering the fragile nature of some of the equipment. When this is combined with the rapid evolution/revolution in VE devices and the rapidly changing nature of VE applications, this challenge can be a showstopper for deploying VE technology. Any VE technology deployment will have to address this challenge to survive scrutiny.

3. USER CHALLENGES

Management can be convinced, if the rank and file have powerful applications for technological innovation. The potential users of VE technology have challenges to overcome in their own right about discovering and explaining these applications.

3.1 The "Killer Application"

Worldwide, the market for business virtual reality services, software, hardware, and peripherals is seen as rising from 1995's level of 134.9 million to a little over \$1 billion no later than 2001 (Boman, 1995). However, the marketplace is still hampered by the lack of a "killer application" (Stanney et al., 1998). The concept of a killer application dates from the development of the business spreadsheet, which motivated the purchase of millions of personal computers. Two years ago three-dimensional (3-D) and virtual technology on the Internet identified potential key applications: games, e-commerce, collaboration, education, training, and visualization. However, significant applications for VE in these fields are still just potential (Leavitt, 1999).

3.2 Physical Ergonomics

Cybersickness and related syndromes continue to be significant obstacles to widespread use of VE technology (see chaps. 29–32, and 37–39, this volume). At least for some users, cybersickness is a significant problem, and many organizations are reluctant to make significant commitment to technologies that clearly bypass significant portions of their population.

For example, wearers of head-mounted displays (HMDs) have been known to suffer stress because they are unable to utilize eye convergence and accommodation when viewing virtual objects at different distances (see chap. 37, this volume). In general, some people are very sensitive to unfamiliar motion stimuli, such as that generated in a VE, and these individuals may be discomfited by VE exposure (Vince, 1995).

Beyond cybersickness, much VE technology is uncomfortable or unpleasant to use (see chap. 41, this volume). Stuart (1999) notes some current VE technology limitations for users:

1. Position trackers with small working volumes, inadequate robustness, and problems of latency and poor registration.
2. HMDs with very poor resolution, somewhat limited field of view, and encumbering form factors (i.e., weight and tethers).
3. Virtual acoustic displays that require a great deal of computational resources in order to simulate a small number of sources.
4. Force and tactile displays, still in their infancies, with limited functionality.
5. Image generators that cannot provide low-latency rendering of head-tracked complex scenes, requiring severe trade-offs between performance and scene quality.

In addition to these limitations for users, Stuart notes developers of VEs experience limitations with the real-time capabilities of operating systems and inadequate software development tools.

3.3 Cognitive Ergonomics

As discussed, one of the primary benefits of VE systems is their ability to assist users in developing knowledge about subject matters portrayed in the virtual world. However, VEs developed to date deliver little of this promise. Stuart (1999) notes that in order for VEs to fulfill their promise they will have to deliver:

1. Sociability: the capability to permit multiple users to share an environment (see chap. 44, this volume).
2. Veridicality: the accuracy with which a VE reproduces its modeled environment (fidelity) (see chaps. 12 and 17, this volume).
3. Resolution: the level of precision and detail provided by a VE system (see chap. 3, this volume).
4. Immersion, presence: the extent to which users believe that they are “in” a virtual environment (see chap. 40, this volume).
5. Engagement: the extent to which users are deeply involved and occupied with what they are doing in the virtual environment (see chap. 40, this volume).
6. Reconfigurability: the capability to modify a VE model.
7. Responsiveness: the ability of a VE to respond to user inputs (lag, latency; see chap. 3, this volume).
8. Stability: lack of jitter or oscillation in the VE display (see chaps. 3, 11, 13, this volume).
9. Robustness: the ability to function correctly across all operational ranges.

4. DOMAIN-SPECIFIC CHALLENGES

4.1 Design and Testing

One of the first, and still most important application, of VEs has been for architectural design (see chap. 13, this volume). The success of this application has led to experimentation

with VE in other kinds of product design and testing. The use of VE systems for designing and testing new products and systems is gaining acceptance, particularly as a complement to computer-aided design technology (Boman, 1995; chap. 52, this volume). The Boeing Company's 777 commercial airliner marked a significant milestone in the fielding of "paperless" design techniques, centered particularly on virtual representations of the aircraft. Less well-known is the application of these techniques to projects such as the international space station and the B-2 aircraft. Virtual representation of product design has been particularly helpful in the automobile industry in shortening product design cycle times.

4.2 Manufacturing

Virtual environments offer much potential for improving manufacturing productivity, particular in the emerging "mass-customization" marketplace (see chap. 54, this volume). Most applications to date have been with experiments in laying custom assembly instructions over a standardized work area. Breakthroughs in this domain await improvements in the physical ergonomics challenges discussed (see chap. 41, this volume).

4.3 Operations

Experiments have been successfully conducted in using VE technology to support operations, such as feeding firefighters real-time maps of buildings as they fight fires (Bliss, Tidwell, & Guest, 1997). Breakthrough applications in this domain await more robust (i.e., not fragile) VE equipment to support the harsh demands of varied operating environments.

4.4 Information Management

Successful VEs have been developed and fielded for information management problems, such as database maintenance (see chap. 53, this volume). This domain is limited by the cognitive ergonomics problem discussed earlier.

4.5 Entertainment

The broadest and most successful application of VE technologies has been for entertainment, both home-based and location-based systems (see chap. 55, this volume). The Disney Corporation has demonstrated its commitment to exploring the advantages of VE-based entertainment with its Aladdin VE ride at Epcot Center and Disney Quest arcade. However, the fact that 5% to 10% of Aladdin visitors experience dizziness or nausea is a reminder of the problems that may hinder mass appeal of VE systems (Boman, 1995).

4.6 Medicine

Extensive experimentation continues in the use of VEs for medicine, particular in the specialized field of medical training (see chap. 47, this volume). Beyond medical training, researchers are investigating the use of VE for aiding people with disabilities, cognitive rehabilitation, and telepresence for remote surgery (Boman, 1995). The National Institute's of Health's Visible Human Project is creating complete, anatomically detailed, 3-D representations of the male and female human body. The project's data sets are designed to serve as a common reference point for the study of human anatomy. The data sets are being applied to a wide range of educational, diagnostic, treatment planning, virtual reality, artistic, mathematical and industrial uses by over 1,000 licensees in 41 countries. But key issues remain in the development of methods

to link such image data to text-based data. Standards do not currently exist for such linkages. Basic research is needed in the description and representation of image-based structures and to connect image-based structural-anatomical data to text-based functional-physiological data (Card, Mackinlay, & Shneiderman, 1999).

4.7 Education and Training

Many observers believe that education and training will be a major application domain for VE technologies (see chaps. 43–46, this volume). The few systems developed to date, however, have yet to demonstrate the kind of competitive advantage required for widespread adoption of this technology. Some specific applications include astronaut, military, and sports training (Boman, 1995).

5. CONCLUSIONS

Virtual environment technology offers exciting potential for revolutionizing the way work is performed in many domains. However, VE technology will fail to deliver on its potential if system developers do not begin to understand and grapple with the problems facing organizations desiring to adopt this technology. Chief among these challenges is the need for “killer” applications in varied domains, supported by robust and stable equipment. It is tempting to project the adoption of VE technology based on our experience with related technologies, such as the personal computer. However, any such projection would be conjecture as sufficient information about the degree to which VE is actually similar to such technologies, and ubiquitous applications do not yet exist.

1. INTRODUCTION

Virtual environments (VE) employ dynamic images to produce the vicarious experience of immersion and presence in flight simulators and helmet-mounted displays (HMDs). However, these exposures often produce unwanted side effects such as motion sickness-like symptoms, balance disturbances, profound drowsiness, and coordination problems (see chaps. 29–32, this volume). Not everyone appears to be affected to the same extent, but such changes, when they occur, imply that the human nervous system has been temporarily recalibrated, or adapted, to the virtual world. This adaptation involves fundamental, significant changes in the basic function of an individual that may not be noticed when the individual exits the virtual environment (see chaps. 37–39, this volume). As individuals subsequently perform routine tasks, unaware of any lingering effects of VE exposure, negative consequences in the form of accidents may occur; thus, these aftereffects may have implications for safety and health. If a VE product occasions problems, the liability of VE developers could range from simple accountability (i.e., reporting what happened) to full legal liability (i.e., paying compensation for damages). In order to minimize their liability, manufacturers and corporate users of VE devices (i.e., companies) can proactively assess the potential risks associated with human factors by using a comprehensive systems safety approach. Human factors systems safety actions undertaken include the following: (1) systems should be properly designed; (2) aftereffects should be removed, guarded against, or warned against; or (3) adaptation methods should be developed; or (4) users should be certified to be at their preexposure levels; or (5) users should be monitored and debriefed.

2. AFTEREFFECTS FOLLOWING USAGE OF A PRODUCT

While most VE product manufacturers have given only slight, if any, consideration to issues of litigation involving aftereffects of VE exposure, the inevitable risks incurred by placing these products into wide circulation must be considered. It has been established, for example, that exposures of humans to simulated environments, for entertainment or education, produces motion sickness-like discomfort and aftereffects such as balance disturbances (Stanney, Mourant, & Kennedy, 1998; see chaps. 29–32, 37–39, this volume). The military flight simulators of the 1960s, which were the VEs of that day, first called our attention to this problem (Miller & Goodson, 1960). In those early days fielded devices had equipment limitations such as excessive transport delays, optical distortions, and flickering imagery; these equipment problems were considered to be the agents of the discomfort. Many of these equipment problems have been remedied in modern simulator and VE systems. At the same time, technological advances in simulation engineering have enabled newer systems to portray even more compellingly realistic dynamic scenarios. Yet varying degrees of motion sickness-like symptoms persist and have been reported in nearly every flight simulator fielded by the military services.

Although carefully controlled studies that employ comparable experimental design, kinematics (i.e., velocity and spatial frequency of a visual scene), equipment features, participants, durations of exposure, and other have not yet been conducted, it is known from survey work (Kennedy, 1998; Kennedy, Stanney, Drexler, Compton, & Jones, 1999) that the overall incidence of VE sickness (cybersickness, McCauley & Sharkey, 1992) appears to be greater than it ever was with flight simulators. In this chapter, some of these reports of motion sickness-like symptoms occasioned by VE exposures are described for purposes of illustration only. The reader is referred elsewhere in this volume for more complete treatments dealing with the cause and incidence of cybersickness (see chaps. 30–31, this volume). Here we merely wish to suggest that if sickness occurs, accidents could result, and if so there may be an issue of product liability. Specifically, it is known that VEs and simulators are products intended for use by adults and children and that they are designed to be manufactured and sold. Sickness, which may occur in connection with usage, may imply a hidden defect in the product or, alternatively, it may be an expected outcome of the product's usage. Also, in addition to the obvious symptoms of sickness, other adverse consequences of exposure may occur, and the symptoms of discomfort may only be a harbinger of other outcomes.

For the purposes of this discussion, the established definition (McCauley, 1984) that describes simulator sickness as the experience of symptomatology during and after the use of a VE that would not ordinarily be experienced if the same activity were carried out in the real world is followed. Obviously, when a real environment ordinarily occasions sickness, if a replicated VE also produces sickness then the simulator actually provides a "good" simulation.

Outcomes known to exist following exposure to VEs and simulators include nausea (up to 30% of exposures), eyestrain (up to 40% of exposures), drowsiness, salivation, sweating, headache, and dizziness/vertigo, as well as loss of postural stability (Kennedy, Fowlkes, & Lilienthal, 1993). Vomiting is infrequent (< 1%) and when it occurs, it is usually more than one hour after exposure. Long-term aftereffects, including visual flashbacks and disorientation, have been routinely reported to have occurred up to 12 hours after simulator exposure (Baltzley, Kennedy, Berbaum, Lilienthal, & Gower, 1989; Lilienthal, Kennedy, Berbaum, & Hooper, 1987), but such data are only now being collected experimentally. Sleepiness and fatigue are symptoms reported by large numbers, but the significance of this for subsequent performance is not well appreciated (see chap. 30, this volume). The incidence of all of these long-term aftereffects is generally low (< 10% of all exposures) and is correlated with the strength of aftereffects immediately after exposure and the duration of exposure. Although less than 10% with long-term aftereffects may seem like a low proportion, the huge number

of persons who are exposed each day to such devices is staggering and may be expected to increase; 10% of a growing number of exposures represents a serious number of persons who may be expected to experience long-term aftereffects.

Visual and vestibular scientists have previously experimented with ancillary aftereffects when they were examining distortion due to tilted figures (Ebenholtz, 1988, 1992) and altered lenses (Wallach & Kravitz, 1965, 1968, 1969). These same distortions can be found in today's HMDs. The vestibulo-ocular reflex (Leigh, 1996; O'Leary, 1992) produces involuntary rotation of the eyes in the direction opposite to head movement in order to maintain fixation and reduce slippage of images across the retina (see chap. 30, this volume). The human internal calibration of this reflex seems to depend upon the recent experience of a relationship of head movement and the resulting image motion (Gonshor & Melville-Jones, 1976). If a new and consistent relationship between head movement and scene displacement is introduced, such as via an HMD, the scenery will at first appear to move because eye rotation will fail to stabilize the image (cf. Dizio & Lackner, 1997; see chap. 38, this volume). Apparent shifts in the scene with head movement may produce impressions of actual individual movement (vection), motion sickness, and eyestrain (Kennedy, Hettinger, Harm, Ordy, & Dunlap, 1996; see chaps. 30–32, this volume). Eventually, the individual will adapt so that the new relationship elicits eye rotation that yields a stable retinal image (see chaps. 37–39, this volume). However, the adapted individual will experience aftereffects; once adjusted to distortion, a head movement that produces the ordinary displacement of the visual scene will again appear to shift. Readaptation to the natural environment will be required. From the dynamics and kinematics of the helmet mounted VE displays, one can predict that such a recalibration is occurring in users, although this problem has only infrequently been studied (Prothero & Parker, 1999). Considerable research needs to be conducted in order to determine the size, time course, and duration of such aftereffects.

This peculiar kind of adaptation can be expected to occur with increasing frequency as VE systems are employed for longer exposure periods, the natural consequence of using them as training devices. This effect, when it occurs, can produce significant disability when entering the real world; indeed, initial exposure to VE would probably be a lot like getting used to a new pair of glasses and eventually could be no more troublesome than changing glasses. Nevertheless, this adaptation involves fundamental, significant changes in the function of the individual at a level at which he or she may be unaware. If developers take steps to address and prepare for the potential safety hazards involved with VE system interaction, they may be able to minimize harm. Companies that take such proactive measures and perform extensive preliminary safety analyses may circumvent product liability issues.

Other aftereffects are worth noting, particularly balance problems, which imply that the human nervous system has been temporarily recalibrated to the virtual world, and time may be required before the individual is ready to navigate safely in the "stable world." "Sea legs" or "le mal de débarquement" (Gordon, Spitzer, Shupak, & Dowek, 1992) is a related malady that also results in perturbed posture (see chap. 39, this volume), but such perceptual and motor aftereffects have long been known to occur. See studies of human perceptual distortion in connection with mirror and prism use (see chap. 31, this volume). They have also been reported following weightlessness. One could argue that if such effects outlast the period of time an individual is under the control of the VE device owner/manager, care for well-being should extend beyond the owner's property line. More is said about this later.

In one particularly interesting simulator study (Gower, Lilienthal, Kennedy, & Fowlkes, 1987), U.S. Army pilots who were exposed to the flight simulator daily for two weeks reported less sickness, as would be expected, with each subsequent exposure. But ironically, and perhaps with implications for safety, they also demonstrated progressively more balance problems over this same time frame and as adaptation ensued (Kennedy, 1993).

Similarly, in a remarkable case following VE exposure, posteffects were reported to have occurred in a middle-age man after he spent approximately 2 hours in a three-story VE entertainment facility (Kennedy, Stanney, & Fernandez, 1999). After exposure, the individual, who historically had not been judged supersensitive to motion sickness, exhibited the characteristic signs and symptoms (viz., nausea, imbalance, dizziness, vertigo, sleep difficulties) of motion sickness and had to remain in bed for his first 48 hours at home. Subsequently, in medical examinations (neurologic and otolaryngologic) no organic cause for his symptoms could be found. The symptoms persisted for weeks, and then months, and he was still experiencing significant distress as much as six months after the initial exposure. Fortunately, by the ninth month he recovered, and now, several months later, he is considered to be symptom-free. If, during a bout of aftereffects, he were to become injured in an auto accident related to the persistent illusory perception of motion, it could be argued that the VE exposure caused the accident.

Note that the legal issue that surfaced here is not simply whether one can recover from cybersickness or any other form of motion sickness. The problem concerns the individual's ability to safely perform routine tasks. If his mental and physical functioning appears to have been perturbed because of his exposure-related distress, were this individual to fall from a roof, have an automobile accident, or participate in some other activity that he had not been warned about, then entities responsible for placing the VE device "in the stream of commerce" may be liable. For example, suppose that a driver of an automobile were to have a balance disturbance following a VE exposure, and suppose that his balance performance was equivalent to the disturbances seen with a .10% blood alcohol concentration level (Kennedy, Turnage, Rugotzke, & Dunlap, 1994). In this case, it could be argued that if postural equilibrium is disrupted, steering ability is also likely to be disrupted, and the cause of the degraded performance could be associated with a VE exposure. If that individual had an auto accident and had had no alcohol, he could argue that his imbalance might relate to the aftereffect experienced in the VE exposure.

Finally, profound drowsiness, sleepiness, and the experience of fatigue, frequently reported by-products of VE and simulator exposure, may occur during that period after a user is released from the VE device and is occupied with walking or driving home. These aftereffects can represent real hazards in the operation of motor vehicles and in certain types of work and recreational activities. Time may be required before the individual is ready to navigate safely in the "real world." Therefore, developers of VE systems should take steps to warn VE users about potential aftereffects and their implications for safety.

How long aftereffects may last after individuals leave the VE is an important question for which there are scant data. In one survey Baltzley et al. (1989) has shown that with 2- to 4-hour exposures in flight simulators, 1% to 10% of the operators had one or more symptoms that lasted a period of time after exposure and persisted after subjects left the simulator building. Careful analysis of problems associated with VE may help developers take proactive steps (such as the use of warnings, certification tests, and/or checklists) to assure that people who are exposed to VE may safely reenter the real world and to minimize developers' legal liability.

3. PRODUCT STANDARDS

With this potential for negative aftereffects from a product that may achieve wide usage in the private sector for education and training, as well as for entertainment, developers of VE systems should have concern over product liability issues. The law of product liability has its origins in tangible property, but has been extended beyond tangible goods to include intangibles such as electricity after it has been delivered to the consumer (Phillips, 1998). It has also been

applied to other items such as natural products and real estate fixtures such as a house (Phillips, 1998). The rationale for imposing strict product liability rests on the following ideas: (1) that the manufacturer is in the best position to reduce the risk and insure against the risk; (2) that the manufacturer is the one responsible for the product being on the market; and (3) that the consumer lacks the means and skill to investigate the soundness of a product for herself. This section will deal with product liability issues and definitions of ordinary defects, unknowable defects, and product and consumer expectation, among others. The relevance of defective warnings and negligence on causation will be discussed.

If a commercial product is placed in the stream of commerce and injury occurs, then the product may be adjudged defective because it occasions injury, and the responsible person or entity who knew or should have known it was defective can be held liable (Phillips, 1998). This liability can be attached to any individual or business that profited from the defective technology. For legal liability to be found, a product "defect" that is "unreasonably dangerous to the user" must be proven (Phillips, 1998, p. 53). Liability may also be imposed for inadequate design and/or inadequate warnings for foreseeable risks of harm that could have been avoided by the adoption of a reasonable alternative design or by reasonable instructions or warnings (American Law Institute, Restatement 3rd of Torts, 1997). In the present case, the VE system must be considered "dangerous to the extent beyond that which would be contemplated by the ordinary consumer" (p. 11). If VE systems have this known propensity for aftereffects documented in published scientific literature, the ordinary consumer may not be aware of any of the effects, or of all of the effects. Furthermore, if they do not use reasonable care, the potentially adverse consequences of product liability may accrue, to persons involved in research and development of these systems for purposes of bringing them to consumer use.

Because of the postural unsteadiness, drowsiness, and the discomfort of vomiting and retching, it would appear likely that aftereffects could result in accidents after usage of a VE system (Kennedy & Stanney, 1996a). This is a likely scenario since, while many users of VE technology are aware of the possible side effects of cybersickness, and, when afflicted, these individuals may restrict their own movements, predictably few are aware of the potential for loss of balance and eye-hand incoordination effects (Kennedy, Stanney, Compton, Drexler, & Jones, 1999) as well as long-term aftereffects. As an extreme example, there are reports of sickness following exposure to immersive video games at commercial amusement parks where vomiting occurred less than 15 hours later; our own research has shown that vomiting can occur long after the experience of a 60-minute exposure to a VE display (Kennedy, Stanney, Dunlap, & Jones, 1996). Incidentally, a similar situation occurs with the posteffects following long durations in microgravity (Reschke et al., 1994), although the number of persons exposed to extended durations in space is far smaller than the anticipated number that will be exposed under training regimes planned for the military (see chap. 43, this volume) and other federal services and those exposed in educational (see chaps. 45–46, this volume) or recreational settings (see chap. 55, this volume). In our research, we advocate the use of a procedure to certify that an individual has recovered to at least preexposure levels. This process, if in force, can protect users, as well as vendors, manufacturers, and other purveyors of VE systems from potentially damaging lawsuits.

Manufacturers might wish to follow the trend in modern law to avoid costly, time-consuming litigation all together by anticipating and responding to any potentially compromising possibilities. Thus, in order to minimize legal liability, VE systems may need to be properly prepared and accompanied by warning labels and appropriate directions (i.e., debriefing protocols) to raise the level of consumer awareness of the potential for harm. In order to provide effective debriefing protocols, objective measures of adaptation resulting from VE exposure are needed. Specifically with respect to VE, rather than waiting for issues to arise, it might be prudent to address safety concerns before they result in crisis or harm. A proactive rather than reactive

approach may allow researchers to identify and address potentially harmful side effects related to the use of VE technology. Standards or criteria need to be developed to guide VE developers' decisions, such as the principle of harm minimization. Under this principle, an activity should minimize harm to all exposed, which requires recognizing the concerns and interests of the various individuals involved (Kallman, 1993). More principles need to be established to guide and direct the safe development of virtual technology.

4. PRODUCT WARNINGS

Under a product liability theory, a manufacturer (or seller) of products may be liable for failure to provide adequate warnings as to dangers associated with its products. Generally, a manufacturer has a duty to warn against the latent dangers resulting from foreseeable uses of its products that it knew or should have known. An adequate warning is one that is reasonable under the circumstances (Lehto & Miller, 1986). To be adequate, a warning must describe the nature and extent of the danger involved (Cunitz, 1981). Often warning cases involve issues of providing adequate instructions for safe use of a product. A warning is distinguished from an instruction in that instructions are calculated primarily to secure the efficient use of a product, whereas warnings are designed to insure safe use (Phillips, 1998). A product distributed without adequate warnings or instructions is sometimes treated as one with a design defect. Therefore, a product may be faultlessly manufactured and designed, but may be defective when placed in the consumers' hands without an adequate warning concerning the manner in which to use the product safely. It is important to note that, ultimately, a manufacturer's liability for breach of duty to warn will depend on the plaintiff proving causation. This means the plaintiff must prove that he or she would not have suffered the harm in question if adequate warnings and instructions had been provided. Even though this element could be difficult to prove in many cases, it is of course in the manufacturer's best interest to protect from liability by giving adequate warnings. A warning must also be effectively communicated, and if it is, then failure to read the warning as given may bar recovery for a plaintiff (Lehto & Miller, 1986).

While there exists nothing in the case law addressing the situation of a consumer who is ultrasensitive to motion sickness, we do know that such persons exist in many environments (cf. Crampton, 1990). Furthermore, an analogy of hypersusceptibility can also be made to the allergic consumer where the duty normally owed to allergic users is one of warning, and then only when the plaintiff is a member of a substantial or appreciable number of persons subject to allergy, where the defendant should have known of this risk (Phillips, 1998). A seller may be required to warn that his product contains an ingredient that is a known allergen and may have to warn of the symptoms associated with an allergic reaction (Phillips, 1998). There is precedent for this action in that certain video games have been sold with labels that warn of the prospect of epileptiform seizures (see chap. 29, this volume) by susceptible individuals.

Furthermore, a "postsale" or "continuing" duty to warn generally exists where a manufacturer is responsible for warning of a defective product at any time after it has been manufactured and sold if the manufacturer becomes aware of the defect. This means that the manufacturer is under a duty to issue warnings or instructions as they later become known to the manufacturer, or even as they should become known, and that the manufacturer is expected to stay informed about advancements in the state of the art and/or of later accidents involving dangers in the product. For example, a drug manufacturer is treated as an expert and is under a continuing duty to keep abreast of scientific developments in regard to a product and to notify the medical profession of any additional side effects discovered from its use. Similarly, this idea could be applicable in the case of VE systems already in existence, imposing a continuing duty on the

manufacturers to keep up with developments and to provide proper warnings (American Law Product Liability 3rd, 1988).

5. PRODUCT LIABILITY ISSUES

The increase in product liability claims and settlements witnessed in the last half of the 20th century may be linked to the development of more sophisticated products. The sheer complexity of modern products is a source of danger because consumers may not understand safe use; risks may not be readily apparent. Additionally, consumers may not possess the knowledge to judge the quality, efficacy, and safety of a product; thus, assurance of minimum standards of performance is demanded from manufacturers (Howells, 1993).

In recent years, product liability litigation has been extended into many areas, including recreational equipment such as pool tables, trampolines, amusement rides, and attractions. Cases have arisen involving injuries on amusement park rides, such as water slides and roller coasters, where the amusement park and/or manufacturer were sued under a product liability theory. In some cases, a higher standard of care is imposed on amusement park operators, as well as manufacturer-designers of amusement park rides, because of the risk created to thousands of passengers, many of them children, for monetary gain (this is similar to the higher standard of care imposed on a common carrier, who is required to exercise great care to protect passengers).

It is true that there is generally no duty to warn users of an open and obvious danger incident to a particular use of a recreational product that was not defectively designed or manufactured (for example, diving into a swimming pool). However, in the case of VE sickness, the duty to warn most likely will exist, because the danger is not open and obvious.

Product liability law involves four basic types of liability standards: contractual or warranty standards, which involve products that fail to meet the promised standard; negligence standards, which judge the conduct of the defendant in light of risks and benefits that result from his conduct; strict liability standards, which do not judge the conduct of the producer/supplier but rather assess the product; and absolute liability standards, which are based on proof of damage caused by the product (Howells, 1993). Although any of these standards might be the basis for litigation in a case involving VE sickness and manufacturers of VE systems, negligence standards, in particular, merit careful consideration.

Negligence has been defined as conduct that involves an unreasonably great risk of causing damage (Terry, 1915) and, alternatively, as conduct that “falls below the standard established by law for the protection of others against unreasonably great harm” (Restatement [Second] of Torts, 1965, sec. 282). To make out a cause of action in negligence, the plaintiff does not need to establish that the defendant either intended harm or acted recklessly. Negligence focuses on the conduct of the various participants who are responsible for the product’s creation and entry into the marketplace. The judge balances the risks and benefits of the defendant’s conduct; risks include those that the defendant knew of, or ought to have known of, at that time. Risks that become known at a later date are irrelevant unless they could have been discovered by the defendant via testing or research that he or she could be expected to have undertaken (Howells, 1993).

The reasonable manufacturer is expected to be aware of current industry-wide standards and technology. Although evidence that a manufacturer has met self-imposed standards, voluntary standards, or even statutory standards is significant, such evidence alone does not establish that the manufacturer is not negligent. An entire industry can be found negligent for continuing to apply unacceptable standards of manufacture (Hooper, 1932) or for failing to make currently available technological improvements. The flexibility of the negligence standard is achieved by permitting interplay among three factors. In every negligence action, the court must consider:

(1) the probability that harm would occur; (2) the gravity of the harm; and (3) the burden of taking precautions to protect against the harm—what the manufacturer might have done to minimize or eliminate the risk of harm.

Because all human activity involves an element of risk, a defendant's conduct is deemed negligent only when it falls below what a "reasonable" person would have done under similar circumstances (Brown, 1991). Risks to health justify more precautions than risks to property, and the more serious the risk, the greater the precautions required. Although this assessment is made at the time of the alleged negligent act, for example, the time of manufacture of a defective product, there may be a separate postmarketing duty to monitor the product. When risks are discovered it may be necessary to either order the recall of the product or to take other steps to avert any danger (Howells, 1993).

Even though such safety principles are developed, unintended outcomes may occur. Thus, after performing a safety analysis to minimize harm, the issue of who is accountable (i.e., the appropriate person to respond when something undesirable occurs), responsible, and/or strictly liable when harm occurs must be resolved (Johnson, 1993). Responsibility is broken into role responsibility (i.e., responsibility linked to an individual's duties or by virtue of occupying a certain role), causal responsibility (i.e., a person who does something or fails to do something and this causes something else to happen), blameworthy responsibility (i.e., a person who did something wrong that led to an event or circumstance), and legal liability responsibility (i.e., one is legally liable when it is claimed that the individual must pay damages or otherwise compensate those harmed). If a VE product malfunctions, the consequences for the VE developers could range from simple accountability (i.e., reporting what happened) to full legal liability (i.e., paying compensation for damages). If VE products are being employed for training purposes, whether or not the training is internal to the company or carried out under contract may also influence liability issues. In addition, a company's position on this liability continuum may be related to how proactive that company was in terms of product standards and how extensive a preliminary safety analysis was performed.

6. SYSTEMS SAFETY APPROACH

In order to minimize their liability, manufacturers and corporate users of VE devices (i.e., companies) can proactively assess the potential risks associated with human factors by using a comprehensive systems safety approach. The human factors system safety approach, as originally put forward by Christensen (1993), has five elements, including: (1) design, (2) remove, (3) guard, (4) warn, and (5) train, in general order of preference of application. We follow the Christensen model, and for purposes of the VE product safety rendition offered below, provide two new approaches which can usefully be added to the case for VE systems: (6) certification and (7) monitoring/debriefing (Kennedy & Stanney, 1996b).

1. *Design.* Design new products to be as free of hazard as possible. Obviously, the first method of choice would be to eliminate any known hazard, which requires knowledge of the exact causes of safety concerns. Unfortunately, the exact causes of simulator sickness associated with VE use are not currently well understood, which underscores the need for cautious introduction of new products.

2. *Remove.* Remove hazards from existing systems. The ability to fix existing systems is limited by the same lack of knowledge that hinders the ability to design safe new systems. Making changes in existing systems and observing the impact on sickness incidence represents the best methodology for gaining knowledge to deal with the problem.

3. *Guard.* Where hazards cannot be eliminated or removed, users should be prevented from coming into inadvertent contact with the hazard. Guards must be convenient, obviously

essential, and must not impair operations. If a guard is not effective in eliminating a problem or interferes with training it should be eliminated.

4. *Warn.* Warn users of remaining hazards. A simulator sickness field manual has been developed by the Department of Defense (NTSC, 1989) and is distributed at simulator sites. The scientific basis of this field manual is described in a "guideline" report (Kennedy et al., 1987). The "field manual" and "guideline" are used to teach instructors and trainees to recognize simulator sickness symptoms and have been distributed to the three military services and the U.S. Coast Guard; they are also available in NATO countries. The "field manual" warns trainees using military simulators about potential risks involved when resuming activities, including flying, immediately after a bout of simulator sickness. Similar manuals and guidelines might be provided to users of VE systems. It is important to note, however, that warning is a less preferable alternative than the first three approaches (i.e., effective design, removing hazards, and guarding, Christensen, 1993).

5. *Training.* Even the best products may require training for safe usage. Were humans not so adaptable to altered sensory environments, no one would be able to tolerate simulator training or VE devices. Much of the advice contained in the field manual described above has to do with how to facilitate sensory-motor adaptation to the simulator and readaptation once outside it.

Teaching people to adapt rapidly to the peculiarities of VEs will be the primary means of enhancing the benefits of these devices while reducing the discomfort and risk that they may produce. If the first four methods (i.e., design, remove, guard, warn) are not sufficiently effective, a program of training can be prepared so that users can be taught to avoid hazards. In the case of VE sickness, perceptual adaptation is likely to occur (cf. Kennedy, Smith, & Jones, 1991; Uliano, Kennedy, & Lambert, 1986; see chaps. 37-39, this volume) and can be employed to reduce symptoms if proper schedules are followed.

6. *Certification.* In connection with the five main human factors system safety approaches outlined by Christensen (1993), we believe two additional approaches should be added (Kennedy & Stanney, 1996b). The first concerns measurement of the effectiveness of the freedom from hazard. This is called *process certification*. Should human factors problems be suspected, VE systems should be measured to determine the level of hazard they are expected to represent. Until recently, self-report was the chief method for certifying that a simulator was safe. Currently, objective measures and tests of human balance are being developed that could be used for certification purposes (Kennedy & Lilenthal, 1994).

7. *Monitoring/Debriefing.* The second additional approach involves measuring individuals to determine if they have been adversely affected by exposure to VE systems (Kennedy & Stanney, 1996b). Even if a system "passes" its certification procedure, human variability is such that some individuals may still be adversely affected by VE system exposure. In order to limit one's liability, it may be prudent to establish monitoring procedures, such as a postexposure balance test. The same or similar tests of human balance used for certification could also be used for monitoring. For those individuals who "fail" or marginally "pass" the balance test, debriefing protocols could be developed that provide information to those affected so they can act accordingly to minimize harm.

7. CONCLUSIONS

Virtual environment systems, while holding much promise to educate, train, and entertain, also have the potential to harm. Individuals exposed to VE systems may experience malaise during exposure and adverse aftereffects that could linger days or even months after exposure. System

developers can follow the systems safety certification approach discussed in this chapter to ensure they have exercised due care in protecting their patrons from harm.

1. INTRODUCTION

It is now generally accepted that virtual environment (VE) technology has immense commercial and educational potential, but so far the development of truly focused markets for VE applications is at an early stage. This chapter describes some of the factors at this early stage that will influence the ultimate growth of the VE market. In particular, the chapter stresses that high-selling costs can constrain the growth of the market, to the near-term detriment of the predominantly small-to-medium-size enterprise vendor/developer base. These technology and service suppliers face high selling costs because they have to educate the user. Their efforts have to be spread across a wide range of sectors, and many users need to see sector-specific applications of VE to convince them that it is worthwhile to invest in the technology. In the face of these high selling costs, some suppliers may be tempted to "hype up" the product they offer, sometimes making claims beyond what can be delivered at present. While this may lead to additional sales in the short term, it can also lead to dissatisfied customers, and dissatisfied customers at an early stage can depress the growth of the market in the longer term. The chapter is based on a simulation model of the selling process in VE, which was originally featured in an unpublished work by Stone (1996a). The model contributed to a series of strategic recommendations on the future of British VE efforts as part of a market study conducted on behalf of the U.K. government (Stone, 1996b). The present paper builds upon this to explore some of the constraints on market growth and to draw out policy implications for a code of good selling practice for virtual environments.

Those in the VE business are understandably very enthusiastic about the future for their technology. Robert Voiers, the founder director of the EDS Detroit Virtual Reality Center, is quoted as saying, "Virtual Reality is beginning to change the way we engineer and manufacture

our products. It's early days yet, but I believe we may be witnessing the start of a new industrial revolution".¹ However, these views are not only held within the VE industry. In their influential book, *Competing for the Future*, business school "gurus" Gary Hamel and C. K. Prahalad (1994, p. 103) described VEs, often known as virtual reality (VR) in commercial industries, as, "a technology with profound implications for almost every industry." Virtual reality, they concluded, "is a powerful perceptual tool."

Although the market for VE technology is still growing, a number of commentators have forecast a bright future (Bubley, 1994; Helsel & Jacobson, 1994; MAPS, 1995; Stone, 1996b; Thompson, 1993). Nine of the fifteen Technology Foresight sector panels set up by the British government highlighted VE as a technology with strong potential in their sectors: communications, construction, defense and aerospace; health and life sciences; information technology and electronics; leisure and learning; manufacturing production and business processes; transport; and financial services.

More and more companies are using VEs, at least in an exploratory way: at least 21 out of the top 30 from the U.K. Department of Trade and Industry's (DTI) World R&D Scoreboard. Recent market research commissioned by the U.K. VR Forum (Cydata, 1998, 1999) backed up to some extent by more international reviews (CyberEdge, 1997, 1999, 2000) found clear evidence that VE has now advanced far enough to enable a wide range of commercial applications, some of which are showing the prospect of substantial business benefits.

And yet the market for VE is still at an early stage. Given all this potential, why has it not developed further or at a more accelerated pace? Is it something to do with the particular character of the technology—the futuristic image of users sporting head-mounted displays (HMDs) and other forms of cyber gear? Or is it something to do with the early history of the market, with its high-tech bias toward leisure and entertainment? The aim of this chapter is to shed some light on these questions by examining what lessons business and economic thinking about the growth of markets generally has for the VE market in particular. In pursuing this aim, a model of the selling process in the VE business as developed by Stone (1996a) can be turned into a powerful simulation model to explore these questions.

It can be shown that selling strategies can have significant effects on the ultimate market potential. The simulation model described in this chapter is highly path dependent in the sense that the early history of selling strategies can have significant effects on the ultimate market potential. As Stone (1996a) emphasizes, selling costs can be very high at this formative stage of the market, essentially because customers know little about the technology and have to be taught—often at the expense of the pioneering producer. If companies try to reduce selling costs by cutting corners and perhaps by selling systems to customers who do not really stand to gain from the purchase, then this adverse experience can reduce the ultimate market potential for the technology. Good selling practice at an early stage may be costly for the pioneering producer, but by gradually building a community of highly satisfied users this can help to establish the long run market potential for the technology.

This chapter is organized as follows. Section 2 summarizes some of the key ideas in the economics of diffusion, that is, the rate at which new technologies are adopted by different types of end user. Then, section 3 sets out the background to the business process model of selling in VE, and section 4 sets out the basic structure of the model. Section 5 summarizes how the basic model is solved in each simulation, and what the structure of each simulation looks like, and section 6 summarizes some of the preliminary simulation results. Section 7 summarizes the conclusions for the future of the VE market.

¹VR News 7(2), March 1998, p. 15

2. THE DEMAND FOR NEW PRODUCTS: LESSONS FROM ECONOMICS

Projecting the market for a new technology is probably one of the most difficult questions in economics. Thomas J. Watson's celebrated underestimate of the potential market for computers is one famous example. These difficulties emerge for at least three reasons:

- It is customary to assume that tomorrow's markets are just more developed versions of today's, but in fact new needs, applications, wants, and sources of competitive advantage may be evident tomorrow that are not present today.
- We usually fail to recognize how "path dependent" is the evolution of demand for a new technology—meaning that the minor historical details and events of today can have a decisive role in influencing the potential future market for the technology.
- Demand projections will depend on the evolution of this technology, but also of its rivals, and the latter is not always easy to foresee. Moreover, one of the regular features of competition in new technologies is that new rivals emerge from unexpected directions—especially when technologies are converging. This makes it very hard to know what will be the most important technological trends that influence demand for a particular technology.

In economics and other areas of business studies, writers use the term *diffusion* to describe the spread in use of a new technology. In this section some of the main economic thinking about the diffusion of new technologies is summarized, as this will be an essential background to what follows. Much of what follows is about the rate at which a new technology diffuses, but it also touches on the absolute level of diffusion that may be achieved in the long term.

2.1 “Epidemic” Models

Economists use the term *epidemic* to indicate that there is a certain similarity between the diffusion of a new technology amongst a population of users and the spread of an infectious disease amongst a population of people who do not have resistance. In its simplest possible format, the epidemic model assumes (as with the infectious disease) that the rate of new cases (of adoption) is proportional to the product of the number infected (who use the technology) and the number who are not infected, but could be (the potential future adopters). This simple form yields the familiar S-shaped diffusion curve, showing how the number of adopters increases over time. Simple mathematical considerations show that the rate of diffusion is fastest toward the middle of the diffusion process, and in the simplest version of the model the fastest rate of adoption per period is when 50% (exactly) of the target population are “infected.”

Other, more subtle “epidemic” diffusion models generate slightly different patterns, but the basic story is the same. More complex models recognize that more complex patterns of interaction are required before one user will “catch” the technology from another. This leads to more detailed models of the buying and selling process.

The social process that spreads the use of a technology is taken to be the exchange of information amongst potential users, and the pioneer plays an important demonstrator and educational role in this. In more subtle models of this sort, it is not just the number of pioneers that count, but also their quality. Moreover, the effect that the pioneer has on subsequent adopters is also dependent on his experience with the technology: Good experiences promote diffusion, whereas bad experiences retard diffusion. This has important implications both for government policy and for the business strategy of VE companies.

In the very long term the level of diffusion approaches (asymptotically) a maximum or saturation level of diffusion. This technique is useful for projecting how fast the uptake will

be, given a certain saturation level of diffusion, but it does not in itself help to estimate the saturation level. Moreover, speeds of diffusion will vary enormously from one technology to another—compare the diffusion of the car and a particular pop record, for example.

2.2 Diffusion Driven by Rising Income or Other Buyer Characteristics

Another force leading to diffusion is related to rising income, increasing turnover, or other characteristics of the buyer. As income per capita rises gradually over time, consumption of some products will rise. At an early stage, buyers may be limited to those on relatively high incomes, but as the average level of incomes rise, more and more buyers enter the market. The same principles can be applied to the diffusion of new technologies among firms. For some expensive new technologies, early buyers may be the larger firms (in a particular industrial sector), but as the smaller firms grow, they too would be potential buyers.

This approach to the analysis of diffusion can also be used with other consumer or firm characteristics. As customers become more educated they are more likely to buy certain products. Likewise, as firms become more concerned to seek new sources of competitive advantage in an ever more competitive market, they may be more likely to buy into some new technologies.

As far as VE is concerned, it appears that within a particular sector, and holding other factors constant, the larger companies are more likely to be early adopters. But the average size of companies in those industrial sectors that are pioneering the application of VE may not be as high as in some nonpioneering sectors.

In general, diffusion promoted by growth in incomes, revenues, or other buyer characteristics tends to be a slower process than diffusion attributable to other effects. The reason for this is simply that the rate of growth of incomes is typically quite a small percentage rate. Gross domestic product (GDP) per head rises at perhaps 3% per annum on average, and most consumers' incomes rise no faster than that. Large companies do well to grow any faster than that. Some smaller companies of course can grow a good deal faster, but they are outnumbered by companies that don't. And once again, this approach is useful as one of the factors determining the rate at which a technology diffuses, but does not in itself indicate the likely saturation level of diffusion.

2.3 Diffusion Driven by Falling Prices and Rising Quality and Performance

In many high-technology markets the main driving force behind the diffusion of a new technology is that as it becomes cheaper and/or better, ever more buyers are willing to adopt. Moore's law is a classic example of this. The law states that the rate of increase in the number of "gates" per semiconductor chip is doubling every 18 months or so, and also implies an exponential decline in the price per component. As the price per bit falls over time, so ever more users are drawn into the market. The speed of diffusion here depends on the speed of price decline and the variance of the willingness to pay of different buyers. As noted above, these rates of change provide a more rapid impetus to the diffusion of the technology than rising incomes or turnover.

A more subtle version of this story gives due account to the role of improvements in performance as well as reductions in price. The usefulness of this more subtle picture is that it can distinguish between the effects of improving quality (at given price) and falling price (at given quality). It can also show how the market is segmented between base-quality, superior-quality, and top-quality versions of the technology and how this segmentation would change over time. The rate of diffusion in this process, again, depends on the speed at which prices fall and quality improves.

2.4 Strategic Models of Diffusion

In the approaches described above, a company or consumer's decision to buy is assumed to be independent of what others decide. However, for both the individual customer and the industrial buyer, this need not be so. This observation opens up two important strands of diffusion analysis.
