The first arises when the fact that others are already using a technology makes a new buyer more likely to adopt. This could arise when there are benefits from adopting a technology that has a large installed base of users. The existence of a large installed base is often a powerful signal to some buyers that this technology is no longer the risky prospect that it appeared at first. This feature makes for a very powerful and rapid diffusion process, where if one technology gets ahead of the field, the market will quite rapidly lock into that technology. This approach is used to model the emergence of *de facto standards* or *dominant designs* in markets.

This feature of rapid take off can also arise when firm B faces competitive pressure to adopt a new technology because their rival firm A is using it with good effect to take market share away from B. While firm B may not be especially interested in adopting the technology on its own merits, it may become interested if firm A exploits the technology for competitive advantage. This can lead to a "me too" attitude to adoption and a very rapid rate of diffusion.

This process of diffusion due to competitive pressure, operating in addition to the other processes described above, can further accelerate the process of diffusion. One major feature of technological change noted above is that firms tend to find new competitors emerging from new and unexpected directions. That means the technology adoption decisions of an ever greater number of firms can impinge on the decision faced by one particular firm. This proliferation of competitors can make diffusion due to competitive pressure a very pervasive as well as a very rapid process and will continue to raise the level at which the market reaches saturation.

So far, the case where the fact that others already use a technology makes the new buyer more likely to adopt has just been described. For completeness it should be mentioned that it is well recognized in consumer buying behavior that consumption may be as much influenced by the behavior of the *distinction group* from whom the consumer wishes to distinguish himself, as by the behavior of the *peer group* with which he wishes to associate. When this feature is important, it tends to suggest that there are likely to be clear upper limits to diffusion, covering far less than 100% of the potential population.

In principle these effects can also arise in the context of industrial buying, though it is not clear whether they are relevant in the context of virtual environments. They could be relevant if a group of pioneering VE buyers is (for whatever reason) seen as a distinction group by another large set of industrial buyers. This would happen if early applications in some sectors were generally thought to be unsuccessful and if other companies seek to distinguish themselves from the "tainted" early users. Or, as some VE vendors observe, the success of VE as a "games" technology may discourage some business users who see VE as a "toy" and not a serious business technology. This emphasizes again how important it can be that early applications of a technology are successful to maximize its ultimate diffusion.

3. BACKGROUND TO THE STONE MODEL

Stone (1996a) set out a detailed model of the buying and selling process that operates in virtual environments. In particular he charted a detailed description of some of the many stages between the first tentative meetings between the VE company and prospective buyers

and the eventual adoption and use of the technology, with identified risks and nominal costs (labor rates and on-costs) to “VR users,” “VR suppliers,” and “VR developers.” Consideration was given to such processes as evidence of relevant demonstrators, development of technology demonstrators, provision of relevant “educational” and informative material, recruitment, and training. It was shown that issues such as VE technology (hardware and software), education, standards and quality, future government roles, academic research, health and safety, plus other barriers to entry all affect the uptake of VE into a business and the further integration and development of the technology within that business (see also Appendix 3, which presents a checklist for potential VE users, published as part of a later “VR Awareness” CD by Virtual Presence [U.K.], under contract to the U.K.’s Department of Trade and Industry). Some of the flowcharts underpinning this model, together with a brief description of part of the initial (“Primary Education Process”), are included at the end of this chapter.

A prominent characteristic of the early markets for VE applications is that sellers face very high selling costs. For any new technology these selling costs can be high, but they do appear especially high in the case of virtual environments. As Stone (1996a) pointed out, sellers need to devote a high level of resources (especially the time of senior staff) toward educating prospective buyers.

These education costs can be expected to fall over time as customers become more familiar with the technology and as a larger base of established users is available to provide demonstrations of how the technology can be applied in a particular setting. While the purchase decision at an early stage may well involve a feasibility study, this may become less important at a later stage because the existence of established users able to provide relevant demonstrations may give the user sufficient confidence to proceed.

The model set out by Stone (1996a) could be placed in the “epidemic” tradition of diffusion models. As described above, these models have been so called because the diffusion of the new technology is a little like the spread of an infectious disease. Stone’s model is a good deal more subtle than the basic epidemic model; in the latter, one meeting is sufficient to spread the disease, whereas in the case of a new technology many more stages are of course involved. Nevertheless, the basic structure of the model is the same, for it is as a result of a sequence of meetings and dialogues that the adoption or rejection decision is made.

It is also clear that in Stone’s (1996a) model, that the quality of adoption—by which we mean the extent to which the adopted technology has been satisfactory or otherwise—can depend on the details of the selling process. To quote the terminology in Stone’s model, if sellers who know little about the target business choose to “go in blind” rather than do some preliminary market research, then that can reduce the chances of a purchase. And if sellers who see that VE does not currently have a promising application in a user company decide to “come clean,” then while this may reduce their sales revenue in the short term, it will also ensure that the percentage of satisfied adopters is kept up.

The preliminary model set out in Fig. 28.1 is a refinement of Table 1 in Stone’s (1996a) paper. This corresponds to the Primary Education Process, from preliminary exploratory meetings up to the stage where the user company procures a VE system for in-house use. (Note: The model uses the more commercial term VR rather than VE) As such, it does not cover the subsequent stages when the company experiments with the in-house system before deciding whether to implement it long term. The preliminary model was cut off after this first stage of the process not because the subsequent stages are unimportant, nor because they are not amenable to analysis in this way, but simply because it was thought appropriate to test what is already a reasonably complex model before proceeding to build a more complex version.

As noted before, most of this model is in the *epidemic* tradition. But there also some important demonstration effects and *network externalities*, so that the probability of one user adopting is dependent on the number of others who have already adopted. For this reason, the

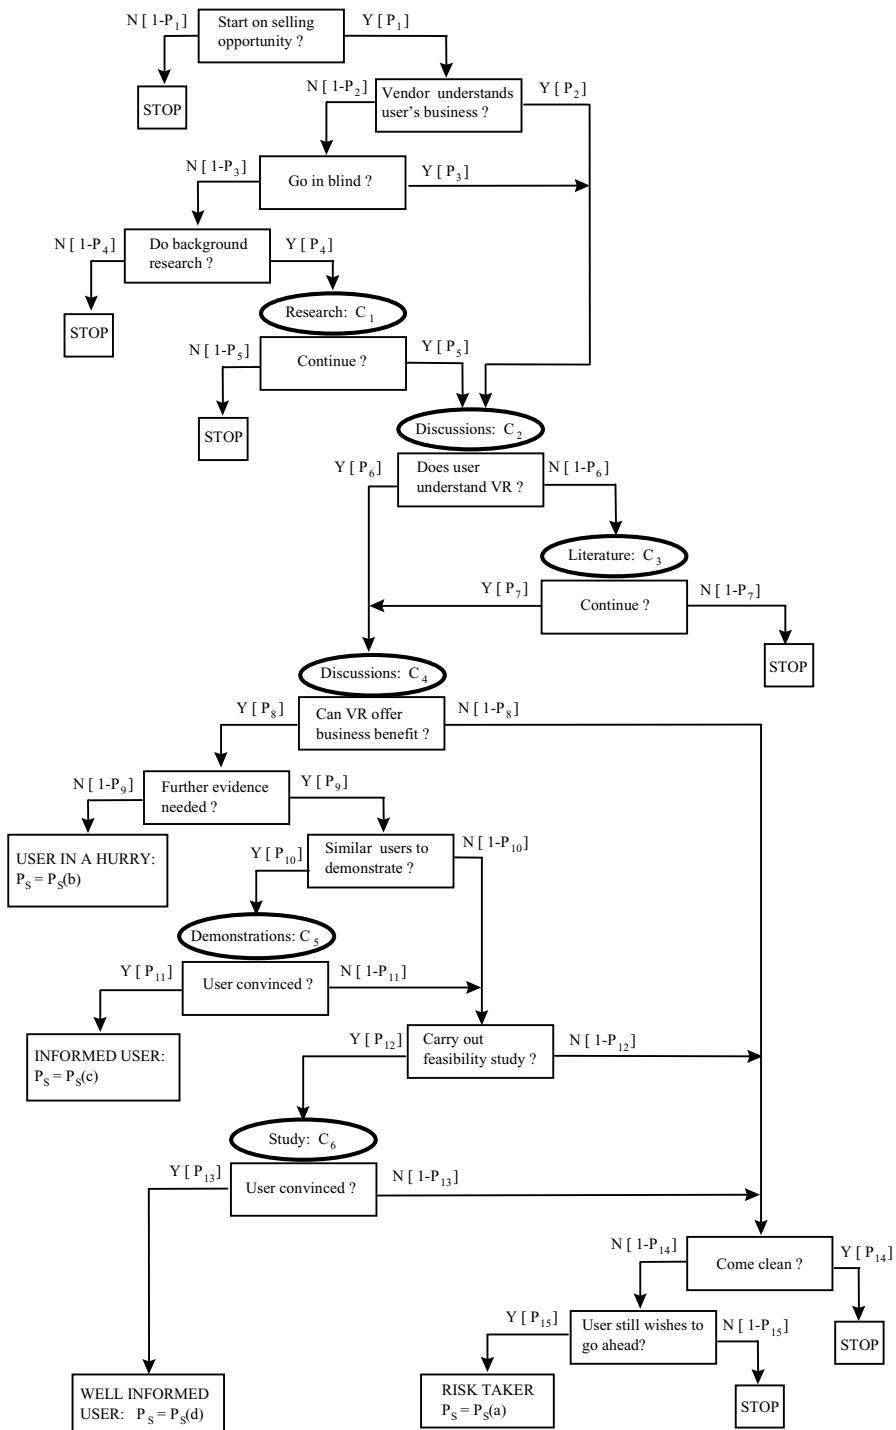

FIG. 28.1. Model of selling VR.

simulation model is able to make use of some of the features used in the simulation of market defined (or de facto) standards (Shurmer & Swann, 1995).

4. CREATING A SIMULATION MODEL

In this section the main relationship and parameters in the model are summarized. The full equations are set out in an appendix to this paper. Roughly speaking, each box in Fig.28.1 containing a question translates here into an equation yielding a probability. Thus for example, the box containing the question "Is the target business understood by the VR expert?" is turned into an equation stating the probability of a yes as a function of several variables and parameters. In particular, the probability of a yes is an increasing function of the sales "focus" of the producer, the accumulated knowledge of the producer, and the general level of diffusion of the technology.

The main components of the model are as follows. The first equation (Equation 1) simply reflects the fact that as the "focus" (or core competence) of producers narrows then the number of business opportunities they pursue will decline. On the other hand, as discussed below, an increased focus may improve the probability of success. If the producer does pursue the business opportunity, then the second equation (Equation 2) models the probability that the seller understands the user's business. Equation 3 models the decision of whether to "go in blind" or whether the vendor will consider doing background research on the user's business (Equation 4).

Equation 6 describes the probability that VR is actually understood by user's representatives. This is more likely as the general level of diffusion increases, but it also depends on the probability that the seller "goes in blind," knowing nothing about the user's business. When this happens, the chances that the user can understand the potential of VR will decline. If the user does not understand VR, then Equation 7 summarizes the chances that the seller's "literature" or other educational efforts will succeed in explaining to the potential user what VR can do. This probability is assumed to depend on the quality of the "literature" and also on the probability that the seller has adequately informed himself about the user's business before preparing the "literature."

If this educational process is successful, then the model proceeds to the next stage (Equation 8), which is to assess the probability that VR can offer a satisfactory business benefit to the user. This probability is assumed to follow an S-shaped function of the level of diffusion: the greatest competitive incentive for adoption accrues when other users have adopted. The analysis of strategic incentives for adoption recognizes that more subtle responses may be relevant here (previously mentioned). If the answer is yes that VR can offer a satisfactory payoff, then the next equation (Equation 9) asks whether it is likely that further evidence is needed before the user can make a decision about whether to procure a VR system for in-house use. This probability falls as the general level of diffusion increases, because the technology is perceived to be less risky. It also falls if sellers have chosen to inform themselves about the user's business (see above), for once again this means that the user sees the investment as a less risky one. If the user decides that no further evidence is needed to convince him that procuring a VR system is worthwhile, then he proceeds to the first "adoption" stage, and this is classified as a "user in a hurry."

If more evidence is needed, the first question (Equation 10) is whether there are similar users who have already adopted who could demonstrate the application of the technology to the prospective user. This probability increases as the general level of diffusion increases, and there is an important parameter in the equation describing the rate at which this probability increases. If the answer to this is yes, then the next question (Equation 11) is whether the

user is convinced by such a demonstration. The probability of a convincing demonstration depends on the level of applications “focus” chosen by the seller (previously discussed): If this focus is high, then it is more likely that the demonstration will convince. This probability also depends on the proportion of satisfied adopters amongst the population of all adopters: The higher this is, the more convincing a demonstration will be. If the user is convinced, then he proceeds to the adoption stage and is classified an “informed user.”

The next equation (Equation 12) in the model picks up the remaining unconvincing users. Do they ask for a feasibility study from the VR producer? This probability is proportional to the proportion of unsatisfied adopters amongst all adopters: The higher this is, the riskier is adoption, and so the greater the need for a feasibility study.

The next equation (Equation 13) models the probability that those who commission a feasibility study where there is a demonstrable commercial payoff to adoption will be persuaded by the feasibility study to proceed to procuring an in-house VR system. These are classified as well-informed users, but in the case of those who do not commission a feasibility study, and/or who are not convinced by the evidence, the next equation (Equation 14) models the probability that the seller chooses to “come clean.” The vendor who “comes clean” would say that this investment does not look worthwhile, but those who don’t may proceed with a sale, but one that has a smaller probability of a satisfactory application. This probability that the seller will “come clean” depends on the same parameter that influenced the seller’s decision to “go in blind” (though inversely) and also increases as the general level of diffusion increases—because it is assumed that sellers have less incentive to make such sales when the market is larger. (In some cases we have made the rate of increase small or zero because the level of competition may also increase as the market size increases, and that could sustain the need for such sales.)

If the seller “comes clean,” then it is assumed that the sale falls through; if he doesn’t, then it is assumed that there is a 50% probability that the user will proceed and buy, and a 50% probability that he abandons the project. Those who buy are classified as “risk takers” because there is a reduced probability that adoption in such circumstances would lead to a satisfactory outcome.

In the model there are four routes to the decision to procure a VR system: the “well informed,” the “informed,” the “user in a hurry,” and the “risk taker.” It is assumed that the probability of success is highest in the first case. (Indeed, we set that probability at 1 and smallest in the last case. In the exploratory simulations it was set at 0.5, though in practice a lower figure may be relevant). There are also a number of “exit points,” at which the user decides to abandon the project.

5. SOLUTION STRUCTURES

The model described above has been programmed into a simulation model. Each simulation involves the following steps:

1. For each possible sequence in the model, a probability is computed.
2. These probabilities are aggregated into five categories:
 - All paths leading to a “well-informed” decision to adopt
 - All paths leading to an “informed” decision to adopt
 - All paths leading to a “user in a hurry” decision to adopt
 - All paths leading to a “risk-taker’s” decision to adopt
 - All paths leading to an abandonment of the VR project

TABLE 28.1
Parameter Values and Ranges

Parameter	Maximum	Minimum	Fixed Value
b_1 ("focus")	0.99	0	
b_2 ("vendor knowledge")	1	0	
b_3 ("go in blind [1]")	1	0	
b_4 ("go in blind [2]")	0.5	0.001	
b_5 ("user understand")	1	0	
b_6 ("literature quality")	1	0	
b_7 ("business benefit")	1	0.1	
b_8 ("need for evidence")	1	0	
b_9 ("similar users")	1	0	
b_{10} ("need for study")	1	0	
b_{11} ("come clean")	1	0	
$P_s(a)$ ("risk-taker")			0.5
$P_s(b)$ ("user in a hurry")			0.7
$P_s(c)$ ("informed user")			0.85
$P_s(d)$ ("well-informed user")			1.0
C_1 ("research")			20
C_2 ("first discussions")			10
C_3 ("preparing literature")			10
C_4 ("second discussions")			50
C_5 ("demonstrations")			50
C_6 ("feasibility study")			100
$X(0)$ (total diffusion at $t = 0$)			10
$X_s(0)$ (satisfied diffusion at $t = 0$)			5
$X_u(0)$ (unsatisfied diffusion at $t = 0$)			5

*For definition of model equations, see Appendix 2.

Simple probabilities are computed for each of these aggregates. In the case of the four paths that lead to adoption, the model assumes that the probabilities that adoption will be successful and that the user will be content depend on how well informed the user is at the time of adoption: the better informed, the higher the probability of success. This is captured in parameters $P_s(a)$ to $P_s(d)$, as shown in Fig.28.1 and defined in Table 28.1.

3. Each investment (or selling cost) on the part of the seller is given a weight or cost. These are the costs of: researching the users' business (C_1); discussions with the potential user about the applications of technology (C_2); preparing "literature" and other educational material for the inexperienced user (C_3); further discussions with the potential user about prospects to obtain a satisfactory payoff from VR investments (C_4); the costs of setting up demonstrations of other users' VR applications (C_5); those costs of setting up a feasibility study that fall on the seller (C_6).
4. The elementary probabilities for each path are weighted by the costs incurred along that path and summed to obtain an expected selling cost for each simulation.
5. Each simulation is run for 20 periods (where the length of the period is essentially indeterminate, though it is more likely to be a month than a year).

6. SOME SIMULATION RESULTS

Simulations have been run for a group of 5,000 parameter sets. Each simulation result consists of a set of solutions for each of the equations discussed above in section 4. Table 28.1 gives the range of values for those parameters that vary from simulation to simulation and also the (constant) values of parameters that do not vary across the simulations.

Before summarizing these simulation results in full, it is useful to explore some of the properties of the model by varying one parameter at a time and holding all other parameters constant. This is done by setting the values of the b parameters equal to the midpoint of the range described in Table 28.1.

Figures 28.2 to 28.5 show how the model responds to variations in four of the parameters. Parameter b_1 describes the degree of focus in the vendor's selling strategy: the higher is b_1 , the more the vendor focuses his selling on a particular set of end-user markets. The striking thing in Fig. 28.2 is that the "best" strategy—best, at least, in the sense that it minimizes selling costs per satisfied new customer—requires an intermediate degree of focus. If the seller is too focused, that is if $b_1 \rightarrow 100\%$, then sales are very low. If the seller is not focused, he does not know enough about the user's business to make a well-informed sale. He has either to incur research costs (C_1) or run the risk of making sales were the buyer is not well informed about VR—and such sales run the risk of building up a community of unhappy customers.

Fig. 28.3 summarizes what happens when parameter b_3 is varied, which could be described as the first "go in blind" parameter. It is the parameter in the numerator of Equation 3, and hence the higher it is, the more likely the vendor will "go in blind." Figure 28.3 shows a series of dots representing steps of 2.5% in the value of b_3 . As this parameter increases from zero, total new diffusion rises steadily—even if little of this is to satisfied customers. Indeed, beyond about $b_3 = 0.5$, satisfied new diffusion actually falls even if total new diffusion continues to

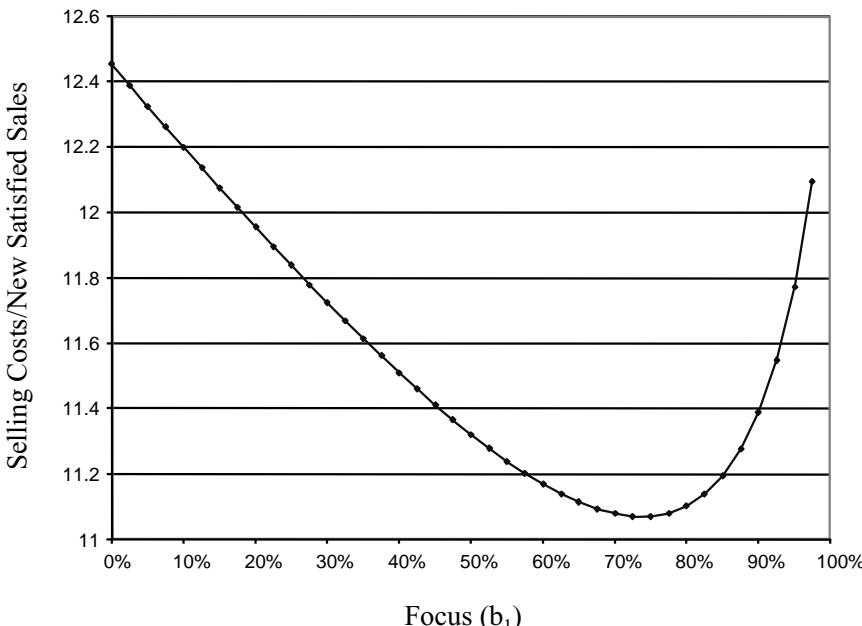

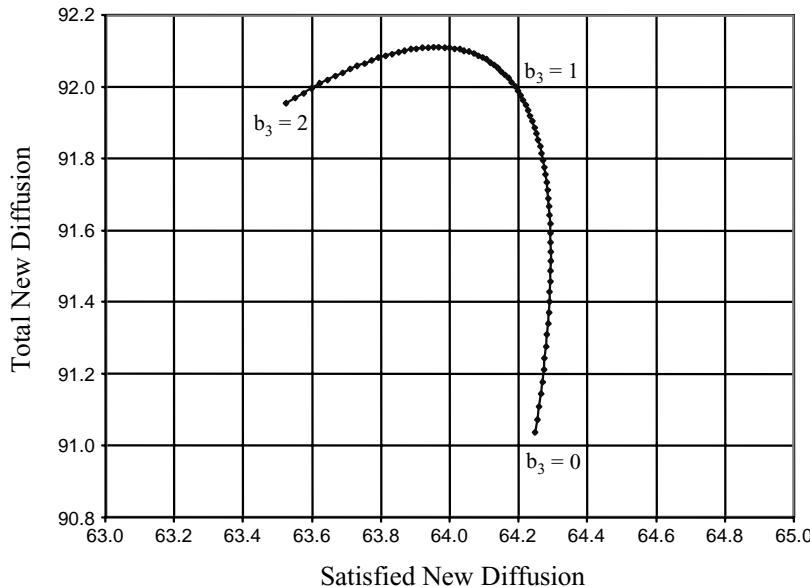

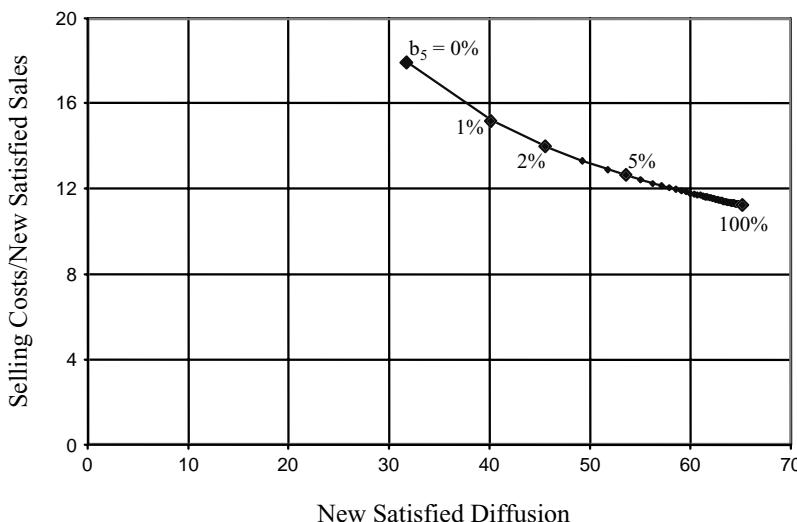

FIG. 28.2. Varying the "focus" parameter (b_1).

FIG. 28.3. Varying the “go in blind (1)” parameter (b_3).FIG. 28.4. Varying the “user understanding” parameter (b_5).

increase. Beyond about $b_3 = 1$, even the total new diffusion starts to tail off, and at very high values of b_3 , total diffusion starts to fall. The implication of this is clear. A certain amount of “going in blind” may be essential to increase overall diffusion, but it does not do much for customer satisfaction. But too much “going in blind” will mean that the vendor does not collect any sales—not even unsatisfied customers.

Figure 28.4 shows a similar graph for different values of b_5 , the parameter describing how the user’s understanding of VR increases as total diffusion of VR increases. Starting from a

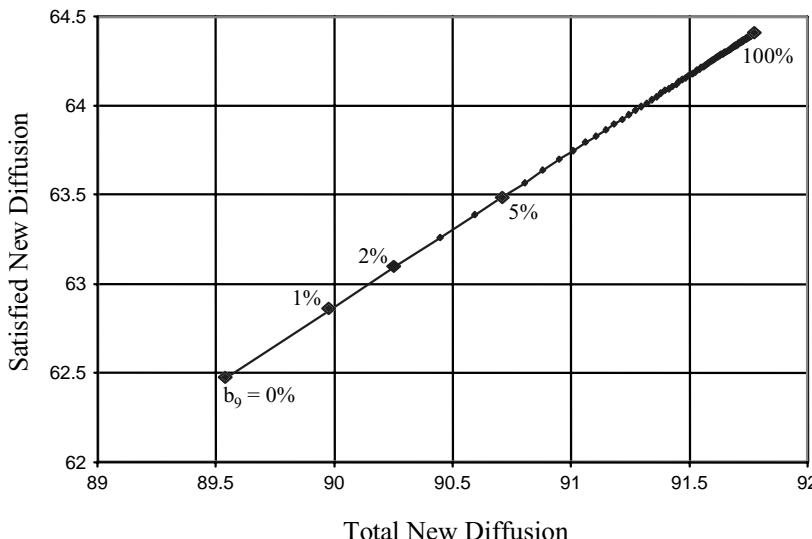

FIG. 28.5. Varying the “similar user” parameter (b_9).

base of $b_5 = 0$, it is clear that as this parameter increases the selling cost per satisfied customer falls and diffusion to satisfied customers increases. Indeed, for the particular set of values for all other parameters (see Table 28.1) it only takes a quite modest value of b_5 to generate these beneficial effects. The key point is that ideally the user should learn *something* from general diffusion of virtual reality.

Finally, Fig. 28.5 presents a similar picture for parameter b_9 , which describes how the probability of finding a similar user to demonstrate an application to a prospective buyer increases as general diffusion increases. Again, as this parameter increases total diffusion and satisfied diffusion both increase. Indeed, it is the first few percentage points that are critical here: raising b_9 from 0% to 5% achieves about the same effect as increasing it further from 5% to 100%. The rate of increase in satisfied diffusion is not quite so high as total diffusion—suggesting a small amount of dissatisfied diffusion, but the former dominates.

Now the discussion turns to the full set of simulation results. As those familiar with simulation will know, it is easy to generate multidimensional complex simulation results and then lose sight of what the results indicate about the essential features of the model under evaluation. To avoid that, a procedure is adopted that has been used to good effect elsewhere (Shurmer & Swann, 1995), which is to summarize those simulations that are best at satisfying certain criteria. For the present study, the three criteria are as follows:

1. A high proportion of adopters are satisfied with the technology
2. High levels of total diffusion
3. Low selling costs per satisfied customer

Table 28.2 summarizes the simulation results as follows. Using each of the above criteria in turn, the simulation results are sorted into the “best 20%” and the “other 80%.” Table 28.2 then shows the average value of each criterion and each parameter in the “best 20%” compared to that for the “other 80%.”

The first two columns show the results when simulations are sorted by criterion (a). Here the “best 20%” contains the simulation results where the ratio of satisfied to unsatisfied customers

TABLE 28.2
Summary of Simulation Results

	<i>Sort by Criterion (a)</i>		<i>Sort by Criterion (b)</i>		<i>Sort by Criterion (c)</i>	
	<i>Best 20%</i>	<i>Other 80%</i>	<i>Best 20%</i>	<i>Other 80%</i>	<i>Best 20%</i>	<i>Other 80%</i>
New satisfied/new unsatisfied	2.70	2.33	2.32	2.42	2.35	2.41
Total diffusion	51.8	94.8	158.4	68.1	60.1	92.7
Selling costs/satisfied customer	14.6	12.3	12.6	12.8	10.9	13.2
<i>b</i> ₁ (“focus”)	68%	45%	12%	59%	67%	45%
<i>b</i> ₂ (“vendor knowledge”)	50%	50%	51%	50%	58%	48%
<i>b</i> ₃ (“go in blind [1]”)	38%	52%	50%	50%	55%	48%
<i>b</i> ₄ (“go in blind [2]”)	26%	25%	26%	25%	25%	25%
<i>b</i> ₅ (“user understand”)	49%	51%	54%	49%	61%	48%
<i>b</i> ₆ (“literature quality”)	49%	50%	53%	49%	55%	48%
<i>b</i> ₇ (“business benefit”)	62%	54%	57%	55%	70%	52%
<i>b</i> ₈ (“need for evidence”)	19%	57%	52%	49%	72%	44%
<i>b</i> ₉ (“similar users”)	53%	49%	51%	50%	49%	50%
<i>b</i> ₁₀ (“need for study”)	60%	48%	51%	50%	49%	50%
<i>b</i> ₁₁ (“come clean”)	53%	50%	50%	51%	49%	51%

is greatest. It is interesting to note that in these simulations, the typical total level of diffusion is considerably less than in the “other 80%.” This reveals a typical (though not inevitable) trade-off in this simulation model between scale of diffusion and proportions of satisfied customers. And to achieve this degree of satisfaction requires slightly higher selling costs per satisfied customer than in the “other 80%” of simulations. The “best 20%” of simulations on this criterion have relatively high average values for *b* parameters 1 (“focus”), 7 (“business benefit”) and 10 (“need for feasibility study”), and relatively low values for *b* parameters 3 (“go in blind [1]”) and 8 (“need for evidence”). In short, the model generates outcomes with a high proportion of satisfied customers:

- When sellers pursue focused selling strategies where they are well informed about the prospective user’s business and do not “go in blind”
- When sellers are prepared to help in the costs of feasibility studies when required
- When business benefits grow steadily as diffusion increases

Turning now to the second criterion, the second pair of columns shows that the “best 20%” of simulations achieve far higher levels of diffusion than the “other 80%.” The proportion of satisfied customers is slightly lower in this “best 20%”—though not much—and selling costs per satisfied customer are indeed slightly lower in the “best 20%” than in the “other 80%”. How is this? The main difference in parameter values between the “best 20%” and the “other 80%” here is that the simulations in the “best 20%” have far lower focus (*b*₁). Otherwise, there is little difference between the two sets of simulations, though the “best 20%” have higher values for the “user understanding” parameter. In short, an essential part of a strategy to achieve diffusion on a large scale is that selling should not be focused, but it also helps if users are quick to learn from the general diffusion of VR.

Finally, turning to the third criterion, the third pair of columns in Table 28.2 show that the “best 20%” can achieve substantially lower selling costs per satisfied customer, but only achieve this at substantially lower levels of diffusion. These lower selling costs also show up in a slightly lower proportion of satisfied customers. Here many parameters show a much higher average in the “best 20%” than in the “other 80%.” These include b parameters 1 (“focus”), 2 (“vendor knowledge”), 3 (“go in blind (1)”), 5 (“user understand”), 6 (“literature quality”), 7 (“business benefit”), and 8 (“need for evidence”). In each case a higher value of the parameter helps to reduce the costs of selling per satisfied customer.

7. CONCLUSIONS AND POLICY DISCUSSION

This chapter has provided a brief summary of a simulation model of the VE selling process, based on the description of that process set out in Stone (1996a). Some preliminary simulations with the model have yielded the following preliminary and tentative conclusions.

Selling costs, which are high in the VE market at the stage of development, are seen to play an important role in the subsequent development of the market. To achieve a large proportion of satisfied customers in the diffusion process, it is necessary to incur high selling costs. It is not possible to achieve the highest proportions of satisfied customers with the lowest selling costs. And this satisfaction among early adopters can be important for the health of the subsequent diffusion process.

A focused selling strategy is effective if the desire is to keep selling costs low or if the desire is to achieve high proportions of satisfied customers. But to achieve the highest levels of diffusion a less focused selling strategy may be required. On the other hand, it generally pays if sellers as a group “do their homework” about the businesses of prospective users before trying to sell the technology, rather than “go in blind.” In the same way, it is best if sellers as a group tend to “come clean” with users when prospects for a successful application of VE in their business look poor. The incentives that must exist for some sellers to break rank and behave “badly,” but trusting “good” sellers to follow this public-spirited approach to selling have not, however, been explored here.

It is generally helpful for diffusion and user satisfaction if the pool of similar established users of virtual environments, who can demonstrate its potential, grows rapidly. This suggests that sector-specific case studies of the successful adoption of VE could have an important role in promoting diffusion. Moreover, for the model parameters selected for these simulations (and these may not be representative), high-quality educational “literature” seems to play a valuable role.

7.1 Policy Implications

Pandit et al. (1997) explored whether the especially high level of selling costs found in the formative stages of the VE market made a case for government activity to fund awareness activities. The essence of their argument was as follows. Traditionally, economists looking at microeconomic policies for microeconomic issues (as opposed to macroeconomic management) used the principle that policy intervention would be called for where there is market failure. The problems with this are:

1. Market failure is very common, but not always too serious.
2. Regulatory failure may be worse than market failure in some settings.
3. Some policies suffer from a lack of additionality. They cannot always distinguish between

(1) subsidizing activities that would not have happened otherwise (additionality) and (2) subsidizing activities that would have happened anyway. Category (1) seems desirable while category (2) looks wasteful. Some skeptics fear that (2) may be quite large unless government agencies incur large monitoring costs.

In fact, even these observations do not tell the full story. Category (2) is an undesired transfer payment from the taxpayer to a company, but at least it does not distort incentives away from the "true" ones. Category (1) may induce some who should buy to do that, but may also persuade some to buy who probably should not. The implications of this are discussed later.

For these various reasons, the existence of market failure on its own is rarely a sufficient case for industrial policy. But the fact that pioneer producers in VE have to incur an educational cost in selling to inexperienced buyers is a potentially important case of market failure. The educational activities of pioneers convey benefits (externalities) on later entrants to the market. This is a part of the rationale for the DTI's current VR Awareness Programme.

Pandit, Swann, & Watts (1997) argued that a more compelling argument for industrial policy in this area is as follows. In those areas of industry where the market outcome is highly path dependent, a small and finite investment at the formative stages can shift the market onto a higher growth path. Indeed an increasing number of economists would now consider that most markets for new technologies show highly path-dependent behavior, meaning that the eventual market size is influenced by all kinds of second-order historical events throughout the life of the technology, and particularly at the formative stages. In particular, the analysis of standards and dominant designs above has stressed how small events at the formative stages of a market can influence which technology wins a standards race.

Some generic government policies have in the past been designed to try to promote diffusion by subsidizing pioneering users. The traditional measure of success here is that of *additionality*: A subsidy is only worthwhile if it promotes adoptions where adoption would not otherwise have happened. If the subsidy simply pays a company to do something that it would have done anyway, then it is at best irrelevant, and at worst an arbitrary and undesirable transfer payment.

The epidemic model described above and the Stone (1996a) model of the selling and buying process offer a somewhat different perspective. Additionality is not enough on its own; it must be additionality plus good experiences from adoption. If a subsidy creates an additional adopter who has good experiences from adopting the technology, then this is well and good. But if the subsidy creates an additional adopter who would not have adopted in the absence of a subsidy and who does not have good experiences from adoption then this is not just wasteful, but may also be damaging.

This suggests that any diffusion-oriented policy to promote pioneering users of VE should take care to ensure that these users' experiences will be as positive as possible. This suggests that such a policy should articulate a code of good practice in selling. Moreover, it may be best if resources are directed at increasing the information available to firms deciding whether or not to adopt virtual environments technology or applications. In that case, companies can make well-informed decisions taking into account local circumstances, rather than be swept along with a bandwagon that may not help them at all.

Appendix 1. Example Model Expansion: The Primary Education Process

At its highest level, the model developed by Stone (1996) is a six-stage process, with the following headings:

Introduction: whereby individuals or teams from a given industry sector first come into contact with VR.

Primary Education: the process whereby those individuals (technology “champions” by this stage—the power of ownership should not be underestimated) gain more information about the technology and make their initial commitments;

Secondary Education: typically quite a lengthy process whereby the technology champions, often with external support, organize demonstrators for exposure to their own local team(s) and to higher echelons within the organization. During this stage, much effort is expended in commercially justifying possible adoption of the technology:

Adoption/Rejection: Adoption can take two forms. One is relatively straightforward in that the organisation, having indulged in the secondary-education process, procures a turnkey VR system and begins to develop its own internal exploratory studies. The second involves continued VR development with external support (and frequent demonstrations), usually resulting in the delivery of a turnkey bespoke VR system. Rejection can, of course, occur if (a) little or no support is forthcoming from within the user organization, despite (sometimes many) demonstrations, or (b) if a VR system has been procured under false pretences (i.e., from the outset, VR stood little or no chance of solving the user’s problem or delivering a quality application, but a system was, nonetheless, purchased by, or sold to him).

Integration: This is a process which has yet to be studied in detail, due mainly to the fact that few—if any—VR systems have been integrated within an organization’s business practices with a suitable period of postintegration review. Also, no real methodologies or guidelines exist as yet to assist in the integration process.

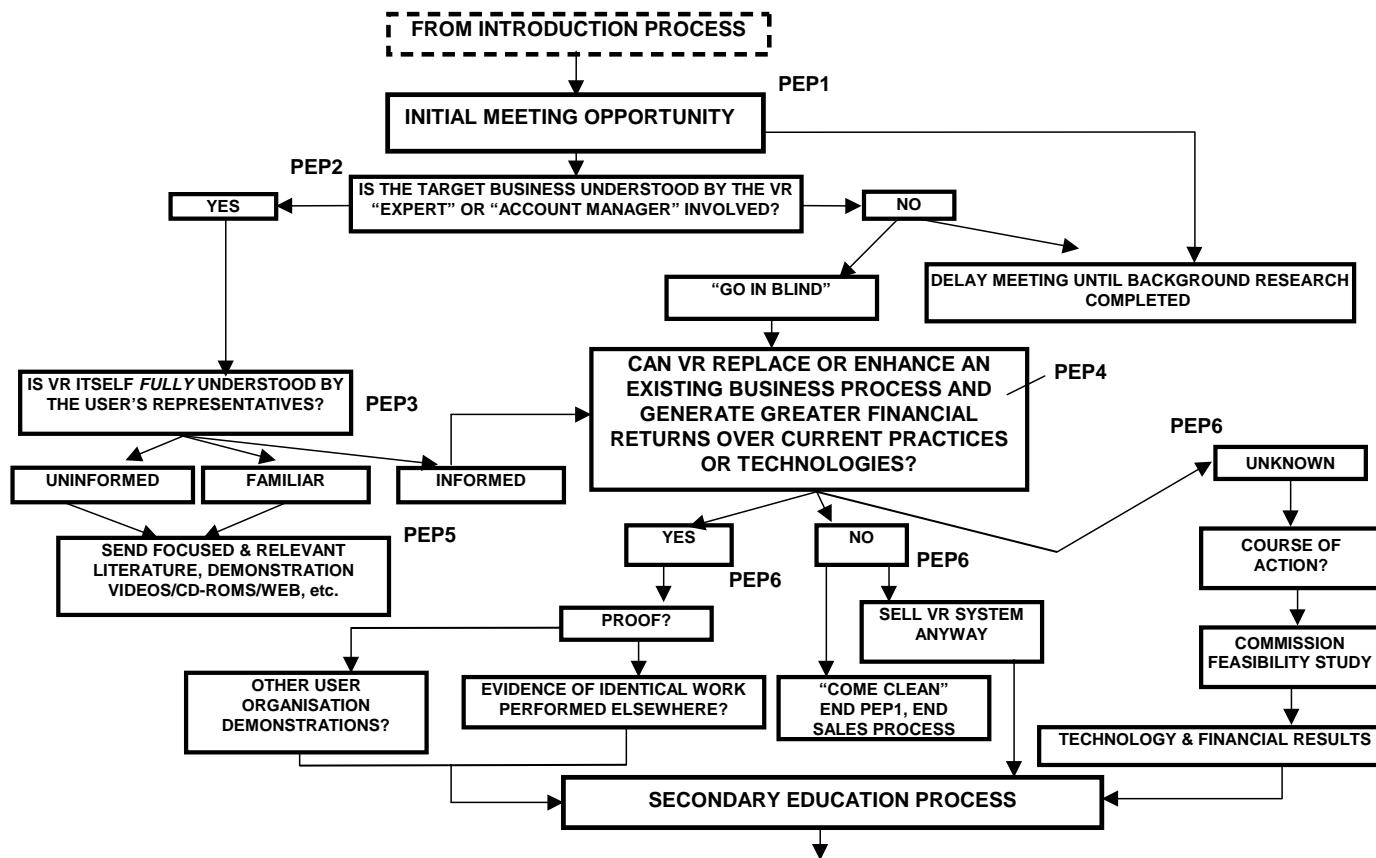

FIG. 28.6. "The Stone Sales Model": Primary Education Process (PEP).

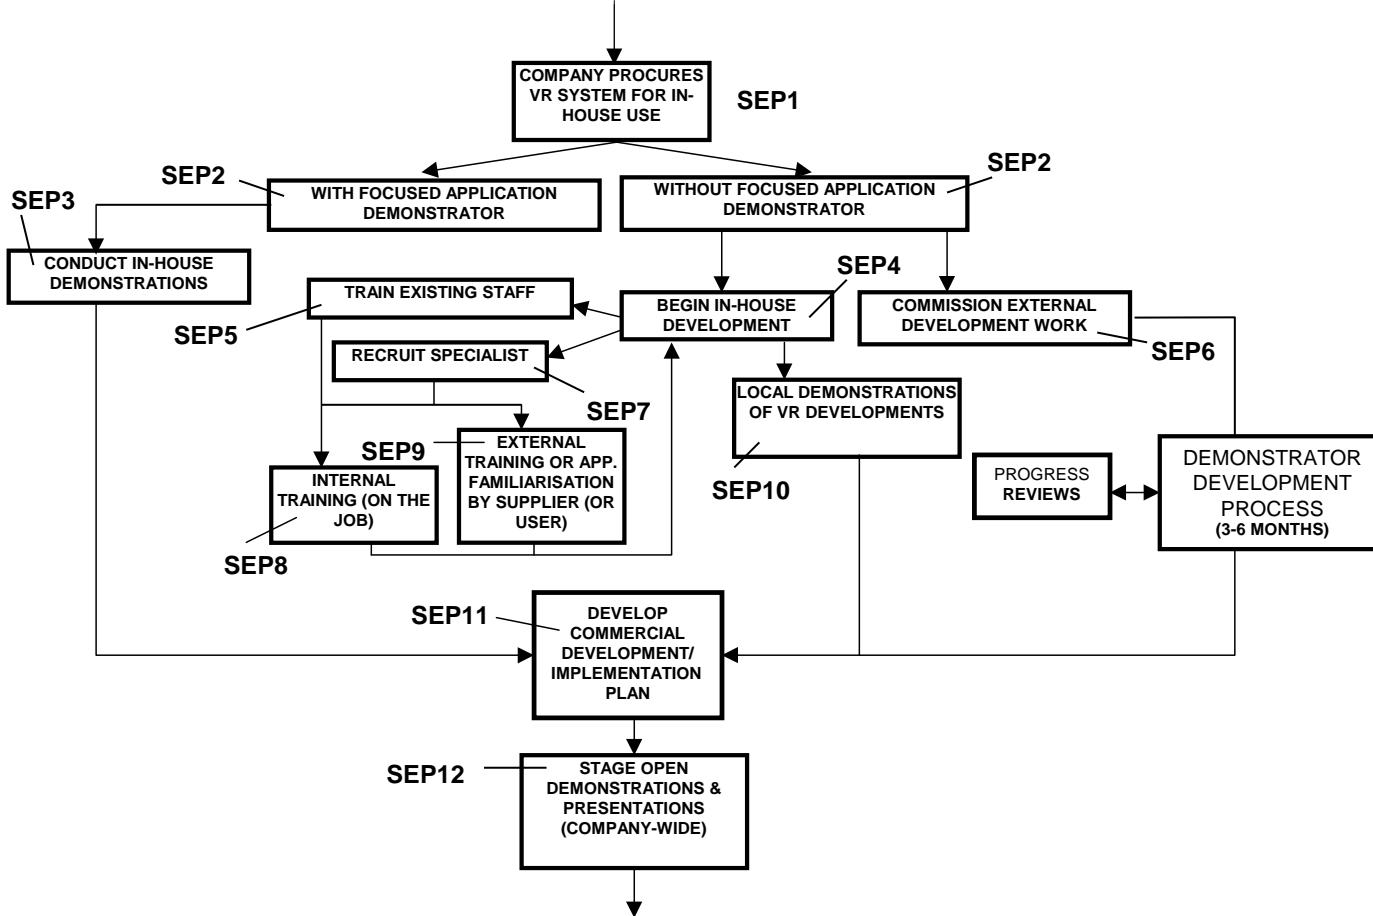

FIG. 28.6. (Continued)

Development: Development refers to how the organisation develops its business and growth strategies around the integration of the VR technology. Important issues include recruitment, training (and retraining), system enhancement (with, hopefully, original supplier and developer support), corporate and supplier communications and data sharing, quality, standardization, and so on.

Only the Primary Education Process is expanded here. See Fig. 28.6.

PEP1: THE INITIAL MEETING OPPORTUNITY

Following the event at which the organization's VE champion first decides to take his initial lines of enquiry further (cards having been exchanged, inquiry forms filled out, telephone inquiries made, etc.), meetings are set up, either at the potential user's premises, at the offices and demonstration facilities of the supplier or developer, or both. Factors that influence the timing and location of the meetings are:

- Supplier/developer schedules and commitments
- The degree to which the supplier or developer perceives the user as a serious potential bringer of business
- The supplier's or developer's geographical location
- Availability of traveling salesmen ("account managers" in more recent terminology)

Note that the judgment made by the supplier or developer as to the perceived value of a user is not as clear-cut as one might expect (i.e., wealthy user = significant business). Even the most basic of contact with a user classified as having a "nonserious" application could bring short-term commercial value—in the form of future prestigious press releases, for instance—something VE companies are very responsive to.

PEP2: IS THE TARGET BUSINESS UNDERSTOOD BY THE VE "EXPERT" OR "ACCOUNT MANAGER" INVOLVED?

This is a most significant question in terms of VE business development. Virtual environment technology is still very much a "technology push" rather than "market pull" domain. Yet, the salesman or account manager who makes no attempt to understand the business of the user he is about to visit (or be visited by), and entertains the user's representatives "blind," runs the risk of seriously damaging his company's chances of securing business, not to mention adversely affecting the still-fragile industrial and commercial status of the VE market. Virtual environment proponents or sales teams who have, for the sake of a quick sale, portrayed just the plus points of the technology (rather than "coming clean" about what the technology can and cannot do, vis-à-vis the user's business) have already caused problems, the effect of which has swept rapidly through both supplier or developer and user communities.

If the target user's business is understood, then an important follow-up question has to be asked:

PEP3: IS VE ITSELF FULLY UNDERSTOOD BY THE USER'S REPRESENTATIVES?

Depending on how the user's representative first came into contact with VE technology, she will most likely have a preconceived idea as to what the technology is and what it might do

for her organization. In the worst case, the user might still foster an impression that VE is quite a low quality technology, based on her exposure to advanced graphics from film and television advertising media (this suggests immediately that the user has not grasped the real-time significance of VE technology and the impact this driving feature has on the need to be “economical” with graphics quality). She might be further concerned about such issues as cost, quality, the “necessity” to wear HMDs or gloves, or the health and safety debate (see chap. 41, this volume). There may be a significant degree of skepticism (or even fear about loss of jobs) among her colleagues, particularly those involved in other electronic media, such as CAD, digital design and art, and so on.

As part of the supplier’s/developer’s role in the education process, it should be a mandatory requirement to provide the potential user with VE data sheets which are both informative and independent from any one product or solution. Should the user require further information, then this could be supplied in the form of video or CD-ROM applications examples and preagreed contact details with a range of other, more active users.

Whilst this list of “shoulds” is but an ideal at the moment, it is well within the VE community to produce something of relevance which could be held centrally for distribution by nominated “information brokers”—VE societies or respected magazines, such as *VR News* (see chap. 56, this volume). Until that happens, however, potential users will continue to be inundated with glossy brochures and press release statements from VE suppliers. In fact, these collections of often irrelevant data sheets actually do little to provide the user’s representative with the information he needs, save some element of encouragement and motivation that “somebody else might doing something relevant out there.” The documents typically fall into two categories. One category comprises technical data—polygon counts, rendering facts, chipset specifications, benchmarks, and so on. Often these may well confuse a practicing VE specialist, let alone a newcomer to the field. The other category comprises documents that are often major “cut-and-paste” affairs, featuring the same “pro-own-product” statements from the supplier’s managing director and filtered “pro-their-product” statements from the “satisfied” user. It is amazing how many users actually express concerns other than those published when quizzed at a later date.

Whatever is forwarded to the user before a meeting or demonstration, it should be based on the supplier salesman’s attempt at gaining some understanding of the business she is trying to penetrate, as highlighted in PEP2. Irrelevancy, as is often the case, can be as damaging as no information at all. An initial meeting should not normally be held until sufficient time has elapsed for the user’s representative to digest all information.

Finally, the supplier or developer must, prior to the initial meeting, be thoroughly prepared for the following question:

PEP4: CAN VE REPLACE/ENHANCE AN EXISTING BUSINESS PROCESS AND GENERATE GREATER FINANCIAL RETURNS OVER CURRENT PRACTICES OR TECHNOLOGIES?

Is there a significant amount of retraining necessary? Do specialists need to be recruited? What changes to the user’s internal and external infrastructure need to be made? How much will it cost?

If the answer to the question posed under PEP4 is genuinely no, then two things might happen (PEP7). Either the salesman continues with the hard sell approach and convinces the user to purchase an entry level VE system, or the salesman can “come clean” and admit that he believes that VE is not yet ready to solve the commercial problems or enhance the organization’s business process at this time. The effect of the former can be quite disastrous. Depending on the level at which the selling attempt is pitched, it has also been shown that

overselling an inappropriate product can delay a company's adoption of VE for the better part of a year.

If there is still some uncertainty associated with the answer to PEP4, then one solution might be (and sometimes is, currently) to commission an off-site proof-of-concept demonstrator, which falls under the next main section, "Secondary Education." Another solution, which is becoming increasingly popular, is to commission a feasibility study (PEP8), addressing the specific problem in hand and proffering technical and fully costed solutions (typically with a range of options from low-level desktop VE implementations to full-blown immersive and projection systems), plus a semiformal proposal for the main phase of work, if successful. Depending on the customer, feasibility studies can cost anything from £UK3,500 (approximately \$5,000) to £UK25,000 (approximately \$36,250). Some 80% of feasibility studies result in paper report deliverables; the other 20% demand either a simple demonstration of the application on- or off-site. Some supplier companies, anxious to secure business, will carry out feasibility studies free of charge. Of course, the results of these studies tend to be completely biased towards the supplier's own product range. Also, any free VE modeling work carried out as part of the study tends to be put together extremely quickly (minimizing distractions to the supplier's core business), often resulting in a poor quality demonstration.

If the answer to PEP4 is a definite yes, then the responsibility falls on the supplier or developer to deliver "proof," typically in the form of a relevant case study conducted by or for another organization (typically delivered verbally, as few complete case studies yet exist), backed up by demonstrations (PEP6). Again, depending on the user company involved, this next step can sometimes be paid for (indeed at this stage, some companies are quite forthright in informing the user that the consultancy "clock" has been started). Alternatively, some of the larger supplier companies might, as recorded above, donate VE modeling and demonstration work for free. An interesting effect can occur at this point which has potentially damaging consequences for some user organizations. If the demonstrations are held in one of the (increasing number of) so-called reality or demo centers (in both commercial and academic circles), then there is evidence of an attitude among some user representatives that VE appears far too expensive to be even considered at this stage. The overemphasis on presentation quality—the demonstration environment, the method of display, even the decor—coupled with the rather glitzy entertainment flavor of the demonstrations presented, detracts from the serious message that VE can bring technical and commercial benefits. Worse still (and this is becoming increasingly evident in academia) is that the reality center or CAVE (Cave Automatic Virtual Environment, see chaps. 11 and 13, this volume) facility has no quality content (research or otherwise) associated with it, and the technology is being used to deliver rather poor "fly-throughs" or other developers' demonstrations.

Appendix 2. Mathematical Model: Equations

(For interpretation of these equations, refer to section 4 and Fig. 28.1 in the chapter.)

Equation 1: Start on selling opportunity?

$$P_1 = 1 - b_1$$

Equation 2: Does VR seller understand user's business?

$$P_2 = b_1 \cdot \left(1 - \frac{1}{1 + b_2 X} \right)$$

Equation 3: Does VR seller elect to "go in blind?"

$$P_3 = \frac{b_3}{1 + b_4 X}$$

Equation 4: Does VR seller do background research on user's business?

$$P_4 = 1$$

Equation 5: Does VR seller continue with selling opportunity?

$$P_5 = 1$$

Equation 6: Does user representative fully understand VR?

$$P_6 = \left(1 - \frac{1}{1 + b_5 X}\right) \cdot [1 - (1 - P_2) \cdot P_3]$$

Equation 7: After reading literature, does user interest continue?

$$P_7 = b_6 \cdot [1 - (1 - P_2) \cdot P_3]$$

Equation 8: Can VR offer business benefits to the user?

$$P_8 = 1 - \frac{1}{1 + b_7 X}$$

Equation 9: Does the user require further evidence?

$$P_9 = \frac{1 - (1 - P_2) \cdot P_3}{1 + b_8 X}$$

Equation 10: Are there other similar users who can demonstrate?

$$P_{10} = 1 - \frac{1}{1 + b_9 X}$$

Equation 11: After seeing demonstrations, is user convinced?

$$P_{11} = b_1 \cdot \frac{X_s}{X}$$

Equation 12: Is it necessary to carry out a feasibility study?

$$P_{12} = b_{10} \cdot \frac{X_u}{X}$$

Equation 13: After seeing the feasibility study, is the user convinced?

$$P_{13} = 1$$

Equation 14: Does the vendor "come clean" that VR may be of limited use to this user?

$$P_{14} = (1 - b_3) \cdot \left(1 - \frac{1}{1 + b_{11} X}\right)$$

Equation 15: Does user still decide to go ahead?

$$P_{15} = 0.5$$

Appendix 3 (continued). Specific Business Questions

- Would you describe your organization as creative in the sense of how you design and create a visual impact for your product or service?
- Do you do your own marketing?
- Do you take part in a major exhibition, specific to your market, at least once a year?
- Do you supply to an organization already using or considering using VE technology
- Are your competitors evaluating VE (are you certain that your competitors aren't evaluating VE)?
- Do you already have an installed computer base?
- Are any of these computers Pentium II-33 or better?
- Are any of these computers equipped with special graphics boards (e.g., Permedia 2, Riva TNT, Voodoo, nVidia GeForce, or other Open GL-compliant cards)?
- Do you already use computer-based visual "techniques" for design, sales, marketing, training, or communication (e.g., MacroMedia, Alias, PhotoShop, 3DStudio, etc.)?
- Do you make the information technology (IT) investment decisions for your business? If not, how much influence do you have on those who do?
- Does your organization have an IT implementation or expansion plan for the next 2 to 5 years?
- Would you describe your organization's expenditure on IT research, investment, and regular upgrades as "healthy" (i.e., do you keep reasonably up-to-date with purchasing hardware, software or services of relevance to your market)?
- How receptive is your organization's board generally to advanced forms of IT? Are they aware of VE technology?
- Are board members likely to be more receptive to VE if you could show them something specific, relevant, and with evidence of commercial returns?
- Would your organization be prepared to sanction expenditure of, say:
 - £UK7,000 (approximately \$10,000) for an entry-level VE system (which, if unsuccessful, could be redeployed elsewhere in the organization)?
 - £UK3,500 (approximately \$5,000) for an independent review and presentation on VE and its relevance to your business?
 - £UK5,000 (approximately \$7,250) to allow one or more members of your organization to undergo basic VE training?
- Do you have access to the Web?
- Are you networked with local (office/building/national) parts of your business?
- Are you networked with remote (international) parts of your business?

1. INTRODUCTION

To deal with the effects that virtual environment (VE) technologies might have on users, the categorization of direct versus indirect effects is herein used. *Indirect effects* affect the user at a high functional level. Indirect effects include psychological effects, such as modification of phobias and enhancement or repression of emotions. Indirect effects also include neurological effects on the visual system (eyestrain, modification of stereoscopic vision, and visual acuity). Virtual environments can also affect the motion detection system and may result in imbalance, nausea, and motion sickness. Research and recommendations into indirect effects including eyestrain and motion sickness are reported in chapters 30 to 32 and 36 to 39 (this volume). *Direct effects* of VEs are less complex to study and control, but are potentially as great a hazard to users. The direct effects of a VE system are those that act at a direct tissue level, as opposed to the body systems level of the indirect effects. Direct effects are the influence of energy on body tissues from the technology and the risk of trauma because of encumbrances (e.g., weight of a helmet-mounted display [HMD]). Trauma is a particularly important issue, because the essential features of VEs are *interactivity* and *immersion*, where the user interacts in three dimensions with computer graphics. Irrational exuberance by users totally absorbed in the virtual experience might occur in some situations and result in injuries. Fortunately, dealing with direct effects of VEs is mostly a matter of common sense and awareness.

2. DIRECT TISSUE EFFECTS

2.1 Visual System

In the evolution of VE systems, considerable development efforts have gone into construction of visual displays. In the visible, ultraviolet, and infrared wavelengths of light, there are hazards to the eye. See Table 29.1 for a delineation of biological hazards to the eye from these light wavelengths.

Light energy can be concentrated enough to damage ocular structures directly; however, such light levels are unlikely to be used in VE systems, as they would be uncomfortable to look at and not serve any purpose in the display. There are a few possible exceptions. Note that eyestrain from visual displays will be discussed in chapter 37 (this volume). This chapter includes a discussion of seizures and migraine headaches induced by flashing lights and moving images.

2.1.1 *Visible Light*

A novel approach to development of visual displays is the use of scanned laser light directly onto the retina. In practice, as with the conventional displays described above, there should be little hazard. However, high-power light could potentially be introduced to the eye, so care must be taken (see Table 29.2). These light scanning systems use high-frequency vertical and horizontal scanners to scan tightly focused noncoherent light or coherent laser light directly onto the retina. The Virtual Retinal Display (VRD) (TM, Microvision Incorporated, Seattle, Washington) is one such display. The VRD was invented at the University of Washington in Seattle and uses laser light to scan images onto the retina. Practical use of the VRD in room light conditions has shown that images that appear very bright can be generated with very-low-power light levels, typically on the order of 100 to 500 nanowatts. The power limit for a Class 1 laser as defined by the American National Standards Institute (ANSI) is 400 nanowatts (ANSI Z136.1, 1993). Lasers with wavelengths only in the visible range that emit less than this power level can be viewed continuously without damage to the retina (ANSI Z136.1, 1993). Beyond this power level (Class 2 and above), damage can occur to the retina or the optics of the eye, depending on the wavelength, the duration of exposure, whether the exposure is pulsed or continuous, and the intensity. The ANSI standard explains how the risks can be determined.

The VRD has a potential risk when it is used as an augmented reality display, that is, where the computer-generated image is viewed superimposed on the ambient visual scene. If the

TABLE 29.1
Summary of Basic Biological Effects of Light on the Eye

<i>Photobiological Spectral Domain</i>	<i>Eye Effects</i>
Ultraviolet C (0.200–0.280 μm)	Photokeratitis
Ultraviolet B (0.280–0.315 μm)	Photokeratitis
Ultraviolet A (0.315–0.400 μm)	Photochemical UV cataract
Visible (0.400–0.780 μm)	Photochemical and thermal retinal injury
Infrared A (0.780–1.400 μm)	Cataract, retinal burns
Infrared B (1.400–3.00 μm)	Corneal burn, aqueous flare, IR cataract
Infrared C (3.00–1000 μm)	Corneal burn only

Source: OSHA technical manual.

TABLE 29.2
Laser Classifications—Summary of Hazards

<i>Applies to Wavelength Ranges</i>					<i>Hazards</i>		
<i>Class</i>	<i>UV</i>	<i>VIS</i>	<i>NIR</i>	<i>IR</i>	<i>Direct Ocular</i>	<i>Diffuse Ocular</i>	<i>Fire</i>
I	X	X	X	X	No	No	No
IA	—	X*	—	—	Only after 1000 sec	No	No
II	—	X	—	—	Only after 0.25 sec	No	No
III A	X	X**	X	X	Yes	No	No
III B	X	X	X	X	Yes	Only when laser output is near Class III B limit of 0.5 watt	No
IV	X	X	X	X	Yes	Yes	Yes

Key: X indicates class applies in wavelength range.

* class IA applicable to lasers “not intended for viewing” only.

** CDRH Standard assigns Class IIIA to visible wavelengths only. ANSI Z 136.1 assigns Class IIIA to all wavelength ranges.

VRD were used in very-high-altitude aircraft, superimposition of the images on the ambient scene might require very-high light power levels to provide a perceived image of adequate brightness and contrast. These power levels could damage the eye. It should be noted, though, that such images would be uncomfortably bright and probably would not be usable without attenuation of the light from the external scene and from the VRD.

Safety of laser light can be analyzed through straightforward means and calculations using the ANSI standard. Interestingly, the same intensity limits might well be applied to noncoherent (nonlaser) light. Such analyses would be most relevant for displays using scanners.

2.1.2 Infrared and Ultraviolet Light

There are a few circumstances where infrared (IR) and ultraviolet (UV) light could be encountered in VE systems. The most likely reason would be incidental output of these wavelengths from the particular display technology. As with visible light, safety of IR and UV can be readily determined with simple measurements and calculations. These can also be found in the ANSI standard or in other sources. If there is no need for these wavelengths, inexpensive and effective optical coatings can be used to prevent their transmission into the eye.

Occasionally, UV or particularly IR can be useful. The technique of video-oculography (VOG) can measure the eye movements of a VE system user (see chap. 9, this volume). To obtain these measures, the user wears a head-mounted video camera, usually based on a micro CCD chip. Good illumination of the eye is necessary in order for the video image recognition technology to work. In order to avoid interfering with viewing, the illumination and video imaging are done in infrared. Cameras for capturing the images of the moving eye are mounted on the head. In a VE system, they can be mounted inside an HMD. The cameras are generally fitted with filters to block light above about 800 nanometers. The eye is illuminated with an infrared emitting LED, whose illumination is not visible to the eye. High-output infrared LEDs can be a hazard to the eye, as they can lead to cataracts. Furthermore, as the eye cannot see the illumination, the user is not aware of the hazard. Class 1 light emission device limits are generally a good place to start. The FDA regulation Part 1040—Performance Standards for Light Emitting Devices, describes the calculations. The most stringent standard

is for continuous viewing: defined as longer than 10^4 seconds. For example, for infrared light of 850 nm wavelength the permissible radiant power is 7.6×10^{-5} W. The regulations and basis for calculations can be found at www.fda.gov/cdrh/radhlth/cfr/21cfr1040.10.pdf or through the Food and Drug Administration.

2.1.3 Photic Seizures

Statistics show that 1.1 in 10,000 people are prone to photic seizures (Quirk et al., 1995). A photic seizure is an epileptic event that is provoked by flashing lights. A bright light pulsing at the rate of 1 to 10 Hz can drive repetitive firing of neural cells in large groups. If enough of these cells begin firing in synchrony, the activity causes a chain reaction spreading throughout reasonably large portions of the brain. Individuals who experience such neural activity generally show a brief period of *absence*, where they are awake but do not respond. Rarely, photic seizures will become generalized convulsions. In standard neurological tests for epilepsy or the tendency for epilepsy, pulsed bright lights are used to see if seizure activity can be induced and recorded on an electroencephalograph. These types of events are at times triggered accidentally in a seizure prone driver passing a picket fence with the sun behind it, or with other sources of repetitive light flashes. Video images in the 50 to 60 Hz range showing striped patterns have been used to induce seizures (Kasteleijn-Nolst Trenite et al., 1999). Repeated seizures can lead to brain injury and a lower threshold for future episodes.

A well-publicized incident of large numbers of induced photic seizures occurred in Japan, where a cartoon television program featured a scene in which red and blue frames alternated at 12 Hz (Takada et al., 1999). Hundreds of children viewing this program had absence attacks. A similar event could occur, inadvertently or deliberately, if pulsing light was shown to a VE user. A plausible scenario involves transport delay: the processing time from the movement of a user's head to the movement of the scene in an HMD. If a complex scene is in the VE system, the computer processor may slow in the real-time reconstruction of the scene. If the slowing went to several frames per second, the potential for flashing in the range that provokes photic seizures might occur. As with most safety problems, this circumstance could be detected by an individual dedicated to safety monitoring from the company producing the images. Producers of VE display technologies and content would do well to have a reviewer monitor their products for prolonged flashing imagery. The National Society for Epilepsy Web site states photic seizures are triggered by flashing images or lights in the range of 5 to 30 Hz (5 to 30 flashes per second) (<http://www.epilepsynse.org.uk/pages/info/leaflets/photo.html>). It follows that designers and reviewers of VEs should avoid flashing images in the range of 5 to 30 Hz. The National Society for Epilepsy Web site also suggests if using a television, to utilize one that possesses a 100 Hz or greater rate of refresh. The Job Accommodation Network Web site recommends providing a high-resolution VGA monitor/flicker-free screen and glare guards or tinted computer glasses for photic seizure prone computer users (<http://www.jan.wvu.edu>).

2.1.4 Migraines

Migraines are a common phenomenon in the general population, occurring in 15% to 20% of women and approximately 10% of men (Stewart & Lipton, 1992). Migraine sufferers have a constellation of possible symptoms including the well-known headache, aurae (i.e., an ocular sensory phenomena immediately preceding the migraine attack), dizzy spells, and others. Migraine sufferers are prone to motion sensitivity, as well as light and sound sensitivity, particularly during an attack. Thus, the sensory experiences created in VE systems are the very phenomena that might make a migraine sufferer uncomfortable, if not ill. Fortunately, there are few serious consequences, but a bad experience could influence migraine sufferers to avoid

TABLE 29.3
Minimizing Migraine Stimulation in Virtual Environments

<i>Sensory Stimulus</i>	<i>Control Measures</i>
Visual imagery	Minimize brightness, give brightness control to subjects
Visual motion	Minimize visual motion, especially point-of-view image motion (view from a head or body mounted camera viewpoint)
Auditory	Minimize loud pulsing sounds
Duration	Minimize duration, provide breaks, allow user control

future VE exposures. Virtual environments should provide explanations of the experiences that they create. Migraine sufferers are often aware of their sensitivities, and so many would avoid experiencing something described as “the ultimate roller coaster” or “a sound and light explosion.” As with the problems with photic seizures described above, a technology or content producer might want to have a reviewer consider the amount of visual motion, brightness and contrast, and loudness of sounds that their system produces. Particularly for systems intended for training or other general purposes where migraineurs might be required to work in a virtual environment, control of the amount and intensity of motion, sound, and light contours would be prudent. Control of the duration and repetition of intense sound and light experiences is also recommended. Some useful guidelines are provided in Table 29.3.

2.2 Auditory System

Sound is an essential part of VE experiences, not only for making more realistic sensations, but also for providing cues to actions in the environment (see chap. 4, this volume). Sounds for VE can be presented through speaker systems or through headsets worn over or in the ears. The realism of some VE experiences might depend on loud sounds (e.g., an aircraft) presented through a headset. Prolonged exposure to such sounds can result in noise levels that exceed the United States Federal Department of Labor, Occupational Safety and Health Administration’s (OSHA’s) permissible exposure limit (PEL; OSHA, Technical Manual). The OSHA PEL is 90 decibels, averaged over an 8-hour period on the A scale of a standard sound-level meter set on slow response (OSHA, Technical Manual). Noise levels exceeding OSHA’s PEL will cause hearing damage (OSHA, Technical Manual). While no guidelines exist for VE systems, user guides for a typical Walkman-style audio player headset suggest avoiding continuous loud sounds, and that the headset should be removed every 30 minutes. Unfortunately, few users pay attention to such warnings. Manufacturers might thus consider limits on the intensity of sounds produced by their systems.

OSHA has established safety standards for sound exposures (OSHA regulations [Standards-29CFR], occupational noise exposure—1910.95). The standards establish sound level exposures that require monitoring or head protection for workers. The louder the average noise level, the lower the amount of time of exposure allowed. For example, an OSHA “action level” is 85 dBA averaged over an 8-hour workday. Exposure to noise of this level requires a hearing conservation program consisting mainly of regular hearing tests. If the sound level is over 90 dBA averaged over 8 hours, hearing protection is required. A level of 100 dBA exposure over 2 hours per day also requires hearing protection. These sound-level standards are for continuous

sounds. It should be noted that repeated high-intensity pulsatile sounds can cause hearing loss as well. Industrial users of VE systems would do well to review the sound levels produced by their experiences and determine the amount and duration of exposures for users. These could then be compared to the guidelines set by OSHA to determine if the VE system should be used in moderation to prevent hearing damage (see Table 29.4 below).

Of note in VE systems is “spatialized” or three-dimensional (3-D) sound systems (see chap. 4, this volume). The same standards presented above apply to 3-D systems, but the variation in intensity over the virtual sound field should be considered. If loud sounds occur within a VE system, users might intentionally or unintentionally get close to the loud sound source. Controls to reduce prolonged exposure to such intense sounds may be needed. If a user is receiving a prolonged exposure to a loud sound, a safety circuit to automatically reduce the sound levels might be a desirable design feature.

2.3 Skin

The use of VE systems can injure the skin via body-worn technology. Sensible reviews of the technology should take place. For example, if the system produces X rays (e.g., some cathode ray tube), there is a risk of inducing carcinomatous changes in the skin (Cade, 1957). Similarly, systems producing high electromagnetic fields (EMF) at other frequencies (such as magnetic position trackers or infrared emitters) should be monitored for heat generation. Finally, there is a potential to transmit infective agents through objects worn on the skin of one user and transferred to the skin of another, such as bacteria, viruses, and fungi. In the absence of specific governmental guidelines in the workplace, contamination of shared devices will be reduced by the use of materials resistant to infective agents (e.g., metals and plastics, as opposed to porous materials) and materials that can be disinfected.

The skin is sensitive to prolonged physical pressure, which can result in skin irritation or breakdown. Furthermore, there is a risk of passing on skin contaminants such as bacteria between multiple users, as previously noted. Fortunately, there are numerous other types of devices with similar patterns of use as public VE systems already in practice (e.g., goggles for 3-D movies, public telephones), and there appears to be minimal risk associated with them. Developers of haptic feedback devices (see chaps. 5 and 6, this volume) and applications using them should be on the lookout for feedback or other unusual situations that could produce high

pressure from their devices and cause injury. The devices for force generation should have limits on the maximal forces generated in order to minimize risk to hands and fingers.

3. TRAUMA

The encumbrances of many VE systems present a risk to users for physical injury. By its nature, VE has compelling visual imagery that obliterates or obscures the visual world. Furthermore, the scenes and sequences that occur are often intended to induce the user to move, rapidly at times. Sound systems can produce disorienting sensations and the myriad cables, weights, and tethers may cause a user to lose balance. For these reasons, system designers should watch ill effects of VE systems carefully. These are not “set and forget” kinds of systems. A “spotter” should watch users and be available to interact with them should ill effects arise. Finally, motion sickness does occur in VE systems (see chap. 30, this volume). Users should thus be monitored for imbalance or attendant symptoms of motion sickness, as its occurrence makes a fall more likely.

4. AVOIDANCE OF INJURY

Fortunately, the use of VE systems is not inherently unsafe. Most circumstances that may involve risk should be mitigated with a little forethought. An individual from VE system development teams should be dedicated to the task of monitoring risks. One important component of the monitoring should be reviews with developers of any hazards or sensations they notice. For example, if developers find they are experiencing motion sickness in the development stage, users should be expected to have the same sensation. Similarly, if developers repeatedly trip over a cable, a reconfiguration should occur to fix the problem. If there is dedicated responsibility for testing and monitoring risks, the possibility of injury will be reduced. The simple framework of this chapter provides an approach for risk review, summarized in Table 29.5.

The body has its own feedback for injury risk. If a light is uncomfortably bright, sound uncomfortably loud, gear uncomfortably tight, or system uncomfortably encumbering in the short term, the risk for long-term injury should be considered. Thus, a straightforward review by potential users should reveal a number of the risks involved with the use of VE technology. Some issues, however, such as those associated with repetitive use or those to which only a portion of the user population will be susceptible (e.g., seizures) should be monitored by safety engineers. In addition, users might need to be screened for their ability to wear and

TABLE 29.5
Minimizing Risk in Development of VE Systems

-
1. Assign responsibility to someone for risk review.
 2. Monitor and review user and developer comments for discomfort.
 3. Review visual stimuli for brightness and visual motion.
 4. Review auditory levels.
 5. Consider emissions from electronics (e.g., heat, ionizing radiation).
 6. Review hazards from cables, tethers, and other devices.
 7. Review the experience being provided.
-

appropriately interact with VE systems prior to allowing unlimited exposure. Warnings and restrictions might be needed in some situations (see chap. 27, this volume).

The type of experience being created for users should also be considered. There are potential indirect or psychological effects from being in virtual environments. The possibility of producing emotional and cognitive changes in users must be considered (see chap. 33, this volume). Indeed, the compelling nature of VE experiences is being used to affect the nervous systems and psyches of patients with a variety of disorders (see chaps. 50 and 51, this volume). Thus, the affects of battlefields or dramatic flight sequences on users should be considered. Indirect effects can combine with direct effects to produce injury. An anxious user might pull on cables or become uncomfortable with headgear. The best method of prevention is close monitoring of users by developers and manufacturers, especially naive users of an environment.

5. CONCLUSION

Virtual environment technology promises to provide a variety of experiences to users: bright visual displays, compelling sound environments, and dramatic interactivity. Further, the influences of VE interaction often result in changes in users' mind/brain via training or therapy. Virtual environment systems can potentially be used to improve the balance systems of patients with disturbed vestibular systems (see chap. 49, this volume), reduce the phobias of people afraid of heights, flying, or spiders (see chap. 51, this volume), and teach concepts of art or science to induce an emotional state or a level of education (see chaps. 43–46, this volume). Yet along with the promise of VE technology, one can postulate the potential negatives associated with VE exposure: bright lights, loud sounds, motion sickness, phobia induction, negative emotions, and destructive tendencies. While harnessing the potential of VE technology, developers cannot neglect to invoke common sense and research into new observations while determining the intent of technology creators to minimize the adverse effects of VE interaction.

1. INTRODUCTION

This chapter describes the unpleasant side effects associated with human exposure to virtual environments (VEs) and other synthetic experiences (SEs). The authors discuss the incidence and nature of the discomfort associated with acceleration, unusual force environments, moving visual fields, flight simulators, and virtual environments. The most widely used scales for assessing the clinical signs and subjective symptoms of SE discomfort are explained, and the usual early warning signs are described. Other less obvious syndromes are mentioned that do not involve frank discomfort yet may pose a significant health and safety risk: These include the sopsite syndrome, loss of visual acuity during head or body motion, and postural dysequilibrium. Situations conducive of SE-related syndromes are discussed, with a special emphasis on the aspects of visual field motion that are most disturbing. The evidence to date indicates that many SEs are capable of producing significant decrements in well-being. Careful assessment

*The views of the authors do not necessarily represent the policy of the U.S. government.

and correction of human factors problems with VEs will be necessary to minimize health and safety risks among users.

The purpose of this chapter is to describe the most common adverse signs and symptoms associated with exposure to synthetic experiences. The phrase *synthetic experience* encompasses technologies such as virtual environments, teleoperators, and augmented reality (Durlach & Mavor, 1995), while not excluding other technologically mediated experiences such as interactive flight simulation or noninteractive viewing of moving visual scenes such as wide-screen movies (Robinett, 1992). The term *SE* may also be applied to the wearing of optical prisms that alter the visual stimulus (Welch, 1978). Many of the principles of adaptation to prism goggles will be similar to those that apply to modern head mounted displays (HMDs; see chap. 31, this volume). Finally, the term *SE* could be applied to simulations that allow people to experience nonterrestrial forces or other feelings of body acceleration (see chaps. 7, 11, and 13, this volume).

The type of SEs known as a virtual environments (Durlach & Mavor, 1995; Fisher, 1990) will be the focus of this chapter. The authors will emphasize the clinical symptomatology of the VE syndrome sometimes referred to as cybersickness (McCauley & Sharkey, 1992), focusing on classical symptoms such as nausea. Where cybersickness findings are scant, the authors will make conjectures based on similar syndromes such as simulator sickness,¹ motion sickness (Irwin, 1975), and visually induced motion discomfort (Crampton & Young, 1953). The present review will aid the reader in comparing human syndromes elicited across different studies by itemizing specific signs and symptoms rather than offering numerical summary scores of “overall sickness,” because the computation and interpretation of summary scores varies from study to study (Lawson, 1993).

In the following pages, the authors describe the incidence of human syndromes associated with SEs, the nature of these syndromes (characteristic signs and symptoms), and the simplest, most reliable methods for measuring these syndromes. This chapter is intended as a practical guide; hence the causal factors of SE-related syndromes will be treated from the standpoint of known eliciting stimuli rather than theories of etiology (see Jones, 1998; Kennedy & Frank, 1985; Kolasinski, 1995; McCauley, 1984; Reason & Brand, 1975). The physiological pathogenesis of SE-related syndromes is discussed in chapter 32 (this volume) and by Crampton (1990) and Money, Lackner, and Cheung (1996). Sensorimotor side effects of VE (postural dysequilibrium and manual incoordination) are discussed in more detail in chapters 38 and 39 (this volume).² While the present chapter will focus on group responses to SE, individual differences in susceptibility and ability to adapt to SE are important topics reviewed by Kennedy, Dunlap, and Fowlkes (1990), Guedry (1991), and Kolasinski (1995).

2. TERMINOLOGY USED TO DENOTE THE DISCOMFORT ASSOCIATED WITH SYTHETIC EXPERIENCES

The term *cybersickness* was coined by McCauley and Sharkey (1992) to describe the motion-sickness-like symptoms associated with VE characterized by “far applications involving distant objects, that is, terrain, self-motion (travel) through the environment, and the illusion of self motion (vection)” (p. 313).³ McCauley and Sharkey (1992) chose *cybersickness* as a more general term than *simulator sickness* (Havron & Butler, 1957) because they considered moving and fixed-base simulators to be a subset of virtual environments. The word *cybersickness* does not

¹Researchers usually attribute “simulator sickness” to Havron and Butler (1957), who were the first to publish an observation of the phenomenon but did not employ the phrase *simulator sickness*.

²See also chapter 6 of Durlach and Mavor (1995), and Stanney, Kennedy, Drexler, and Harm (1999).

³The term *vection* is attributed to Tschermark (1931) in Jones (1998).

denote a diseased or pathological state, but rather a normal physiological response to an unusual stimulus. In fact, in the case of “classical motion sickness” (e.g., seasickness), failure to be susceptible to nauseogenic motion stimuli can indicate an abnormal state (e.g., Graybiel, 1967).⁴

Cybersickness and simulator sickness share much in common with motion sickness, but it is preferable to avoid such terms and instead describe these maladies as syndromes (Kennedy & Frank, 1985). For example, Benson (1988) noted that *motion maladaptation syndrome* was a more accurate phrase than *motion sickness*, a view that has been adopted by Probst and Schmidt (1998) and Finch and Howarth (1996). For convenience, Benson’s apt phrase “motion maladaptation syndrome” could be shortened to “motion adaptation syndrome,” roughly in accordance with the precedent of Nicogossian & Parker (1984), who recommended the phrase *space adaptation syndrome* in lieu of *space sickness*.⁵

3. INCIDENCE AND NATURE OF SYNDROMES ASSOCIATED WITH MOVING DEVICES AND SYNTHETIC EXPERIENCES

3.1 Acceleration and Unusual Force Environments

It is difficult to estimate the proportion of humans who are susceptible to nonterrestrial forces created by passive acceleration within a moving device or by travel into space. The incidence estimate will vary with the stimulus (e.g., frequency, duration), the individual exposed to the stimulus (e.g., susceptibility, experience), and the experimenter’s measurement criteria. The authors estimate that about 10% of the population has not experienced significant nausea during transportation, whereas about 1% of the population will vomit or be made nauseated by vehicles as mild and ubiquitous as the automobile (Birren, 1949; Reason, 1975). The most provocative laboratory tests yield very high incidence estimates. Miller and Graybiel (1970b) found that 90% to 96% of participants will suffer from stomach symptoms by the time they reach the maximum number of head movements called for during a rotation protocol.⁶ Over the years, laboratory tests and some very provocative field tests (e.g., Kennedy, Graybiel, McDonough, & Beckwith, 1968) have shown that persons with normal vestibular function can be made nauseated by motion, whereas participants without vestibular function cannot be made nauseated by motion (Money, 1970). Similarly, participants without vestibular function cannot be made nauseated by alternating periods of weightlessness and high-G (Graybiel, 1967), although at least 67% of shuttle astronauts feel some unpleasant symptoms during their first trip into space (Davis, Vanderploeg, Santy, Jennings, & Stewart 1988).

3.2 Moving Visual Fields

3.2.1 Findings From the Literature

Like motion stimuli, moving visual fields can cause significant discomfort in stationary observers who are healthy, but not in individuals without vestibular function (Chueng, Howard, &

⁴Similarly, if the natural experience being recreated in a simulator is not sickening, then the presence of “simulator sickness” implies that the *simulator* is sick, not the user (Kennedy & Frank, 1985).

⁵There are still some problems with phrases such as *space adaptation syndrome* or *motion adaptation syndrome*, but the phrases are both improvements on earlier phrases such as *space sickness* or *motion sickness*, and seem to have gained some acceptance among groups such as the Motion Sciences Consortium (MSC) whose website is under construction at <http://ait.nrl.navy.mil/MSC>. Please send questions or comments to web@ait.nrl.navy.mil and to blawson@namrl.navy.mil.

⁶In Miller and Graybiel, (1970b), 90% of 250 subjects tested to a prevomiting endpoint experienced at least minimal nausea, epigastric awareness, or epigastric discomfort, whereas another 96% of 25 subjects tested all the way to vomiting experienced one of the aforementioned symptoms of nausea syndrome. The maximum possible number of head movements in the protocol was a total of 204 carried out across ten steps of increasing chair rotation velocity.

Money, 1991). As early as 1895, Wood (1975) described the aftereffects of immersing nearly stationary observers into a swinging room: "I have met a number of gentlemen who said they could scarcely walk out of the building from dizziness and nausea." (Reason & Brand, 1975, p. 110). Using a visual surround that oscillated in the earth-vertical axis, Crampton and Young (1953) found that 46% of participants ($n = 26$) experienced dizziness without nausea, whereas 35% experienced nausea. Benfari (1964) found that all nine of his participants experienced dizziness while viewing a wide-screen film involving vehicle motion, two of whom experienced extreme dizziness and nausea.⁷ Using an optokinetic drum, Lackner and Teixeira (1977) found that 40% of participants ($n = 10$) viewing a moving visual surround terminated the experimental trial because of aversive symptoms. Over all experimental conditions, the most common symptom during or after exposure was dizziness (mean 50%), followed by "epigastric disturbance" (mean 23%), "headache or eyestrain" (mean 20%), and drowsiness (mean 10%). In the head-fixed condition of Teixeira and Lackner (1979), dizziness was observed in 50% of participants ($n = 8$) and eyestrain in 13%. Using the same optokinetic drum as Teixeira and Lackner (1979) but a different velocity profile, Lawson (1993) found that 57% of participants ($n = 14$) experienced stomach symptoms (stomach awareness or discomfort or nausea) during viewing of a rotating visual surround. Using a smaller optokinetic drum (that surrounded the upper body) and summarizing across four previous studies, Stern, Hu, Anderson, Leibowitz, and Koch (1990) concluded that about 60% of people viewing a moving visual surround will report symptoms. The most common symptoms found in the experiment described in Stern et al. (1990) were dizziness, warmth, and nausea (during unrestricted viewing without fixation). Investigators have noticed that symptoms induced by moving visual fields seem to linger for some time after the stimulus has terminated (Crampton & Young, 1953; Havron & Butler, 1957; Lackner & Teixeira, 1977; Teixeira & Lackner, 1979). Similarly, lingering effects have been associated with visual "fixed-base" simulators (see section 3.3 below) and the wearing of scene-altering prism goggles (Dolezal, 1982; Welch, 1978). However, it should be noted that lingering symptoms are not limited to situations involving visual motion only, but can also occur at sea (Reason & Brand, 1975).⁸

3.2.2 Summary

Generalizing across the different visual motion experiments mentioned above, it appears that while a few subjects are unaffected by moving visual fields, 50%–100% will experience dizziness and 20%–60% will experience stomach symptoms of some kind. The frequency of other symptoms cannot be estimated, but it seems that "oculomotor symptoms" such as eyestrain are a prominent feature of human responses to moving visual fields (Ebenholtz, 1992; McCauley, 1984; Teixeira & Lackner, 1979). It is possible that moving visual fields induce more "head" symptoms (Lackner, from NRC Report BRL-CR-629, 1990; Reason & Brand, 1975), such as eyestrain, headache, and dizziness. Such nongastric effects have been observed extensively in flight simulators, which have a strong visual component (e.g., Kennedy, Berbaum, & Lilienthal, 1997).

⁷Note: The experimental conditions also involved varying amounts of peripheral flicker.

⁸Up to 5% of those who put to sea fail to adapt to the motion of the sea throughout the duration of the voyage, and these "chronically motion-sick" individuals may show effects weeks after the end of a voyage (Schwab, 1943, from Reason and Brand, 1975; Tyler and Bard, 1949). Although the biochemical changes associated with repeated vomiting confound the interpretation of the lasting effects of ship motion, Gordon, Spitzer, Dowek, Melamed, and Shupak (1995) have found that *mal de débarquement* can strike persons of widely varying susceptibility after a sea voyage, resulting in feelings of postural instability and perceived instability of the visual field during self-movement (even among some individuals for whom fluid loss due to vomiting is not a concern).

3.3 Simulators

3.3.1 Findings From the Literature

Observing 36 trainees using a U.S. Navy helicopter visual simulator, Havron and Butler (1957) noticed problems in 78% of the participants. The most frequently reported effects were (in descending order) nausea, dizziness, vertigo, blurred vision, and headache. Some effects lingered long after participants left the simulator, particularly nausea, dizziness, and drowsiness. More than half of the participants reported sickness lasting an hour or longer, and 13.9% said the effects lasted overnight.⁹

Soon after the Havron and Butler study, researchers in Pensacola, Florida (Miller & Goodson, 1958, 1960), reported similar effects in 12% of student pilots and 60% of pilot instructors ($n = 36$), using the same model of simulator. Effects included disorientation, nausea, dizziness, vertigo, visual distortions, and headache. Miller and Goodson (1958) also noted that "even those individuals who did not become ill reported that they usually felt very tired after a run. This fatigued feeling lasted frequently throughout the day." (p. 208). Many symptoms lasted for hours after simulator exposure. Kellogg, Castore, and Coward (1984) found that 88% of pilots reported adverse symptoms when exposed to a particularly disturbing simulator, experiencing visual flashbacks (sensations of climbing, turning, or visual inversion) as much as 8 to 10 hours afterexposure (thus confirming the observations of Miller & Goodson, 1958, 1960). In reviewing selected simulator findings between the years 1957 and 1982, McCauley (1984) noted an overall incidence ranging from 10% to 88% across a number of studies. Additional effects mentioned by McCauley during these years included the "leans" (McGuiness, Bouwman, & Forbes, 1981, 1984) and postural dysequilibrium (Crosby & Kennedy, 1984; for a more recent discussion see chap. 39, this volume).

Magee, Kantor, and Sweeney (1988, in AGARD CP-433) found that 95% of their participants ($n = 42$) reported at least one symptom following simulator exposure, with 83% of the symptoms classified as "simulator sickness" (according to the criteria of Kennedy, Dutton, Ricard, & Frank, 1984). The most common symptoms were eyestrain (27%) aftersensations of motion (25%), mental fatigue (22%), physical fatigue (21%), and drowsiness (17%). For 81% of the participants, symptoms lingered for a median of 2.5 hours postexposure, with the most common delayed symptoms being physical fatigue (19%), eyestrain (17%), and mental fatigue (16%). Chapelow (1988) also observed that physical and mental fatigue were the predominant symptoms of prolonged exposure to two different simulators.¹⁰ Gower, Lilienthal, Kennedy, and Fowlkes (1988) estimated an overall "simulator sickness" of 44% across a number of simulator exposures ($n = 434$), with the most common symptoms being drowsiness/fatigue (43%), sweating (30%), eyestrain (29%), headache (20%), and difficulty concentrating (11%).

Kennedy, Lilienthal, Berbaum, Baltzey, and McCauley (1989) reviewed data from 1,186 U.S. Navy flight simulator training sessions involving both fixed and moving base simulators.¹¹ Drowsiness or fatigue occurred in 26% of the hops, eyestrain in 25%, headache in 18%, sweating in 16%, difficulty focusing in 11%, nausea in 10%, and difficulty concentrating in 10%. However, only 0.2% of the hops induced retching or vomiting. The raw frequency with which one or more symptoms characteristic of motion discomfort (i.e., vomiting, retching,

⁹Immediate or lingering symptoms are detailed on page 5 and page 8 of Appendix F from Havron and Butler (1957).

¹⁰The authors of this study pointed out that fatigue symptoms were far more prevalent in the simulator test that required long training exposures. This suggests that duration of stimulator exposure and common fatigue contributed to the symptoms observed.

¹¹The Kennedy et al. (1989) database partly overlapped with that from the Gower et al. (1988) study mentioned in the preceding paragraph.

increased salivation, nausea, pallor, sweating, or drowsiness) was reported ranged from 10% to 60% across several (9) different simulators, with an average of 34.3%. In another analysis looking for lasting aftereffects, Baltzey, Kennedy, Berbaum, Lilienthal, and Gower (1989) found that of 700 pilots queried, 45% felt some symptoms after exposure. These effects lasted longer than 1 hour in 25% of the cases and longer than 6 hours in 8% of the cases.

Studies by Ungs (1988) and Kennedy, Massey, and Lilienthal (1995) indicate that the most frequently reported symptoms of simulator exposure are drowsiness and fatigue. In general, about 30% to 50% of people report fatigue or drowsiness (or both) upon exiting flight simulators (Kennedy et al., 1995). Ungs (1988) found that fatigue was not only the most common symptom after one's first simulator flight (occurring in 34% of participants), but also one of the most severe symptoms (along with sweating and nausea). Fatigue and sleeping problems are still present after several simulator flights, albeit reduced in frequency and severity. These effects seem to occur in both fixed-base and moving-base simulators (Kennedy et al., 1995), and may indicate the presence of the sople syndrome (Graybiel & Knepton, 1976; Lawson & Mead, 1998), which is discussed in section 6.1.

3.3.2 Summary

The incidence and severity of the adverse effects associated with simulator exposure vary widely from one simulator study to the next. Adverse signs and symptoms are experienced by at least 10% and sometimes as many as 90% of simulator trainees; effects include (roughly in descending order of prevalence) eyestrain, fatigue, drowsiness, sweating, headache, and difficulty concentrating. The distribution of susceptibility to such effects is skewed, with approximately 40% of simulator pilots reporting no symptoms and 25% reporting only mild symptoms; however, about 5% of participants may be so severely disturbed that they should restrict subsequent activities until symptoms subside (Kennedy, 1996).

3.3.3 Similarity Between Simulator Syndromes and Other Syndromes

As with visually induced motion discomfort, simulator side effects can bother the sufferer long after simulator exposure ends, in which case the most common symptoms are fatigue and eyestrain. It is interesting to note that the proportion (about 10%) of individuals who do not report symptoms even in the most provocative simulator mentioned above is about the same as the proportion of people immune to real-motion stimuli. Similarly, the proportion of individuals who report profound and lasting symptoms (about 1%–5%) in simulators is roughly the same as the proportion of the population extremely susceptible to real motion (see section 3.1). Finally, the distributions for classical motion discomfort (during transportation) and for simulator discomfort appear to be skewed, with both syndromes showing more individuals with susceptibility below the middle of the range. Thus, the authors conclude that the incidence and nature of simulator syndromes is comparable to other real or apparent motion stimuli, even if different stimuli show different subfactor profiles as measured by the Simulator Sickness Questionnaire or SSQ (Kennedy & Stanney, 1997; Lane & Kennedy, 1998; Stanney & Kennedy, 1997; see sections 3.4.2 and 4.1).

3.4 Virtual Environments

3.4.1 Preliminary Findings From the Literature

The technological aspects of a VE display play an important role in the experience of the user. The fact that displays vary widely among VE devices (and within one manufacturer's device over time) may account for the range of findings reported in the research performed to date.

Wilson (1997) reviewed 12 previous experiments by his research group using 233 participants immersed in one of three HMDs for exposure times between 20 minutes and 2 hours. Wilson found that approximately 80% of the 233 participants experienced some symptoms. For most participants, the symptoms were mild and short lived, but for 5% they were so severe that they had to end their participation.

Specific signs and symptoms were detailed in one of the earliest published studies of the side effects of VEs, conducted by Regan and Price (1994). They reported that about 5% of their participants ($n = 146$) withdrew from the 20-minute experiment due to severe nausea or severe dizziness, whereas 61% reported adverse symptoms at some time during exposure, (25% of whom had nausea). When participants reported some symptoms but no nausea, the most frequently reported symptoms were dizziness, stomach awareness, headache, and eyestrain. Regan and Ramsey (1996) subsequently conducted a drug study during VE exposure using a similar protocol. They found that none of the 39 participants withdrew from this experiment due to severe discomfort, but 15 of the 20 participants in the placebo group reported symptoms at some point during or immediately after VE immersion, 5 of whom reported nausea. The most common symptoms other than nausea were dizziness, stomach awareness, disorientation, and headache.

Howarth and Finch (1999) asked participants to report symptoms every minute during VE use, up to 20 minutes. Fourteen participants completed both conditions of the experiment. It should be noted that 3 of the original 17 participants in the Howarth and Finch experiment chose to terminate their participation, one of whom continued to feel symptoms similar to car sickness for several hours after immersion. All 14 participants reported an increase in nausea, and 43% of the participants reported moderate nausea within the 20-minute immersion period. Howarth and Finch note that an unspecified number of participants who did not terminate their participation also experienced symptoms persisting for hours. The persisting symptoms mentioned included “general discomfort,” “severe hangover,” and “feeling vacant.”

3.4.2 VE Syndromes Compared to Other Syndromes

Reviewing a number of VE studies, Stanney, Mourant, and Kennedy (1998) noted that 80% to 95% of participants exposed to a VE reported adverse symptoms, whereas 5% to 30% experienced symptoms severe enough to end participation. Stanney and colleagues observed “cybersickness” rates higher than had been observed in flight simulators, where they estimated 60% to 70% of users report side effects (Stanney, Kennedy, Drexler, & Harm, 1999). They cautioned that most simulator users are military aviators or aviator candidates, who are likely to be less susceptible to VE than the college students typically used in VE experiments. Of relevance to this assertion is a study by Regan and Price (1994), who exposed 150 participants to VE, 20 of whom were in the military. Eight participants quit prior to the end of the experiment, none of whom were military personnel. However, such a finding can be interpreted in a number of ways,¹² and it should be noted that malaise ratings were not significantly different between civilian and military participants. Further comparisons of different participant groups are needed to explain the apparent difference in prevalence of adverse effects in VE versus other devices (such as simulators). Further device comparisons are needed also, because the latest VE technology may yield a different estimate than was obtained with VE technology of the past decade.

¹²It is possible that people who are highly susceptible to motion are not as likely to join the military, where they may be exposed to a wide variety of challenging vehicle motions. It is also possible that military personnel acquire greater than average adaptation to challenging motions after joining. The observed result could also be explained by a higher level of commitment to finishing the experiment or simply by random chance (due to the relatively small sample of military subjects).

Differences exist in the Simulator Sicknes Questionnaire (SSQ) symptom clusters for simulator discomfort versus VE discomfort.¹³ Kennedy and Stanney (1997; Stanney & Kennedy, 1997) have shown that immediate postexposure profiles usually indicate that VEs produce more of the Disorientation symptom cluster, whereas simulators produce more of the Oculomotor symptom cluster. Ranking the magnitude of each symptom cluster, they found that the SSQ profile for VEs is “Disorientation > Nausea > Oculomotor,” whereas the profile for simulator discomfort is “Oculomotor > Nausea > Disorientation.” For comparison, the profile of space adaptation syndrome is “Oculomotor > Disorientation > Nausea,” whereas the profile aboard ships and planes is “Nausea > Disorientation > Oculomotor” (Kennedy, Lanham, Drexler, Massey, & Lilienthal, 1997; Kennedy & Stanney, 1997; Stanney & Kennedy, 1997). The distinct VE symptom profile (wherein the Disorientation cluster predominates) has been replicated with five different VE display systems (Stanney, Mourant, & Kennedy, 1998).

3.4.3 Summary

At least 60% of VE users will report adverse symptoms during their first exposure. A conservative prediction that can be made from the limited VE research is that at least 5% of all users will not be able to tolerate prolonged use of current VE, whereas at least 5% of users will remain symptom free. The number of people highly susceptible to VE side effects during their first exposure appears to be about the same as the number of people highly susceptible to motion stimuli, moving visual fields, and simulators. The number of people immune to VE effects may be lower than for some of these aforementioned stimuli, but it is too early to be certain. Virtual environment stimuli seem to share in common with moving visual fields and simulators the tendency to elicit lasting symptoms following the cessation of the stimulus. Finally, both VE and optokinetic drums appear to produce discomfort during visual scene oscillation in pitch, roll, or yaw (Cheung et al., 1991; So & Lo, 1999). However, VE syndromes appear to be distinguishable from other syndromes via the ranking of symptom clusters from the SSQ (Kennedy & Stanney, 1997; Stanney & Kennedy, 1997), with the Disorientation symptom cluster most in evidence.

4. TECHNIQUES FOR ASSESSING SIGNS AND SYMPTOMS ASSOCIATED WITH MOTION AND SYNTHETIC EXPERIENCES

4.1 Development of the Most Widely Used Measures of Symptomatology

4.1.1 Consensus Regarding Symptomatology and the Need for a Prevomiting End Point

The clinical techniques for measuring dizziness, nausea, and similar effects associated with SEs derive from controlled laboratory studies. As pointed out by Durlach and Mavor (1995), motion discomfort is relatively easy to identify in the laboratory because fairly provocative stimulation is usually employed, multiple and systematic measurements of symptomatology are taken, and trained observers are present.

¹³The three symptom clusters of the SSQ include Nausea, Disorientation, and Oculomotor. The Nausea cluster is composed of “general discomfort,” “increased salivation,” “sweating,” “nausea,” “difficulty concentrating,” “stomach awareness,” and “burping.” The Disorientation cluster is composed of “difficulty focusing,” “nausea,” “fullness of head,” “blurred vision,” “dizzy” (rated with eyes open and with eyes closed), and “vertigo.” The Oculomotor cluster is composed of “general discomfort,” “fatigue,” “headache,” “eye strain,” “difficulty focussing,” “difficulty concentrating,” and “blurred vision.” The four descriptors that appear across more than one symptom cluster are “nausea,” “difficulty concentrating,” “difficulty focussing,” and “blurred vision.”

Experts tended to agree about the chief characteristics of motion discomfort by the middle of the twentieth century. For example, Birren (1949), Tyler and Bard (1949), and Chinn and Smith (1955) all agreed that motion can elicit nausea, vomiting (or retching), (cold) sweating, and pallor. Tyler and Bard (1949) and Chinn and Smith (1955) additionally mentioned drowsiness, (increased) salivation or swallowing, epigastric awareness or discomfort (usually defined as a sensation just short of nausea), headache, and dizziness. In a comprehensive review, Money (1970) found that the four most frequently reported side effects of motion are pallor, cold sweating, nausea, and vomiting. (However, Money enumerated dozens of other characteristics that had been mentioned in the literature.)

Early researchers struggled with the identification of an end point for the termination of nauseogenic testing. Vomiting has the advantage of being a clearly observable end point that lends itself easily to ratio scaling. However, vomiting is not necessarily a good predictor of a participant's relative stress level, since some participants can be in great distress and still not vomit, although others vomit early on in the testing before nausea is well developed. When vomiting is used as an end point, systemic side effects (such as the accompanying fluid loss) can confound efforts at continued measurement of physiological responses or repeated testing of motion sickness susceptibility. Moreover, the unpleasantness of vomiting raises difficulties with participant recruitment, human-use approval, and the comfort and convenience of the participant and experimenter. Some of the early attempts to draw up a list of prevomiting signs and symptoms and scale them collectively were made by Hemingway (1943) and Alexander, Cotzin, Hill, Ricciuti, and Wendt (1945). These techniques obtained quantitative scores for an individual's overall discomfort based on a number of signs and symptoms besides vomiting, but they did not employ a checklist wherein data concerning each sign or symptom could be tabulated and analyzed separately before the final score was tabulated.

4.1.2 First Widely Used Multiple Symptom Checklists

The first diagnostic categorization of multiple motion-related symptoms that saw widespread use was initiated by Ashton Graybiel and developed by a number of researchers associated with the Pensacola Naval Air Station,¹⁴ mostly as part of studies of well-being and performance during adaptation to a rotating room. These efforts started with a rudimentary checklist that recorded the presence ("yes or no") of a number of distinct signs or symptoms, including general malaise, sweating, nausea, vomiting, dizziness, headache, apathy, and the number of hours slept during the day (Graybiel, Clark, & Zarriello, 1960; Kennedy & Graybiel, 1962). Soon after, the list of signs and symptoms was expanded and rated on a 0-to-3 scale (Graybiel & Johnson, 1963). Many related forms of this diagnostic categorization system were produced during these prolific years. For example, the Pensacola Motion Sickness Questionnaire, or MSQ (so named in Kennedy & Graybiel, 1965), consisted of more than 20 signs and symptoms initially presented in Hardacre and Kennedy (1963). The MSQ reached a relatively mature form in Kennedy, Tolhurst, and Graybiel (1965), which is one of the best of the early guides to the MSQ. Kennedy et al. (1965) categorized minor, major, and pathognomonic diagnostic criteria, which were scored variously and tabulated as a single malaise score.

A shorter table was published around the same time by Wood, Graybiel, and McDonough (1966); it employed seven criteria, including the pathognomonic sign of vomiting, the major sign of retching (later upgraded to a pathognomonic sign in Miller & Graybiel, 1970b), and a number of other signs and symptoms whose classification as minor or major depended on

¹⁴The laboratory complexes housed at Pensacola Naval Air Station have been extant since 1939 and have gone by various names during that time, most recently the Naval Operational Medical Institute (www.nomi.navy.mil) and the Naval Aerospace Medical Research Laboratory (www.namrl.navy.mil).

their severity, including nausea, increased salivation, pallor, cold sweating, and drowsiness. These seven criteria contributed strongly to the participant's overall malaise score and were considered the cardinal characteristics of motion discomfort; the presence of one (or more) of these characteristics has also been used as the criterion for simulator discomfort (Kennedy et al., 1989).

4.1.3 Cardinal Signs and Symptoms

Many investigators (e.g., Harm, 1990; Reason & Brand, 1975) restrict the list of seven "cardinal" signs and symptoms to those four mentioned most frequently in the motion discomfort literature (according to Money, 1970), namely, pallor, cold sweating, nausea, and vomiting. However, it should be remembered that two of these four cardinal characteristics (pallor and cold sweating) were not more heavily weighted in the Wood et al. (1966) scoring procedure than were the rest of the seven criteria. Moreover, Miller and Graybiel (1970b) found that flushing and feelings of warmth were more commonly reported than was increased salivation. Thus, decisions about the cardinal criteria of motion discomfort are not straightforward and will vary with the factors one considers most important. For example, cardinal criteria such as vomiting and retching are easily quantifiable and yield parametric data; furthermore, they may be the only obvious evidence of discomfort in some cases (Lackner & Graybiel, 1986). However, for stimuli that do not produce vomiting, the cardinal symptom of nausea is likely to account for most of the variance in estimates of overall well-being (Reason & Diaz, 1971). The picture changes again when the feeling of overall well-being is not the paramount criterion, but rather the likelihood of occurrence of a given symptom and the possible deleterious effects that symptom might have on performance of tasks. For example, drowsiness and fatigue are the most commonly reported symptoms of simulator exposure (Kennedy et al., 1995; Ungs, 1988, both from Lawson & Mead, 1998) and armored vehicle operations (Cowings, Toscano, DeRoshia, & Tauson, 1999), and such symptoms have been implicated in transportation accidents (Lawson & Mead, 1998).

Eventually, two mature forms of the diagnostic criteria for motion sickness emerged, as later described. One mature set of criteria was produced by Miller and Graybiel (1970b),¹⁵ who presented a diagnostic categorization table along with an accompanying sheet for scoring signs and symptoms of motion discomfort. They also added a few new signs and symptoms of lesser importance to the list, including epigastric awareness, epigastric discomfort, flushing/subjective warmth, headache, and dizziness with eyes closed or open. Since the Miller and Graybiel table of diagnostic criteria can be somewhat difficult to apply correctly when presented in its original form, a simplified representation of the table of diagnostic criteria (Miller & Graybiel, 1970b) is presented in Table 30.1, rendered as an experimenter's checklist for the scoring of a single motion challenge (e.g., discomfort experienced during one sudden stop following rotation or one head movement while rotating).

The diagnostic criteria in Table 30.1 are derived from Miller and Graybiel (1970a, 1970b), with earlier contributions from Graybiel, Wood, Miller, and Cramer (1968), Graybiel (1969), and others. These authors devised a weighted scoring procedure that recognizes six distinct levels of severity for symptoms indicative of the nausea syndrome and two to four distinct levels of severity for nonnausea symptoms. Cumulative points scored for all symptoms are added to distinguish between different levels of general malaise. For example, a cumulative score of 8 could be reached by a subject reporting moderate or severe nausea, but an

¹⁵The diagnostic criteria which culminated in the Miller and Graybiel (1970b) paper have been referred to by various names, including the Pensacola Diagnostic Index, The Pensacola Diagnostic Criteria, and The Graybiel Scale, but the original publications regarding these diagnostic criteria did not usually employ these appellations.

TABLE 30.1
Diagnostic Criteria of Miller and Graybiel (1970b)

	<i>None</i>	<i>Minimal</i> I	<i>Minor</i> II	<i>Major</i> III	<i>Pathognomonic</i>
	<i>Epigastric Awareness</i>	<i>Epigastric Discomfort</i>	<i>Nausea I (Minimal)</i>	<i>Nausea 2–3 (Moderate to Severe)</i>	<i>Vomiting, Retching</i>
<i>Nausea</i>					
Point Value:	0	1	2	4	8
Other Symptoms					16
Flushing, warmth	0	(N.A.)	0	1	1
Dizziness (eyes closed)	0	(N.A.)	0	1	1
Dizziness (eyes open)	0	(N.A.)	0	0	1
Headache	0	(N.A.)	0	1	1
Drowsiness	0	(N.A.)	2	4	8
Cold sweating	0	(N.A.)	2	4	8
Pallor	0	(N.A.)	2	4	8
Increased salivation	0	(N.A.)	2	4	8

8 would also be assigned to a subject whose only symptom was severe drowsiness. A total score of ≥ 16 points = “frank sickness,” 8–15 points = “severe malaise,” 5–7 points = “moderate malaise A,” 3–4 points = “moderate malaise B,” and 1–2 points = “slight malaise.”

Versions of the Miller and Graybiel scale have been used widely.¹⁶ The scale has changed little over the years, although the way it is used and scored has varied (Lawson, 1993). By contrast, the Kennedy, Tolhurst, and Graybiel (1965) scale continued to undergo a series of further modifications over the years. A notable offshoot of the original Kennedy et al. (1965) scale was the Motion Sickness Severity scale of Wiker, Kennedy, McCauley, and Pepper (1979), which added several more signs and symptoms and offered one of the more convincing attempts to establish the reliability and validity of subjective motion discomfort reporting. The scales derived from Kennedy et al. (1965) eventually emerged in the form of the Simulator Sickness Questionnaire (SSQ), which has seen widespread use in navy simulator studies and has become the most popular measurement technique for the assessment of signs and symptoms associated with simulators and other SEs (e.g., Kennedy, Lane, Lilienthal, Berbaum, & Hettinger, 1992). One of the more recent versions of the 16-descriptor version of the SSQ is described in detail by Kennedy, Lane, Berbaum, and Lilienthal (1993).

4.2 Importance of Subjective Measures of SE Effects

A great deal can be learned by careful inquiry into the subjective aspects of motion discomfort. Researchers have yet to develop a complete description of the relation between the characteristics of different stimuli and the particular signs and symptoms elicited by those stimuli. Important steps in this direction have been taken by Kennedy and colleagues (e.g., Kennedy,

¹⁶The Miller and Graybiel (1970b) criteria have been used by researchers at the Pensacola Naval Air Station, Defense and Civil Institute of Environmental Medicine (Canada), National Aviation and Space Administration, Massachusetts Institute of Technology, Pennsylvania State University, Brandeis University, and other institutions.

Berbaum, & Lilienthal, 1992; Kennedy, Lanham, Drexler, Massey, & Lilienthal, 1997). To date, much inquiry has been restricted to a consideration of acute motion discomfort during short-term exposure to provocative stimuli. Little is known about such aspects of motion discomfort as the rate and retention of adaptation that occurs during prolonged or repeated exposures, or the distinct symptoms that can be elicited by long-term, low-grade exposure (e.g., the sople syndrome described by Graybiel & Knepton, 1976). Graybiel and Lackner (1980) suggested that the aspect of motion discomfort that is most operationally relevant will depend upon the stimulus situation and the goals of the mission; for example, rate of adaptation to flying discomfort and length of retention of that adaptation may prove more important than an aviator's inherent susceptibility on initial exposure. A better understanding of these aspects of motion-related symptomatology may prove immensely useful in the future. Ultimately, the best approach to the quantification of signs and symptoms associated with SEs will not rely entirely on any one type of measure (subjective, physiological, performance), but will employ multiple cross-validated measures in order to get the best look at SE-related syndromes (see chaps. 29–32 and 37–39, this volume).

4.3 Modifications of the Original Motion Discomfort Scales

The authors have little reason to think that the motion discomfort criteria of Kennedy et al. (1965) or Miller and Graybiel (1970b) could be made much more reliable (Calkins, Reschke, Kennedy, & Dunlap, 1987; Kennedy, Dunlap, & Fowlkes, 1990; Miller & Graybiel 1970a, 1970b; Reason & Graybiel, 1970). However, there is some question as to the metric assumptions made in obtaining the numerical summary scores of overall motion discomfort yielded by these methods (Bock & Oman, 1982). Reason and Diaz (1971) were probably the first to publish a symptom checklist scoring procedure that used criteria nearly identical to those in Miller and Graybiel (1970b), but did not assume ratio scale data. During the development of the SSQ, Lane and Kennedy (1988) also dropped many of the metric assumptions in the original Kennedy et al. (1965) scale and opted for a simple 0-to-3 scale of severity for all signs and symptoms. Lawson (1993) similarly created a 0-to-3 version of the Miller and Graybiel (1970b) scale that minimized the unequal weighting of signs and symptoms of equal severity and eliminated doubling of points with increases in severity of certain symptoms (see Table 30.2). The Lane and Kennedy (1988) and Lawson (1993) scales showed good test-retest reliability and correlated well with the earlier scales that had made more assumptions. The Lane and Kennedy SSQ was specifically designed for the relatively nonprovocative (low vomiting incidence) situation of simulator exposures and is probably the most useful of the "Pensacola School" techniques, in that it allows for a three factor assessment of underlying symptom clusters. The Lawson (1993) adaptation of the Miller and Graybiel (1970b) criteria (see Table 30.2) is recommended for those investigators committed to using the original Miller and Graybiel criteria, but wishing to limit their metric assumptions to avoid making erroneous conclusions about the null hypothesis. The MSQ and SSQ (see Table 30.3) are recommended for investigators not committed to the Miller and Graybiel criteria. As administered in questionnaires, the MSQ and SSQ descriptors are usually preceded by a number of biographical questions. Table 30.3 shows only the Likert-type items from the SSQ and MSQ, suitable for administration immediately before and after a real or apparent motion stimulus. The first 16 descriptors listed in Table 30.3 are used in the SSQ to assess symptoms in situations that elicit low vomiting rates and tend to include a visual display, with or without a moving base. The entire list of 28 descriptors is used in the MSQ to assess situations where vomiting is more common and motion tends to be present, for example, in ships at sea. (Descriptors are not in the order shown in Table 30.3, but are mixed in the actual MSQ/SSQ.) Key publications

TABLE 30.2

describing the development, administration, and scoring of the SSQ and MSQ were mentioned in section 4.1 above.

4.4 Other Motion Discomfort Scaling Techniques

Two of the most important motion discomfort scaling efforts initiated outside of Pensacola were the magnitude estimation procedure of Bock and Oman (1982) and the Nausea Profile of Muth, Stern, Thayer, and Koch (1996). The magnitude estimation procedure appears to yield data that are metrically superior to most other techniques, involving a prevomiting end point. The procedure can be explained to subjects easily and the estimates can be gathered from them rapidly once they have experienced the stimulus. The resulting data can be analyzed more easily than data from a symptom checklist. However, in its original form, the magnitude estimation procedure calls for previous exposure to the stimulus of interest (a requirement relaxed by Eagon, 1988) and does not generate multiple-factor solutions for exploring psychometric questions. It is also worth noting that the widely held assumption that magnitude estimation is superior to Likert-type rating has been questioned (Wills & Moore, 1994).

The Muth et al. (1996) Nausea Profile is the only procedure mentioned in this review that measures the construct of nausea per se, regardless of whether the nauseogenic stimulus derives from motion or from some other cause (e.g., illness). The Nausea Profile yields a multifactor solution that is likely to be applicable to any provocative stimulus strong enough to trigger the nausea syndrome. It has proven useful for demonstrating that the subjective sensation of nausea includes factors other than the experience of gastric discomfort. An especially interesting feature of the Nausea Profile is that the descriptors were generated by laymen

rather than experts, thus enhancing the content validity of the scale and making it easier for nonexperts to administer.

4.5 Psychometric Topics for Future Emphasis

With the exception of the SSQ, most of the scaling techniques used to characterize motion discomfort have focused on situations of acute and highly provocative exposure. More emphasis should be given to the human response to mild or nonsickening motions and to chronic exposure situations. Understanding these situations may help elucidate the sople syndrome (Graybiel & Knepton, 1976), an aspect of SE-related discomfort that is not explicitly

measured in the three factor solution of the SSQ, and thus requires looking at greater than 3 factor solutions of the SSQ (Kennedy et al., 1995) or creating a new scale (Muth, Lawson, & Sausen, 1999; see section 4.3).

5. SYMPTOM PROGRESSION OF SYNDROMES ASSOCIATED WITH SYNTHETIC EXPERIENCES: PRELIMINARY INFERENCES FROM MOTION STUDIES

5.1 Limited Findings From the Literature

Most published accounts of simulator and VE exposure display quantitative estimates of total symptom severity before and after exposure without specifying the temporal progression of individual signs and symptoms. There is at least one published account of the time course of postflight simulator symptoms (Baltzey et al., 1989), but the present authors did not find a published account specifically focusing on the onset and time course of symptoms in virtual environments. Because the most thorough elucidation of temporal symptom progression in SEs has come from studies involving actual body rotation, these findings will be discussed below.

Reason and Graybiel (1975) exposed 41 participants to the Dial Test onboard a Slow Rotation Room. The Dial Test involves moving the head and arms in order to adjust dials in various positions around one's body during whole-body rotation in a moving room (with a participant-fixed visual surround). Participants rated their individual symptoms and also gave concurrent "overall well-being" ratings of 0 to 10 (0 = "I feel fine" to 10 = "I feel awful, just like I am about to vomit"). Looking at the overall well-being ratings of about 1 to 1.5 (the initial onset of effects), one finds that the earliest signs and symptoms during the Dial Test in the Slow Rotation Room are usually minimal dizziness and visible nystagmus. Next, at ratings of about 1.6 to 5.0, a number of symptoms appear, including (roughly in temporal order) bodily warmth, moderate dizziness, headache, minimal pallor, minimal cold sweating, stomach awareness, and slightly increased salivation. The symptoms overlap quite a bit, but at ratings greater than 5.5, sweating and pallor tend to increase to moderate levels while stomach discomfort and unequivocal nausea builds.

Miller and Graybiel (1969) assessed symptom progression as well. They tracked the frequency of occurrence among 250 participants of specific symptoms associated with "Malaise I" or "mild malaise" during a now widely used rotation test. The most frequently reported symptoms by Malaise I were stomach awareness or discomfort (56%), minimal cold sweating (14%), and subjective warmth or flushing (9%). By the time participants experienced Malaise III ("severe malaise"), 70% of them felt subjective warmth/flushing and about a 60% felt stomach awareness/discomfort. Additionally, sweating, pallor, and nausea were often seen by the time Malaise III was reached.

5.2 Summary and Caveats

Great individual variability exists in the order of symptoms among participants. However, trained individuals are reliable within themselves regarding their responses to repeated provocative tests (DiZio & Lackner, 1991; Graybiel & Lackner, 1980). In the early stages of motion discomfort, the most likely symptoms to be reported by participants are subjective warmth/flushing, dizziness, and stomach awareness/discomfort. The final stages of motion discomfort during acute testing are usually marked by (at least) minimal nausea. Experimenters often terminate testing upon the appearance of moderate nausea, because an "avalanche effect" can occur

where vomiting happens before the experiment can be stopped. In Reason and Graybiel (1975), participants who exhibited greater resistance to the stimulus also tended to proceed suddenly from well-being ratings of 2 to 4 all the way up to 10. The very act of stopping a rotating chair is a provocative stimulus; hence, adequate time must be allowed to bring the chair slowly to a halt before the participant feels worse.

Some caveats apply to the interpretation of Reason and Brand (1975) and Miller and Graybiel (1969). The methodology of Reason and Graybiel (1975) biased participants to focus on nausea at higher (worse) point levels of "well-being," to the exclusion of other symptoms, because the word "vomiting" was used to anchor the definition for a well-being rating of 10. Similarly, Miller and Graybiel (1969) used a weighted scoring system wherein some symptoms (especially nausea) contributed more than others to the Malaise rating (see Table 30.1). Finally, it should be remembered that although nausea and vomiting are very important aspects of motion discomfort, certain stimuli produce vomiting without marked nausea (Lackner & Graybiel, 1986).

5.3 Implications for Virtual Environments

Attempts should be made to evaluate temporal symptom progression in VE thoroughly to see how it compares to the motion responses summarized above. This would help identify similarities and differences between VE symptoms and symptoms associated with other SEs or with motion. It might also aid the development of health and safety warning labels for virtual environments (see chap. 27, this volume). Since individuals are likely to be fairly consistent in how they respond to a given VE, it is a realistic goal for persons whose jobs will require repeated VE training (e.g., future military pilots) to learn their own unique progression of signs and symptoms so they can pace themselves accordingly. Of course, persons exposed to VE routinely should also avail themselves of dual adaptation strategies that emerge from research (see chap. 31, this volume) as long as the strategies have been proven to enhance performance of the person's job duties.

6. OTHER SIDE EFFECTS OF MOTION AND SYNTHETIC EXPERIENCES

Nausea and vomiting are the obvious manifestations of motion discomfort. Nausea at sea or during space flight can be lessened using appropriate oral drugs, or in extreme cases, drug injections (Graybiel & Lackner, 1987; see chap. 32, this volume). While current interactive synthetic experiences (such as VE) may elicit the nausea syndrome, inexperienced users are not as likely to seek drug solutions as they would for a sea voyage because they may not anticipate that the VE stimulus is a sickening experience for which drug remedies are appropriate. Even experienced VE users may choose to avoid drug therapies because (unlike the occasional sea cruise) an experienced VE user is likely to subject himself to the stimulus frequently and for long durations, and because the magnitude of the stimulus is largely under the user's control (e.g., by restricting head movements, eye movements, or duration of apparent self-movement through the VE).

People who cannot adapt readily to the nausea created by VE are likely to limit themselves to brief exposures. However, the more subtle side-effects of VE syndromes will not deter such persons as strongly as nausea and so may contribute disproportionately to the future health and safety problems that arise among VE users. Some of these other side effects include soplex syndrome, degraded dynamic visual acuity, and postural dysequilibrium.

6.1 Sopite Syndrome

Pensacola researchers Graybiel and Knepton (1976) coined the phrase *sopite syndrome* to describe a sometimes sole manifestation of motion discomfort characterized by such symptoms as motion-induced drowsiness, difficulty concentrating, and apathy. Evidence that the sopite syndrome is somewhat distinct from the nausea syndrome and from fatigue due to nonmotion stimuli are discussed by Lawson and Mead (1998), who review what is known about the scope of the problem and its potentially insidious character.¹⁷ A brief introduction to sopite syndrome will be provided in this section, emphasizing information not previously presented by Lawson and Mead (1998).

The term *sopite* derives from the same Latin root as the more common English words *sopor* and *soporific*, viz., the latin verb *sopire*, meaning “to lay to rest or put to sleep” (Neilsen et al., 1956). Since before recorded history, rocking back and forth has helped adults to relieve anxiety and tension (Watson, Wells, & Cox, 1998) and infants to fall asleep (Ter Vrugt & Peterson, 1973, from Leslie, Stickgold, DiZio, Lackner, & Hobson, 1997). Erasmus Darwin (1795) was probably the first person to publish the observation that motion induces drowsiness; he described a remarkable method that was related to him for procuring sleep by lying on a rotating mill wheel.¹⁸ In 1894, De Zouche (1975, p. 53) described the effects of “chronic seasickness” as “great exhaustion . . . [and] . . . heavy sleepiness.” In 1922, Quix (1976, p. 879) said the effects of motion discomfort include “slow ideation, lack of inclination to work, abulia [slow reaction], weakness, fatigue, feeling of uneasiness, and apathy that can lead to melancholy.”

In one of many rotating room studies carried out at Pensacola Naval Air Station, participants lived aboard a 20-foot diameter rotating room for 12 days (Graybiel et al., 1965). The participants suffered few episodes of overt nausea or vomiting during the study; only one out of four participants vomited as late as day two and none vomited after that. However, the participants (and some onboard experimenters) yawned frequently and complained of strong fatigue and drowsiness throughout the experiment despite frequent naps and sometimes sleeping longer than usual. Participants showed little motivation for mental or physical work until the fifth day and had not fully recovered from the fatiguing effects of rotation by the end of the rotation period. A possible vestibular etiology for the sopite syndrome was inferred by Graybiel et al. (1965) because the participants restricted their head movements intentionally even after the cessation of nausea. Also, normal participants exposed to two days in the rotating room showed evidence of drowsiness and apathy at rotation rates as low as 1.71 to 3.82 rpm, while a control participant who had lost vestibular function was free of such symptoms under the same conditions (Graybiel et al., 1960).¹⁹

Although many researchers are aware of the earliest sopite syndrome paper written by Graybiel and Knepton (1976), fewer researchers know of the sopite-relevant studies that were carried out in the last decade. For example, Wright, Bose, and Stiles (1994) observed worse digit-span test performance among nauseated individuals ($n = 26$) following helicopter flight. However, the experimenters also observed worse digit-span test performance when participants had symptoms indicative of sopite syndrome and nausea was not prominent. This

¹⁷Evidence that the fatigue associated with motion is not entirely attributable to increased energy expenditure (e.g., due to the additional work performed by a person repeatedly traversing the deck of a moving ship) is to be found in Crossland and Lloyd (1993) and Lewis and Griffin (1998).

¹⁸Incidentally, such angular rotation would initially produce rhythmic eye movements known as *nystagmus*, a word derived from the Greek *nystagmos*, meaning “drowsiness” (Neufeldt & Guralnik, 1994).

¹⁹It is also interesting to note that at least one paper on the vestibular malady known as Menière’s disease (Eklund, 1999) compares the aftereffects of an attack of rotational vertigo to sopite syndrome symptoms, which also can appear following motion (described as “late sopite” by Graybiel and Knepton, 1976).

degradation in performance would be attributable mostly to factors other than nausea, such as degraded attention and wakefulness. This notion is supported by studies that indicate low-frequency electroencephalographic (EEG) activity is associated with real or apparent motion. For example, preliminary studies by Miller (1995) and Yano et al. (1999) reported increased EEG alpha activity soon after entry into a driving situation, as well as longer gaze time and slower eye movements.²⁰ Chelen, Kabrisky, and Rogers (1993) and Hu et al. (1999) noted increased EEG delta activity during real or apparent motion.²¹ Woodward, Taubar, Sprelmann, and Thorpy (1990) tested participants ($n = 8$) on two separate days using a parallel swing and found EEG evidence of altered sleep functioning on nights following the motion stimulus. Using a relatively mild stimulus, Leslie, Stickgold, DiZio, Lackner, and Hobson (1997) found that after 10 minutes of optokinetic stimulation, participants ($n = 14$) became significantly more drowsy than after a control condition (reading), but the participants ($n = 13$) from whom good EEG data could be obtained, did not show a significant decrease in sleep latency onset.²²

Wood et al. (1990) observed a slowing of EEG alpha activity and emergence of some theta and delta waves in participants with symptoms of motion discomfort and identified some drugs that alleviate nausea but do not appear to alleviate symptoms of the sopite syndrome. This finding may have implications for the effort to develop drugs to alleviate motion discomfort, because the relief of motion discomfort clearly entails more than alleviating nausea. Earlier, Brandt, Dichgans, and Wagner (1974) had found that either dimenhydrinate or scopolamine were effective in reducing the incidence of vomiting during real or apparent motion stimuli, but that scopolamine subjects still exhibited fatigue, drowsiness, loss of concentration, and decreased performance (see also chap. 32, this volume). It is possible that some anti-motion-sickness drugs that are sedating are very effective in preventing emesis, but may mimic or exacerbate the symptoms associated with sopite syndrome.

An important nondrug therapy for alleviating motion discomfort is to adapt to the disturbing stimulus (see chap. 31, this volume). The U.S. Navy maintains a Self-Paced Airsickness Desensitization (SPAD) program wherein airsick flight students adapt to a rotation stimulus. This has proven to be effective in helping students get over their nausea and return to flight status. However, it appears that whether or not a student returns to flight status is unrelated to how much sopite syndrome he exhibits during desensitization training (Lawson, Flaherty, & Schmorow, in preparation). Since sopite syndrome effects may linger (Graybiel & Knepton, 1976), it is possible that a few of the students who have successfully adapted to motion-induced nausea are returned to further flight training despite their tendency to exhibit greater drowsiness during and after motion stimuli (compared to their fellow students). This possibility should be investigated, because flight training itself is known to produce symptoms indicative of sopite syndrome. For example, Kay, Lawson, and Clarke (1998) found that two of the common effects that Naval Flight Officers in primary flight training experienced during flight days

²⁰Miller (1995) observed EEG (and other) evidence of drowsiness in 80 truck drivers driving late at night. Of potential relevance to the sopite syndrome is Fig. 1 of Miller (1995), which shows the alteration of alpha and theta activity occurring within only about 30 to 40 minutes of transferring from a stationary rest break to a moving state. However, it is possible that the restorative effect of a rest break late at night is short-lived regardless of whether motion is present. Interestingly, the pilot data of Yano et al. (1997) indicated EEG alpha activity and eye movements associated with decreased arousal in three automobile drivers after only 30 minutes of daytime driving.

²¹Chelen, Kabrisky, and Rogers (1993) measured the EEG of 10 subjects during real motion, whereas Hu et al. (1999) measured the EEG of 52 subjects observing a moving optokinetic visual surround.

²²Using an optokinetic drum (the same as in Teixeira & Lackner, 1979) and a brief (10-minute) period of exposure to a 60 deg/sec constant velocity optokinetic stimulus (as used in Lawson, 1993), Leslie et al. (1997) found that scores on the Median Sleep Latency Test dropped from 13.6 minutes to 12.7 mins; $F(1-12) = 3.53$, $p = 0.085$. (The aforementioned sample size of $n = 13$ is deduced from the degrees of freedom of the ANOVA.)

(vs. nonflight days) were “drowsiness despite adequate rest” and “persistent unexplained fatigue.” Similar effects have been observed at sea. For example, Colwell (2000) recently completed an extensive Performance Assessment Questionnaire of individuals engaged in NATO North Atlantic Fleet Operations. Of the subjective variables surveyed, two of the most commonly reported items were “fatigue” and “difficulty sleeping” (the night before), which correlated with the amount of ship motion (as a function of sea state). (Also see Haward, Lewis, & Griffin, 2000; Wertheim, 1998).

Kennedy et al. (1995) have found ample reason to suspect that sopite syndrome is a feature of simulator exposure. The possibility for sopite syndrome as a result of VE exposure was first mentioned in an NRC report (BRL-CR-629, 1990) and has been recommended as a future VE research priority (Durlach & Mavor, 1995; Stanney, Salvendy et al., 1998), but to date, very little is known about sopite syndrome in virtual environments. For example, in some cases sopite syndrome may cause the sufferer to feel detached, distant, less communicative, and less willing to engage in group behavior (Graybiel & Knepton, 1976). Such an affective state would adversely affect the VE user’s sense of presence (see chap. 40, this volume) and degree of performance in shared VEs (Durlach & Slater, 1995; see chapter 18, this volume). Such symptoms might also compromise crew coordination during some military operations, for example, teleoperation of unmanned aerial vehicles, highly mobile amphibious landings, or maneuvers aboard a crew transport vehicle (Cowings et al., 1999). Finally, Space Adaptation Syndrome has been suggested as a factor hindering communication between ground and space crews (Kelly & Kanas, 1993).

6.2 Loss of Visual Acuity During Head or Body Motion

Another likely side effect for VE users is the loss of visual acuity during head or body motion (see chaps. 37 and 39, this volume). Most whole-body motions will elicit a vestibulo-ocular reflex that helps gaze remain stable as the head or body moves. This natural coordination of visual and vestibular function is disrupted when one dons prism goggles that alter the amount of visual field movement corresponding to a given head movement (Gonshor & Mellville-Jones, 1976); it can also be altered when the user attempts to read a head-fixed display during prolonged whole body motion. In this latter situation, interpreting the display requires visual suppression of the ongoing vestibulo-ocular reflex. Anyone who has attempted to read fine print during turbulent flight aboard a commercial airplane will appreciate the difficulty and unpleasantness of the effort. Those who design VE will need to understand the conditions in which a viewer’s ability to suppress his vestibulo-ocular reflex is enhanced without creating unpleasant symptoms (Lawson, Rupert, Gnedry, Grissett, & Mead, 1997).

6.3 Postural Disequilibrium

Postexposure disruptions of balance have been associated with motion and unusual force environments (see Baltzey et al., 1989; chap. 39, this volume). People can adapt to unusual gravitoinertial force environments such as micro-gravity (Nicogossian, Huntoon, & Pool, 1989), high G-force, ship motion, and rotating rooms (reviewed in Crampton, 1990). However, the acquired adaptation disrupts balance and coordination on returning to the stationary world. A familiar example is the way in which sailors must regain their “land legs” on return to shore (Gordon, Spitzer, Doweck, Melamed, & Shupak, 1995).

Postural disruption can also be caused by abnormally integrated visual-vestibular signals. Lee and colleagues (Lee & Aronson, 1974; Lee & Lishman, 1975) showed that a moving visual surround can “drive” postural sway in toddlers standing on a regular floor or in adults standing on compliant surfaces (which degrade ankle kinesthesia). A longitudinal study by Brandt and

colleagues (1978) implied that the maintenance of posture within a moving visual field required the appreciation of the consequences of body movement. The causal and temporal relation amongvection, postural sway, and feelings of discomfort is viewed differently by different researchers (see Jones, 1998, for a recent review). Regardless of the relations involved, it is clear from data gathered in navy ground-based simulators that significant ataxic aftereffects occur after short exposures to certain visual field motions (Kennedy, Lilienthal, Berbaum, Baltzley, & McCauley, 1989; Kennedy, Berbaum, & Lilienthal, 1997). Research by Kennedy and Stanney (1996) suggests that simple measures of postural instability can reveal the aftereffects of VE exposure. These various findings point to a potential health and safety risk associated with the prolonged use of "inertial" and "noninertial" virtual displays (Durlach & Mavor, 1995; Lawson, Rupert, Guedry, Grissett, & mead, 1997; Stanney, Salvendy et al., 1998). Of particular concern is the fact that within another generation, the majority of the population will be routinely exposed to VEs and the segment of the population that is most vulnerable to falls, the senior females, will be larger than it is now (Fregly, 1974; Grabowski, 1996).

7. SITUATIONS MOST CONDUCIVE OF VE-RELATED SYNDROMES

7.1 Moving Visual Fields

7.1.1 *Relation Between Visually Induced Illusions of Self-motion and Feelings of Discomfort*

The role of visually induced illusions of self-motion (vection) in enhancing the experience of VE is treated in detail in chapter 23 (this volume) and mentioned in chapters 3 and 7 (this volume). The present section briefly summarizes the relation betweenvection and discomfort. McCauley and Sharkey (1992) and Hettinger, Berbaum, Kennedy, Dunlap, and Nolan (1990) hypothesized that simulator discomfort and VE discomfort should be correlated with the presence of a visually induced illusion of self motion, known asvection (Fischer & Kornmüller, 1930), and hence could be considered a type of visually induced motion discomfort. Hettinger et al. (1990) observed that 80% of participants ($n = 18$) who reportedvection while viewing a moving visual field also experienced symptoms, whereas only 20% of those who did not reportvection felt discomfort. Crampton and Young (1953) found that nine of their participants (i.e., 35% of $n = 26$) experienced nausea during visual field motion, five of whom perceived themselves to be moving. Studies by Dichgans and Brandt (1978) suggested that if strongvection was being experienced by the participant, head movements could elicit discomfort. However, studies by Lackner and Teixerira (1977) and Teixeira and Lackner (1979) indicated that if head movements were performed prior to the onset ofvection they suppressed thevection illusion and prevented discomfort. Jones (1998) found a weak but significant correlation between magnitude ofvection and "total sickness severity" score following a driving simulation task.²³

The authors of this chapter conclude that moving visual fields often elicitvection, that behaviors (e.g., head movement) that affectvection are likely to affect discomfort, and that symptoms such as dizziness will be experienced in the majority of participants who reportvection. However, it is important to note that participants can reportvection without symptoms and symptoms withoutvection. Similarly, individuals without functional vestibular systems cannot be made sick by motion, yet can experiencevection when viewing visual stimuli

²³Pearson $r = 0.25$, $p < 0.03$, $n = 78$.

(Chueng et al., 1991). Finally, while feelings ofvection should be positively correlated with feelings of presence in a SE, Witmer and Singer (1998) found a negative correlation between measures of presence and simulator discomfort such that greater presence resulted in less discomfort. Possibly,vection is correlated with visually induced symptoms, but it is not a necessary precursor of them (a view expressed by Hettinger & Riccio, 1992, and by Ebenholtz, 1992). A simple view of cybersickness as a subset of visually induced motion discomfort is unlikely to prove adequate in the long term because sensations of self-motion can be elicited by other than visual modalities (Bles, 1979; Lackner & DiZio, 1988), and future VE will not be limited to visual (see chap. 3, this volume) and auditory displays (see chap. 4, this volume), but will incorporate the cutaneous, kinesthetic (chaps. 5, 6, 11, and 38, this volume), and vestibular stimuli (see chap. 7, this volume) as well.

7.1.2 Relation Between Field of View of a Moving Visual Display and Resulting Discomfort

Throughout the literature on simulators, display field of view has been implicated in a trade-off between performance and side effects (e.g., Kennedy, Fowlkes, & Hettinger, 1989; Van Cott, 1990; Westra, Sheppard, Jones, & Hettinger, 1987). Although a larger field of view often enhances performance, it also increases the probability of experiencing side effects. DiZio and Lackner (1997) showed that by decreasing the field of view in a VE (and thus the lag in visual display update), they were able to decrease discomfort ratings.

Symptoms elicited by moving visual fields generated by rotating optokinetic drums are worse if one is viewing a large field-of-view display (Dichgans & Brandt, 1978); however, Andersen and Braunstein (1985) found that 17 of their participants (i.e., 31% of $n = 55$) reported adverse symptoms (9 felt dizzy, 2 had a headache, and 1 felt nauseated)²⁴ while viewing radially expanding patterns subtending only 7.5 to 21.2 dg of visual angle. One can conclude that although the Andersen and Braunstein Stimulus elicited a lower incidence of symptoms than previous experiments that had used a wider field of view (summarized above in section 3.2), it was a stimulus sufficient to induce 10% of the participants to terminate their participation.

7.1.3 Other Aspects of Visual Motion That Cause Discomfort

In simulators, the amount of movement of the visual scene accounts for 20% or more of the variance in simulator discomfort (Kennedy, Berbaum, Dunlap, & Hettinger, 1996). The velocity and spatial frequency of the visual display contributes to this effect (Dichgans & Brandt, 1978). The predominant frequency of oscillation of the visual display (Kennedy et al., 1996) is important to the resulting level of discomfort. It is well-known that real motion is most disturbing when it involves low frequencies of oscillation in the 0.2 Hz range of motion or 1 cycle every 5 seconds (e.g., McCauley & Kennedy, 1984); it is believed that the same generalization will apply to moving visual scenes (Hettinger, Berbaum, Kennedy, Dunlap, & Nolan, 1990; Stoffregen & Smart, 1997). Interestingly, in the case of very low frequency oscillation (0.02 Hz or 1 cycle every 50 seconds) of the visual scene, the visual stimulus can sometimes be more disturbing than real-body motion at the same frequency (Dichgans & Brandt, 1978). The amount of depth information represented by the moving visual display (Andersen & Braunstein, 1985) may also be a factor contributing to the perceived amount of visual motion and discomfort.

²⁴Additional symptoms are mentioned for those five subjects who discontinued their participation in this experiment, but it is sufficient to note that four of them had nausea and one felt faint.

8. DISCOMFORT AS A FUNCTION OF INTERVAL BETWEEN EXPOSURES AND EXPOSURE DURATION

Kennedy, Lane, Berbaum, and Lilienthal (1993) found that repeated exposure in simulators was effective in promoting adaptation and reducing discomfort when the interval between exposures was 2 to 5 days. Watson (1998) obtained similar results in a driving simulator, noting that a 2-to-3 day interval between exposures was best.

It has been estimated that 20% to 50% of the variance in VE-related discomfort can be accounted for by the amount of time a person spends in a VE and the intersession interval (Kennedy, Stanney, & Dunlap, 2000). Kennedy, Jones, Stanney, Ritter, and Drexler (1996) found marked reductions in discomfort in the second of two 40-minute VE exposures. Cobb, Nichols, Ramsey, and Wilson (1999) looked at repeated 20-minute exposures to a passive virtual environment. They observed a reduction in self-reported discomfort over the three exposures spaced a week apart. (They noted that the greatest reduction occurred for the Disorientation symptom cluster of the SSQ). Cobb et al. (1999) reported a preliminary study of four participants interacting with a VE for up to 2 hours. They note that all four participants reported increased discomfort up to 1 hour, at which time two of the participants withdrew. However, the two participants who continued with the experiment reported decreasing levels of discomfort at 75 minutes. At the end of the 2-hour session, their reports of discomfort were back to preexposure levels.

9. DISCOMFORT DUE TO LACK OF CORRESPONDENCE BETWEEN VISUAL FIELD MOVEMENT AND HEAD MOVEMENT

The literature on simulators indicates that an asynchrony between inertial and visual motion will cause discomfort (Frank, Casali, & Wierwille, 1988; Uliano, Lambert, Kennedy, & Sheppard, 1986); this has been suggested as a problem for VE users also (Hettinger & Riccio, 1992). Recently, VE users were observed to have higher levels of disorientation, discomfort, and postural instability as lag increased in the update rate of the visual display (Cobb, Nichols, Ramsey, & Wilson, 1999; DiZio & Lackner, 1997). Problems stemming from a temporal discordance between head movement and visual-field movement are discussed in chapter 6 of Durlach and Mavor (1995). Improving the correspondence between head movement and visual field movement is an important area of VE development (Stanney, Salvendy et al., 1998).

10. DISCOMFORT AS A FUNCTION OF NAVIGATION CHARACTERISTICS

10.1 Extent of Control Over Navigation

Individuals who have little control over the movements of a simulator seem to experience greater discomfort than individuals who are controlling the simulator (Casali & Wierwille, 1998; Reason & Diaz, 1971). Similarly Stanney and Hash (1998) found that giving participants control over their actions will reduce their VE side effects. Stanney and Hash examined three conditions: (1) "active" (using a joystick to maneuver with six degrees of freedom), (2) "active-passive" (using a joystick to move forward and backward, side to side, up and down, and in specific circumstances yaw and pitch), and (3) "passive" (passively observing scripted movements). Stanney and Hash (1998) found that the average discomfort scores were highest

for the “passive” condition. The “active” condition did not reduce the severity of the symptoms as much as the “active–passive” condition. Stanney and Hash suggest that in the “active” condition, the participants might not have been able to adapt as quickly as in the “active–passive” condition, due to the abundant amount of sensory information gathered from unrestricted movements made in the “active” condition.

10.2 Discomfort Related to Navigation Using Head Versus Hand

Howarth and Finch (1999) found that head controlled navigation produced greater severity and sooner onset of nausea than hand controlled navigation, most likely due to greater system lag. Anecdotal evidence has suggested that as users gain experience with a VE, they tend to reduce the number and magnitude of their head movements to avoid discomfort (Cobb et al., 1999; Howarth & Finch, 1999). These findings suggest that exploring VEs via head movements is more provocative than using alternate input devices (see also Durlach & Mavor, 1995; chapter 13, this volume).

11. DISPLAY CHARACTERISTICS THAT CAN CAUSE DISCOMFORT WITHOUT REQUIRING WHOLE-FIELD VISUAL MOTION

Side effects of SEs involving real or apparent motion stimuli are the focus of this chapter. However, certain VE display characteristics can cause discomfort without requiring whole-field visual motion or other apparent motion stimuli. For example, some of the early head mounted VEs used low-resolution liquid crystal displays placed close to the eyes with insufficient contrast or illumination. Current stereoscopic VE displays require the user to accommodate to a particular depth plane while requiring vergence movements to a range of depths (see chaps. 3 and 37, this volume). As a result of such display factors, Wann and Mon-Williams (1997) observed changes in visual functioning that were correlated with reports of discomfort and have replicated these results with various head mounted displays (see chap. 37, this volume).

12. SUMMARY

Humans tend to experience a number of unwanted side effects during and after SEs involving real or apparent (usually visual) motion stimuli. Side effects of SEs are typically measured via symptom checklists, the most popular of which are described herein. The most common side effects of exposure to real motion stimuli, moving visual fields, or flight simulators include the following: dizziness, stomach symptoms (stomach awareness, stomach discomfort, or nausea), flushing/subjective warmth, eyestrain, fatigue, drowsiness, “cold” sweating, headache, or difficulty concentrating. Other classically defined cardinal signs or symptoms include facial pallor, increased salivation, retching, and vomiting. The side effects of VE exposure are not as well studied, but they seem to include many of the symptoms produced by other synthetic experiences. However, it is likely that different SEs produce somewhat different clusters of predominant symptoms.

The most conservative prediction that can be made from the limited VE research is that at least 5% of all users will not be able to tolerate prolonged use of current VEs; this is about the same as the proportion of people highly susceptible to motion stimuli, moving visual fields, and simulators. Virtual environment stimuli also seem to share in common with many other SEs the tendency to elicit symptoms that persist after exposure. Side effects such as stomach

symptoms, dizziness, eyestrain, and headache among susceptible VE users will present an obstacle to widespread acceptance. Less obvious side effects may pose a significant risk to VE users who do not believe themselves to be susceptible; these include sopite syndrome, postural dysequilibrium, and loss of visual acuity during head or body motion.

Most of the techniques used to measure real or apparent motion discomfort have been developed and applied in situations of acute and provocative exposure. More emphasis should be given to stimuli that are mild or nonsickening and to chronic or repeated exposure situations. Careful evaluations of the temporal progression of VE side effects should be made in order to identify the early warning signs of an adverse reaction to a VE and to understand the time course of VE adaptation and postexposure recovery. Since the observable signs and subjective symptoms of real or apparent motion discomfort have proven to be valid and reliable measures of a person's state, they will continue to be important criteria for interpreting physiological and performance data regarding VE side effects.

Adapting to Virtual Environments

Robert B. Welch

NASA—Ames Research Center

Moffett Field, CA 94035

rwelch@mail.arc.nasa.gov

1. OVERVIEW

This chapter describes and illustrates a variety of procedures for helping virtual environment (VE) users overcome the deleterious sensory/perceptual, behavioral, and physical effects and aftereffects that result from current technological limitations of these devices. Many of the most important of these untoward consequences of interacting with VEs are due to the presence of *sensory rearrangements*. A sensory rearrangement (or distortion) exists when the sensory array and/or relationship between sensory systems differs from normal, as, for example, when viewing the hand through a wedge prism. For the observer, the initial exposure to a sensory rearrangement results in misperception, the surprise of violated expectations, and perceptual-motor disruption. Because laboratory experiments indicate that human beings are capable of adapting to a wide range of optical rearrangements, it is reasonable to assume that they are equally able to adapt to the sensory rearrangements found in VEs. It follows that the variables that have been found to influence adaptation to optical rearrangements, for example, active interaction, will apply as well to VE adaptation. Therefore, the VE-training procedures described in this chapter are based on the variables demonstrated by previous research to control or influence perceptual and perceptual-motor adaptation to rearranged sensory environments. It will be proposed that the problematical aftereffects that inevitably result from VE adaptation can be reduced or eliminated by means of systematic readaptation procedures and “dual adaptation” training (i.e., repeated alternation between adaptation and readaptation). Finally, the omnipresence of individual differences in adaptation to sensory rearrangements is acknowledged and its implications for the use of VE adaptation-training procedures considered.

2. THE COMPLAINTS OF VE USERS

Despite tremendous advances in the technology of virtual reality (e.g., Durlach & Mavor, 1995), one rarely mistakes it for reality. Thus, most VEs, including “augmented realities” (e.g., see-through displays), continue to be plagued by such deficiencies as poor lighting, unrealistic graphics, and a multitude of sensory rearrangements that render it a poor imitation of everyday experience. More importantly, these shortcomings are the source of a variety of sensory/perceptual, behavioral, and physical complaints, many of which afflict nearly all VE users to one degree or another (see Table 31.1). The last malady listed in Table 31.1, motion-sickness symptoms (variously referred to as simulator sickness, virtual environment sickness, and cybersickness) is dealt with in length in chapter 30 (this volume). Thus, although the occurrence of simulator sickness is typically considered indirect evidence of the presence of intersensory conflicts and its recovery an indicator that adaptation has taken place, these topics will, for the most part, be ignored here.

3. THE RESPONSE TO USERS' COMPLAINTS

Clearly, the adverse effects of VEs pose a serious obstacle to optimal task performance and training with these devices. Furthermore, as Biocca (1992) has noted, unpleasant experiences in VEs, especially if well publicized, are likely to have a chilling effect on the general diffusion of VE technology. In short, there is ample motivation to do whatever is necessary to overcome the problems that frequently disrupt the human–VE interface. There are two very different, albeit complementary, ways in which to respond to this imperative. The first is to modify (typically, improve) the VE to accommodate the user, and the second is to modify the user to accommodate the VE. Designers and implementers of VEs have typically chosen the first of these strategies. That is, they tend to seek engineering solutions (e.g., more powerful computers, faster tracking

TABLE 31.1
Sensory/Perceptual, Behavioral, and Physical Complaints Afflicting VE Users

Sensory/perceptual problems reported by VE users:

- Momentary reduction in binocular acuity (e.g., Mon-Williams, Rushton, & Wann, 1993)
- Misperception of depth (e.g., Roscoe, 1993)
- Changes in dark accommodative focus (Fowlkes, Kennedy, Hettinger, & Harm, 1993)
- Potentially dangerous “delayed flashbacks” (e.g., illusory experiences of climbing, turning, and inversion) that may not surface until several hours after user has left an airplane simulator or similar VE (e.g., Kennedy, Fowlkes, & Lilienthal, 1993)

Disruptive behavioral effects of VEs:

- Disturbed perceptual–motor (e.g., hand–eye) coordination (e.g., Biocca & Rolland, 1998)
- Locomotory and postural instability (e.g., DiZio & Lackner, 1997)
- Degraded task performance (e.g., Fowlkes et al., 1993)

Physical complaints reported by VE users:

- Eye strain, or “asthenopia” (e.g., Mon-Williams et al., 1993), which may be symptomatic of underlying distress or conflict between oculomotor subsystems (e.g., Ebenholtz, 1992)
 - Headaches (e.g., Mon-Williams et al., 1995)
 - Cardiovascular, respiratory, or biochemical changes (e.g., Calvert & Tan, 1994)
 - Motion-sickness symptoms (e.g., pallor, sweating, fatigue, and drowsiness, although rarely vomiting; e.g., Gower et al., 1987)
-

devices, and improved displays) for eliminating the deficiencies of their devices. According to the second and much less common tactic, the VE is left as it is, and users are provided with systematic training and/or deliberate strategies aimed at reducing, or perhaps merely circumventing, its shortcomings. It is generally agreed that the first of these two approaches will ultimately prevail as computer technology is perfected and becomes more generally affordable. However, the second strategy has the great advantage that it can be implemented now, without having to wait for those improvements to be realized. Some of the limitations of current VE technology, such as poor lighting, small field of view (FOV), and heavy headgear, can only be overcome by technological improvements. However, others, such as discrepancies between felt and seen limb position, delays of visual feedback, and distortions of perceived depth, represent the kinds of sensory rearrangements that have proven amenable to user-training procedures, in particular, those that promote adaptation. It is these procedures that represent the focus of this chapter.

Adaptation to sensory rearrangement is defined here as “a semi-permanent change of perception and/or perceptual-motor coordination that serves to reduce or eliminate a registered discrepancy between or within sensory modalities or the errors in behavior induced by this discrepancy” (Welch, 1978, p. 8). Adaptation is measured in two ways: (1) the reduction of observers’ perceptual and/or perceptual–motor errors during exposure to the sensory rearrangement (the “reduction of effect”); and (2) postexposure “negative aftereffects” (errors in the direction opposite those initially elicited by the sensory rearrangement). Adaptation is automatic and “unthinking.” For example, the negative aftereffects of hand–eye coordination occur even when the subject is aware that the sensory rearrangement has been removed. Perceptual–motor adaptation can occur even when perceptual adaptation has not, as illustrated by a study by Snyder and Pronko (1952) in which, for an entire month, a subject wore a pair of goggles that inverted his visual field. Despite the fact that by the end of this extended period the subject’s perceptual–motor coordination was essentially error-free, the world still appeared to be upside-down to him. In general, it may be concluded that perceptual adaptation predicts behavioral adaptation but not vice versa. Before examining how research on adaptation can assist the design of procedures for training VE users to overcome the sensory rearrangements to which they may be exposed, it will be useful to specify what these sensory rearrangements are.

4. SENSORY REARRANGEMENTS (AND DISARRANGEMENTS) FOUND IN SOME VEs

There are five major deficiencies of VEs for which the processes of perceptual and perceptual–motor adaptation are relevant. These are (1) intersensory conflicts, (2) distortions of depth and distance, (3) distortions of form and size, (4) the loss of stability of the visual field due to visual feedback delays and asynchronies, and (5) sensory “disarrangement,” that is, the presence of randomly varying distortions. This section will discuss each of these in turn.

4.1 Intersensory Conflicts

This category entails mismatches between paired spatial modalities—vision, audition, touch, proprioception, and the haptic and vestibular senses. Thus, the computer-generated surrogate of the observer’s hand may be seen in one location while the actual hand is felt in another, an object may look rough but feel smooth, and a sound source may be seen in one place but heard elsewhere. Some intersensory discrepancies entail the *absence* of one member of a pair of normally correlated sensory impressions. For example, in fixed-base aircraft simulators,

visual motion is often displayed without the vestibular and other inertial cues (e.g., tactal and somatosensory stimuli) that usually accompany it. Likewise, many VEs allow observers to manipulate a virtual object with their virtual hands, but provide no tactal or force feedback about these "contacts."

The type and severity of the effects of an intersensory conflict depend, in part, on which sensory modalities are involved. For example, conflicts between seen and felt position of the limb will produce reaching errors, particularly for very rapid or "ballistic" responses or when visual feedback is precluded (e.g., Welch, 1978, 1986). (Note: The virtual hand of the user will typically fail to look much like his or her own limb. It is not obvious, however, if this visual anomaly will cause any problems for observers except perhaps initial surprise and minor distraction.) On the other hand, the conflicts between visual and vestibular-inertial cues that characterize many flight simulators are likely to cause disorientation, postural instability (ataxia), and motion sickness-like symptoms (e.g., Oman, 1991).

Conflicts between spatial vision and vestibular sensations during movement of the observer's head or entire body are particularly problematic, both because of their unpleasant behavioral and gastrointestinal consequences and the fact that, at least at present, they are very difficult or impossible to avoid. Even very sophisticated VE technology may be incapable of preventing serious intersensory conflicts of this sort. For example, it has been argued (e.g., DiZio & Lackner, 1992) that the ability of VE technology to simulate inertial motion may never improve to the point where some adaptation will not be necessary. Thus, motion-based aircraft simulators may always be afflicted by significant discrepancies between the ranges and amplitudes of the applied inertial forces and the visual motions with which they are paired. As examples, the take-off of a fighter plane from an aircraft carrier or a violently maneuvering airplane will almost certainly produce substantial conflicts between the two senses because the appropriate gravitational forces exceed the capacity of the simulator. The fact that motion-based aircraft simulators tend to be more nauseogenic than their fixed-based counterparts (e.g., Gower, Lilienthal, Kennedy, & Fowlkes, 1987) may be due to the presence of such intersensory conflicts. Further limitations in attempting to simulate gravitational-inertial forces derive from the fact that sustained hypogravity (i.e., $G < 1.0$) cannot be simulated by earthbound VEs, whereas hypergravity, whether brief or prolonged, requires a human centrifuge (e.g., Cohen, Crosbie, & Blackburn, 1973), a device unavailable or unaffordable to most investigators.

A common instance of intersensory spatial conflict in a VE is when a normally correlated modality is simply not there. Here, too, the behavioral and physical effects are diverse. The absence of tactal or force feedback when attempting to grasp a virtual object, although unlikely to disturb gross reaching behavior, may interfere with fine manual control. On the other hand, when visual motion occurs without the normally attendant vestibular and other inertial cues, as in fixed-base aircraft simulators, the operator may experience a dramatic sense of virtual body motion known asvection. This illusion is nauseogenic for some individuals, as is the "freezing" of an aircraft simulator (or other VE) in an unusual orientation which can occur when the user has engaged in an extraordinary maneuver (e.g., McCauley & Sharkey, 1992).

4.2 Depth and Distance Distortions

One form of static depth distortion occurs in some VEs when visual objects that are being depicted as closer to the observer's viewpoint fail to occlude supposedly more distant objects. Another example is when visual objects whose edges are fuzzy due to poor resolution and which, on the basis of "aerial perspective," cues should thus appear far away, are instead presented with the saturated hue and optical sharpness of a much nearer object.

Moving the head or entire body while viewing a VE through a stereoscopic HMD frequently causes virtual objects to appear to change their relative positions (as well as their sizes and shapes) in the distance dimension. This form of dynamic depth distortion is caused because the VE system is unable to calculate correctly and instantly the images presented to the HMD display during the bodily movement. The same is true if the HMD wearer is stationary and the objects are moved around him or her. This movement-contingent depth distortion, referred to by perceptual psychologists as the “kinetic depth effect,” is likely to disrupt the user’s visual-motor interactions (e.g., pointing or reaching) with respect to these objects and may cause simulator sickness. Fortunately, this form of sensory rearrangement is subject to a certain amount of visual adaptation (e.g., Wallach & Karsh, 1963).

Besides such distortions of depth (i.e., relative distance) perception, the apparent absolute distance of objects may be under- or overestimated, as demonstrated, for example, by errors in visually “open-loop” pointing responses (i.e., hand-eye coordination in the absence of visual feedback). Furthermore, in situations that entail very few depth cues distance perception may be ambiguous, which is likely to result in substantial moment-to-moment variability in hand-eye coordination.

A common discrepancy observed with stereoscopic VE displays occurs between ocular vergence and the accommodation of the lens. Under everyday circumstances, fixating an object in the distance dimension entails convergence of the eyes to produce a single image, together with the appropriate shaping of the lens for fine focusing. However, in many stereoscopic VEs the convergence and accommodation appropriate for the visual display are placed in conflict. Thus, the stereoscopic stimuli may be set for a distance that differs from the one for which optimal focusing will occur. Besides leading to reaching errors, this discordance may cause diplopia, asthenopia, and even nausea (e.g., Ebenholtz, 1992). Unfortunately, it may be difficult or even impossible to overcome this problem by means of adaptation since, as Wann and Mon-Williams (1997) have argued, many current stereoscopic VE displays present the operator with a *range* of binocular targets to which they may verge. Clearly, such a situation fails to provide the consistent “rule” required for adaptation to take place.

Roscoe (1993) has demonstrated that pilots who are wearing see-through HUDs and viewing collimated virtual images will not focus their eyes on infinity, but instead toward their resting accommodation (approximately 1 meter away). The results of this misaccommodation are that: (1) the actual visual scene beyond the HUD appears minified; (2) a terrain or airport runway appears to be observed from a higher altitude than is actually the case; and (3) familiar objects look farther away than they really are. The behavioral consequences of these misperceptions are obvious and, according to Roscoe (1993), potentially *lethal*. Unfortunately, magnifying the images in an attempt to compensate for these illusions is not feasible because of the limitation this hardware modification places on display size (Roscoe, 1993). Fortunately, humans are capable of a certain amount of adaptation to such distance and size distortions. Interestingly, the evidence for this claim comes almost entirely from studies of adaptation to underwater distortions caused by the glass-water interface of the diver’s mask (e.g., Ross, 1971).

4.3 Form and Size Distortions

An artifact of many VE systems is the illusory curvature of contours, most notably the so-called pincushion effect, in which the sides of a rectilinear shape (especially one that occupies most or all of the FOV) appear to be bowed inwardly. Magnification or minification of the visual scene or of objects within it can also occur with some VEs, especially those that disrupt perceived distance. Thus, in the example of the see-through HUD previously described (Roscoe, 1993), overestimation of the distance of familiar objects caused them to appear too large, presumably based on the mechanism of “misapplied size constancy scaling” often used to explain the

“moon illusion” (e.g., Rock & Kaufman, 1962). The few published studies on optically induced size distortions have revealed only a modest amount of visual adaptation (Welch, 1978, chap. 8). This same resistance to adaptation applies to prismatically induced curvature, as seen most convincingly in an experiment by Hay & Pick (1966), in which subjects who wore prism goggles for an heroic 7 consecutive weeks underwent adaptation of only about 30% of the optical curvature to which they were exposed.

On the other hand, when head movements are made in the presence of a magnified or minified visual field, the resulting oculomotor disruption (and loss of visual position constancy) caused by the increased or reduced gain of the vestibular-ocular reflex (VOR), while likely to be nauseogenic, can apparently be completely overcome by adaptation (e.g., Collewijn, Martins, & Steinman, 1983). Even the drastic loss of visual position constancy due to head movements while wearing right-left reversing goggles can apparently be abolished (e.g., Stratton, 1897), although it is interesting to note that the resulting loss of VOR under these circumstances resists recovery (e.g., Gonshor & Mevill Jones, 1976).

4.4 Delays of Sensory Feedback

Perhaps the most serious and currently intractable flaw of many VEs is the presence of significant delays (lags) between the operator’s movements and resulting visual, auditory, and/or somatosensory feedback. Such delays can occur because of insufficient refresh rates (which are exacerbated by the use of highly detailed graphics) and relatively slow position trackers. Studies of flight simulation have revealed that lags of as little as 50 msec can have a measurable effect on performance, whereas longer delays cause serious behavioral oscillations (e.g., Wickens, 1986).

An especially disruptive and unpleasant effect of visual delay is the interference of the VOR and concomitant illusory visual motion that occurs during head or entire body movements. Normally, a head movement in one direction causes an approximately equal eye movement in the opposite direction, effectively nulling motion (both real and perceived) of the visual field relative to the head. However, visual feedback delay causes the visual field to lag behind the head movement, initially making the VOR inappropriate and causing the visual world to appear to move in the same direction as the head. This loss of visual position constancy (or oscillopsia) is both behaviorally disruptive and nauseogenic. Furthermore, it has been suggested that these delays can cause simulator sickness and other physical problems even if they are below the observer’s sensory threshold (Ebenholtz, 1992).

Visual feedback delays from motor movements that do not involve vestibular stimulation, such as reaching or pointing, rarely cause motion sickness symptoms. However, they can lead to other problems ranging from simple distraction to serious discoordination. Auditory feedback delays also cause difficulties, particularly with speech (e.g., Smith & Smith, 1962, chapter 13). Even more problematic perhaps is the presence of *variable* delays and asynchronies between the onsets of two (or more) sensory systems, as, for example, with some motion-based aircraft simulators involving mismatches between the onset times of visual and inertial stimuli. Kennedy (personal communication, May 15, 1994) believes that these problems may be an especially important factor in the etiology of simulator sickness.

4.5 Sensory “Disarrangement”

When the size and/or direction of a VE-induced sensory rearrangement vary from moment to moment (rather than remaining constant over an extended time period), a condition of sensory “disarrangement” is said to exist (e.g., Cohen & Held, 1960). Examples with respect

to VEs include: (1) so-called "jitter" (jiggling of the visual image due to electronic noise in the position tracker and/or the image-generator system) and (2) moment-to-moment variability in the absolute and relative accuracy of position trackers in monitoring the operator's limbs and body transport. These limitations have been discussed by Meyer, Applewhite, and Biocca (1992). Such noise can cause the seen and felt positions of the hand to shift randomly relative to each other. Not surprisingly, unpredictably changing sensory conditions such as these resist adaptation since there is no constant compensatory "rule" on which such an adaptive process can be based. However, as discussed in a later section, although no change in *average* perceptual or perceptual-motor performance is likely to take place in the presence of a disarrangement, an increase in moment-to-moment behavioral variability (e.g., Cohen & Held, 1960) will occur, which represents a potentially serious degradation of the user's performance.

It is apparent that many of the sensory distortions found in current VEs are similar or identical to those that have been deliberately created by investigators by means of lenses, prisms, and mirrors (see Welch, 1978, 1986, for an extensive review of this literature). The sensory rearrangements examined include optically induced (1) lateral rotation (yaw) of the visual field (e.g., Held & Hein, 1958); (2) visual tilt (roll, e.g., Ebenholtz, 1969); (3) displacement in the distance dimension (e.g., Held & Schlank, 1959); (4) curvature (e.g., Hay & Pick, 1966); (5) right-left reversal (e.g., Kohler, 1964); (6) inversion (e.g., Stratton, 1897); (7) depth and distance distortion (e.g., Wallach, Moore, & Davidson, 1963); and (8) altered visual size (e.g., Rock, 1965). Acoustical rearrangements have entailed: (1) small (e.g., 10-deg) lateral rotations of the auditory field (e.g., Held, 1955); (2) right-left reversal (e.g., Young, 1928); and (3) functional increases in the length of the interaural axis (e.g., Durlach & Pang, 1986). Another atypical sensory environment to which humans have been exposed and adapted is altered gravitational-inertial force—hypergravity (e.g., Welch, Cohen, & DeRoshia, 1996), hypogravity (e.g., Lackner & Graybiel, 1983), and alternating hyper- and hypogravity (e.g., Cohen, 1992). Finally, underwater distortions caused by the air-glass interface of the diver's mask have been the subject of extensive investigation (e.g., Ross, 1971). On the basis of this vast literature on adaptation to sensory rearrangement, one conclusion is certain: Human beings (and a number of other mammalian species) are able to adjust their behavior and, to a lesser extent, their perceptions to any sensory rearrangement to which they are actively exposed, as long as this rearrangement remains essentially constant over the time interval in which systematic feedback is provided. It is important to note that adaptation is not a unitary process, but rather varies greatly in both acquisition rate and magnitude as a function of type of sensory rearrangement and the specific adaptive component (visual, proprioceptive, vestibular-ocular, etc.) under consideration. Furthermore, as mentioned previously, while human subjects are capable of adapting their *behavior* nearly completely to even the most dramatic visual rearrangements, such as 180-degree rotation of the visual field, adaptive changes in *visual perception* often fail to occur (e.g., Snyder & Pronko, 1952). On the other hand, a certain amount of visual adaptation does result from exposure to lesser distortions, such as prismatic displacement (e.g., Craske & Crawshaw, 1978) and curvature of the visual field (e.g., Hay & Pick, 1966).

Since the technological limitations of many VEs create many of the same sensory rearrangements imposed in laboratory experiments examining adaptation, it is reasonable to conclude that procedures that incorporate the variables that have been shown from these experiments to control or facilitate adaptation will be especially useful for the systematic training of VE users. Expediting this adaptive process should, in turn, facilitate task performance and transfer of training to the real-world task (if any) for which the VE is designed. Let us now look at the variables that have been demonstrated to influence or control adaptation to sensory rearrangement and consider how they might be integrated into VE adaptation/training procedures.

5. CONTROLLING AND FACILITATING VARIABLES FOR ADAPTING TO SENSORY REARRANGEMENTS AND THEIR POTENTIAL APPLICABILITY TO VE TRAINING PROCEDURES

5.1 A Stable Rearrangement

As indicated previously, exposure to a sensory rearrangement that is continuously changing in magnitude and/or direction will fail to produce adaptation. This condition is referred to as *disarrangement* and has been shown to have a degrading effect on hand–eye coordination, as seen by an increase in moment-to-moment variability of open-loop target pointing. This conclusion is illustrated by an experiment by Cohen and Held (1960) in which subjects viewed their actively moving hands through prisms whose strength varied continuously from 22 degrees leftward through no displacement to 22 degrees rightward and the reverse, at a rate of one cycle every 2 minutes. Although this experience had no effect on average target-pointing accuracy along the lateral dimension, (i.e., no adaptive shift), it greatly increased the variability of subjects' open-loop target-pointing behavior over repeated attempts. An analogous result has been reported for auditory disarrangement (e.g., Freedman & Pfaff, 1962) as measured by auditory localization errors in the right-left dimension. Another example of disarrangement is the situation in which delays of visual feedback from bodily movements vary from moment to moment, as may occur in some VEs. Visual delays are difficult enough to handle when they are constant over time, but represent a much more serious problem when they are inconsistent or variably asynchronous (e.g., Uliano, Kennedy, & Lambert, 1986).

In summary, sensory disarrangement represents a distortion whose effects cannot be ameliorated by adaptation-training procedures because the basic premise upon which adaptation is based (i.e., the presence of an unchanging sensory rearrangement) does not hold. It would appear, therefore, that VEs that suffer from this problem must await engineering solutions such as more stable position trackers.

5.2 Active Interaction

Given the presence of a stable sensory rearrangement, one can single out five major variables that control or facilitate adaptation. These are (1) active interaction, (2) error-corrective feedback, (3) immediate feedback, (4) incremental exposure to the rearrangement, and (5) the use of distributed practice.

It is generally agreed that the most powerful of all the controlling conditions for adaptation to sensory rearrangement is active interaction with the altered sensory environment, coupled with the visual consequences of these actions (*reafference*). In short, it has been demonstrated that passive exposure to a sensory rearrangement produces little or no adaptation (e.g., Held & Hein, 1958). Exactly why passive exposure is so ineffectual is, however, subject to serious debate (e.g., Welch, 1978, pp. 28–29). One possibility is that active interaction provides the observer with unmistakable information about the sensory rearrangement, which, in turn, initiates and/or catalyzes the adaptive process. For example, because felt limb position is more precise when bodily movement is self-initiated than when controlled by an external force (e.g., Paillard & Brouchon, 1968), the discrepancy between seen and felt limb position can be assumed to be particularly pronounced during active movement, thereby facilitating the adaptive process.

One caveat to the preceding endorsement of active visual–motor behavior as a facilitator of adaptation is that it is necessary that the motor intentions (*efference*) generating these bodily movements actually be in conflict with the resulting reaference. For example, when wearing

prism goggles, subjects' active hand or head movements initially lead to visual consequences (e.g., errors in localizing a visual target) that conflict with those that usually occur. However, their eye movements will not be in error. Thus, although subjects who are wearing prism goggles and instructed to rapidly turn and face a visually perceived object will err in the direction of the prismatic displacement, they will have no difficulty turning their eyes to fixate the perceived locus of the object. The reason that the latter is true is that the prism goggles do not alter the relationship between retinal locus of stimulation and the appropriate fixating eye movements. On the other hand, if the prisms, instead of being attached to goggles, are affixed to contact lenses or are otherwise controlled by eye movements (e.g., White, Shuman, Krantz, Woods, & Kuntz, 1990), the situation is quite different. With this optical arrangement, not only will head movements be in error, but eye movements as well. The results of the few relevant studies using this unusual arrangement (e.g., Festinger, Burnham, Ono, & Bamber, 1967) suggest that observers who are so accoutered are not only able to acquire correct eye movements but also undergo much more visual adaptation to prismatically induced curvature of contours than is the case with traditional prism goggles. Perhaps adaptation to other discrepancies such as altered size and displacement would also be enhanced by such means. Therefore, for VEs that are designed to be controlled by the operator's eyes, it is possible that any visual discordance that may be present will undergo stronger adaptation than that found with VEs that are controlled by head movements (e.g., those involving an HMD).

It is clear from the preceding discussion that to produce substantial adaptation, VE users must be given the opportunity to actively interact with the sensory environment being displayed. This can be a two-edged sword, however, because before active movement can have this beneficial effect on adaptation it may first cause some users to get sick. For example, VEs that create a sense of gravitoinertial force by means of passive transport in a centrifuge or visual flow field are very likely to induce motion sickness symptoms as soon as the user engages in active bodily movements, particularly of the head (e.g., DiZio & Lackner, 1992). In such situations, those participants who cannot tolerate such unpleasant effects may exit the VE before much adaptation has had a chance to occur.

5.3 Error-corrective Feedback

The combination of making errors and then correcting for them when reaching for objects in a rearranged visual environment facilitates adaptation beyond the effect attributable to visual-motor activity alone. For example, Welch (1969) showed that when subjects were allowed to make error-corrective (visually closed-loop) target-pointing responses, they adapted significantly more than when they actively moved the visible hand in the same manner but without visual targets. Although the facilitating effect of error-corrective feedback on adaptation is now well established, it is not sufficient merely that targets are available in the environment. Rather to be most effective, target-pointing responses must be made either ballistically (i.e., so rapidly that their trajectories cannot be altered enroute to the target) or in such a manner that the outcome of a given attempt is not observable until it has reached its goal (often referred to as *terminal exposure*). The latter condition was used in the Welch (1969) experiment. If instead observers are allowed to make slow, visually guided reaching movements (*concurrent exposure*), they will almost certainly "zero in" on the target on each attempt and thus experience little or no error when the hand finally reaches its goal. The fact that concurrent exposure is thus less informative than terminal exposure is almost certainly the reason why adaptation is much greater in the latter condition (e.g., Welch, 1978, pp. 29–31). In sum, it can be concluded that VE exposure should, where possible, entail numerous targets with which to actively interact, together with unambiguous error-corrective feedback from these interactions, preferably at the termination of each response.

5.4 Immediate Sensory Feedback

Delays of motor-sensory feedback represent one of the most serious limitations of current virtual environments. Even with quite short delays, severe behavioral disruption occurs and is not amenable to adaptation as defined here (e.g., Smith & Smith, 1962). Such a state of affairs would seem to argue against the utility of adaptation-training procedures as a means of eliminating this problem. Fortunately, as will be seen below, there are some situations in which the effects of delayed feedback in VEs are not quite so dire.

The initial effects of visual feedback delays are quite different when the vestibular system and other sources of inertial information are involved than when they are not. An example of the first of these situations is when an HMD-wearing subject views the visual field while turning the head whose movements are being monitored by a relatively slow tracking device. Thus, in this situation the opposite sweep of the visual field begins slightly after head movement has begun and continues briefly after it is completed. An example of the second is rapidly moving the hand and seeing its virtual image lagging behind its true position because the refresh rate of the VE cannot keep pace. While the former condition is characterized by visual-spatial instability and possibly symptoms of motion sickness, the latter seriously interferes with hand-eye coordination but does not appear to be nauseogenic (e.g., Held, Efstathiou, & Greene, 1966).

A further complication involves the situation in which a sensory feedback delay is superimposed on a second intersensory rearrangement, such as a discrepancy between felt and seen limb position. In this case the ability to adapt to the latter condition may be severely impeded. For example, Held et al. (1966) showed that visual-motor adaptation to prismatic displacement is greatly reduced or even prevented by delays of visual feedback as short as 120 msec. Because many current VEs are subject to much greater delays than this, it might seem, as Held and Durlach (1993) have argued, that users will be unable to use adaptation to overcome any spatial (or other) discordance that may also be present. Fortunately, however, this pessimistic conclusion appears to be limited to the type of exposure condition typically preferred by Held and his colleagues in which subjects do not reach for specific targets, but merely view their hands as they move them from side to side before a visually homogeneous background. In contrast, it has been demonstrated that when subjects are provided with unambiguous error-corrective feedback from discrete target-pointing responses, substantial adaptation is possible despite the presence of significant visual feedback delays. For example, in an experiment by Rhoades (described by Welch, 1978, p. 105), subjects revealed significant hand-eye adaptation to prismatic displacement even when error-corrective feedback was delayed by as much as 8 sec. Furthermore, considerable adaptation has been reported in a number of published studies (e.g., Welch, 1972) in which for procedural reasons the investigators were forced to institute visual error-corrective feedback delays of up to approximately 1 second.

What, then, can we conclude about the role of sensory feedback delays for VE adaptation? First, visual feedback delays of a second or more seriously disrupt hand-eye coordination, a problem that VE users may, at best, only be able to circumvent by the use of conscious strategies such as deliberately moving very slowly (e.g., Smith & Smith, 1962). Second, if the feedback delay is superimposed on another discordance, such as a discrepancy between seen and felt limb position, and the observer's task does not entail target-pointing responses, not only will visual-motor performance be disturbed but adaptation to the second discordance is likely to be prevented, even for very short visual delays. Finally, if observers are allowed to engage in discrete perceptual-motor responses accompanied by error-corrective feedback, at least some adaptation to the discordance will occur even with feedback delays as long as several seconds.

5.5 Incremental Exposure

Another important variable for adapting to sensory rearrangement, and presumably to VEs, is the provision of incremental (rather than “all-at-once”) exposure. It has been shown that if exposure to prismatic displacement (e.g., Lackner & Lobovits, 1978), optical tilt (e.g., Ebenholtz & Mayer, 1968), and slow-rotating rooms (e.g., Graybiel & Wood, 1969) entails gradual increases in the strength of the discordance, adaptation and/or the elimination of motion sickness symptoms is much greater than if the observer is forced to confront the full-blown sensory rearrangement from the start.

There are several ways in which this variable could be applied to VE adaptation. First, it has been advocated (e.g., Kennedy et al., 1987, p. 48) that aircraft simulator operators begin their training with short “hops” before attempting longer ones. Second, since intense, rapid actions are likely to cause greater delays of visual feedback than mild, slow ones, training should probably begin with the latter. Thus, perhaps by working up slowly to the longer delays, VE users will be better able to acquire the deliberate strategies (e.g., “wait and move”) needed to make such delays more manageable. A third potentially useful form of incremental training would be to gradually increase the size of the FOV for HMD devices, rather than beginning with their maximum size. That is, because it is known that VEs with large FOVs produce better task performance than those with small FOVs but are also more nauseogenic (e.g., Pausch, Crea, & Conway, 1992), gradually increasing the size of the FOV may serve to reduce the simulator sickness symptoms users would otherwise experience and simultaneously improve their performance.

5.6 Distributed Practice

It has been demonstrated that providing periodic rest breaks facilitates adaptation to prismatic displacement (e.g., Cohen, 1974) and/or results in greater retention of prism adaptation (Dewar, 1970). Presumably, then, the same would be true for adaptation to VEs. Indeed, Kennedy, Lane, Berbaum, and Lilienthal (1993) determined that the ideal inter-“hop” interval for “inoculating” users against simulator sickness with respect to the aircraft simulators they examined was 2 to 5 days; shorter or longer intervals resulted in less adaptation. Thus, it appears that VE training should entail some sort of distributed practice regimen, although the ideal profile of “on” and “off” periods will almost certainly vary from one VE to another.

6. THE OPTIMAL ADAPTATION-TRAINING PROCEDURE AND HOW TO COUNTERACT THE DRAWBACKS OF MAXIMAL ADAPTATION

6.1 The Optimal Procedure

Awareness of the critical roles the preceding variables play in perceptual and perceptual-motor adaptation to sensory rearrangement provides a critical basis for the design and implementation of effective VE adaptation-training procedures. Thus, assuming a VE display whose discordance is constant rather than transient or variable, the ideal procedure would appear to entail: (1) providing operators with many opportunities to interact actively with the displayed environment; (2) providing error-corrective feedback and other salient sensory information about the discordance; (3) avoiding, when possible, significant delays of feedback, especially for conditions of continuous exposure that include no error-corrective feedback; (4) gradually

incrementing the length of exposure and/or the magnitude of the discordance; and (5) using a practice regimen that entails frequent rest breaks distributed in an optimal manner.

6.2 Simulations of Naturally Rearranged Sensory Environments

Some VEs are designed (or could be designed) for the express purpose of simulating real-life sensory environments that are by their nature rearranged and to which individuals must adapt if they are to perform appropriately. In other words, for these VEs the presence of a particular intersensory discordance is deliberate rather than an unintended consequence of inadequate technology. An example is a VE designed to simulate the visual–inertial conflicts of hypogravity caused by the absence of the otolithic cues for gravity and used as a means of assisting astronaut trainees to adapt to this environment before actually entering it. This procedure, sometimes referred to as “preflight adaptation training” (PAT), has shown promising results (e.g., Harm & Parker, 1994 and see chap. 32, this volume). Presumably, PAT procedures could be used to generate adaptive immunity to other disruptive sensory environments such as rocking ocean vessels or the underwater visual world as viewed through a diving mask (e.g., Welch, 1978, chap. 12). Another example of a VE that has been deliberately designed to include a sensory rearrangement is that of Viirre, Draper, Gailey, Miller, and Furness (1998). These investigators proposed rehabilitating people who are suffering from chronically low VOR gains by using a VE to expose and adapt them to gradually incremented gain demands. Obviously, all of the facilitating procedures and conditions for adaptation that have been proposed in this chapter should prove useful in helping users adapt to this and any of the other deliberately imposed VE sensory rearrangements.

Alternatively, a VE might be designed to exaggerate an intersensory discordance on the belief that such a “super” discordance will serve a useful purpose. A good example is the magnification of the interaural axes as a potential means of enhancing the localizability of auditory objects (e.g., Durlach & Pang, 1986). It is important to note that with this arrangement one must hope that auditory adaptation does *not* occur because this would mean that observers’ capacity to localize auditory objects had gone from supernormal back to normal, contrary to the aim of the device. On the other hand, it would probably be advantageous if the observers’ *behaviors* (e.g., hand–ear coordination) did recover, presumably by means of adaptation. Otherwise, they might mis-reach for auditory objects, assuming that these responses were open-loop or ballistic. Whether it is possible in this situation to have things both ways remains to be seen.

6.3 Potential Drawbacks of Maximal Adaptation

6.3.1 Negative Aftereffects and Negative Transfer

Implementation of the optimal training procedures prescribed by the principles of adaptation to sensory rearrangement should maximize adaptation to VEs and thus minimize the behavioral difficulties frequently experienced while using these devices. Naturally, in the case of VEs that serve as training devices (e.g., aircraft simulators) it is presumed, or at least hoped, that such adaptation training will also result in improved subsequent performance of the real-world task for which these devices have been designed. However, assuming that in real life this task does not include the intersensory discordances that are experienced in the VE, it is possible to imagine circumstances in which adaptation will actually make things *worse* for the user. Thus, although adaptation to a VE as evidenced by improved behavior and the reduction or elimination of simulator sickness indicates that users have become more comfortable with the device, it is still possible for this adaptation to cause them to be less capable of controlling

the real-life devices they are being trained to use due to the presence of negative aftereffects and/or negative transfer. Obviously, only if the positive effects of training (i.e., generalization to the real-world task) are found to outweigh these potential deleterious consequences should one advocate and use the adaptation training regimens described here. These are, of course, empirical issues whose answers are likely to vary from one VE to another.

The unavoidable price for maximum adaptation is maximum aftereffects. (Note: It is important to distinguish between the aftereffects of exposure to a VE [or to any sensory rearrangement] and a mere perseveration of effects. Only if a particular effect [motion-sickness symptom, hand-eye miscoordination, etc.] has disappeared by the end of the VE exposure period (or perhaps never occurred in the first place), and then reappears [presumably in opposite form] at some time in the postexposure period, is it correct to say that an aftereffect has been observed. It is not accurate, for example, to refer to postexposure malaise as an aftereffect if the subject was experiencing such malaise just before leaving the VE. The reason why this distinction is important is the assumption, held here, that the presence of a true aftereffect is clear evidence that adaptation had occurred to the VE during the exposure period.) The potential danger of delayed "flashbacks" has already been noted. Furthermore, Biocca and Rolland (1998) raise the plausible example of a surgeon who, after using and adapting to a see-through HUD while operating on a human patient, removes the device to continue the operation and makes a serious mistake due to the negative aftereffect. Is there a way to retain the advantages of maximal VE adaptation while simultaneously avoiding its disruptive and potentially dangerous aftermath? Two solutions for ameliorating postexposure aftereffects may be proposed: (1) institute "readaptation" procedures immediately after the user has exited the VE; and (2) create "dual" (or "contingent") adaptation.

6.3.2 Eliminating the Aftereffects

6.3.2.1 "Readaptation" Procedures. It is reasonable to assume that the unlearning of adaptation (i.e., readaptation to the normal sensory world) is controlled and facilitated by the same variables that operate during adaptation to the rearranged world. Given this premise, it follows that the optimal means of abolishing postexposure aftereffects is to require users to engage in the same activities after exiting the VE (i.e., in the absence of the sensory rearrangement) as they did when immersed in it. Studies of adaptation to the "traditional" forms of sensory rearrangement (e.g., prismatic displacement) have shown that postexposure aftereffects dissipate much more rapidly if subjects are allowed to interact actively with the nonrearranged visual world and receive visual feedback from this activity than if they simply sit immobile in the dark or even in a lighted environment (e.g., Welch, 1978, chap. 4). Consider a simulator designed to train people to pilot an oil tanker and which therefore deliberately duplicates the large delay between turning the wheel and the response of the simulated ship that exists for real oil tankers. Clearly, it would be ill-advised for well-trained users after leaving such a simulator to immediately operate an automobile or other vehicle. Rather, one would want to be certain that their presumed training aftereffects had been completely and permanently abolished before allowing them to leave the premises or, if not, to prohibit them from driving vehicles for a prescribed period of time. Reliance on the latter course of action appears to be based on the assumption (or hope) that, as a simple function of time away from the simulator, the aftereffects of training will disappear, either from "decay" or "unlearning/relearning" from random and unspecified perceptual-motor activities (or both). In contrast, the present proposal would have operators again pilot the virtual ship immediately after the simulator training session, but this time with the device arranged such that there is no delay between the user's actions and their visual consequences. Of course, for VEs with intersensory conflicts that cannot be eliminated, the preceding procedure is inappropriate. In the latter case, if subjects

can at least be presented with a real situation that is similar to the one provided by the VE and then required to make the same visual-motor actions (e.g., hand-eye, head-eye) in which they engaged during VE exposure, readaptation should be accelerated.

It is unclear what causes delayed “flashbacks” from aircraft simulator training sessions. However, it is reasonable to assume that these triggers come about because the individual happens to encounter sensory cues in the environment (e.g., the feel of the automobile steering wheel, the lines on the highway) that are similar or identical to those with which certain perceptions were associated during the simulator training session. The great advantage of the unlearning/relearning procedures suggested here is that they are virtually guaranteed to decondition all such cues, whether or not we can identify them. It can be argued, therefore, that this proposed tactic represents a significant improvement over the current strategy for dealing with delayed “flashbacks” in which, pilots are grounded for 12 to 24 hours after an aircraft simulator training session.

6.3.2.2 Creating “Dual”(or “Context-specific”) Adaptation. Adaptation, as evidenced either by its reduction of effects during exposure or its postexposure aftereffects, does not start from scratch each time one makes the transition between one sensory environment and another. Rather, both anecdotal and experimental observations indicate that frequent alternations between adapting to a rearranged sensory environment and readapting to the normal environment lead to decreased interference (e.g., aftereffects) at the point of changeover between the two situations and/or the more rapid reacquisition of the appropriate perceptions and behavior. This phenomenon of adapting separately to two (and perhaps more) mutually conflicting sensory environments has been referred to as *dual adaptation* (e.g., Welch, Bridgeman, Anand, & Brownman, 1993) or *context-specific adaptation* (e.g., Shelhamer, Robinson, & Tan, 1992). An everyday example is adjusting to new prescription lenses in which, after repeatedly donning and doffing their spectacles, wearers report that the depth distortions, illusory visual motion, and behavioral difficulties they had experienced at the outset have now largely disappeared. Thus, as the result of this alternating experience, the presence or absence of the tactual sensations of the spectacles has become the discriminative cue for turning adaptation on or off.

Empirical evidence of dual or context-specific adaptation comes from a variety of sources. For example, it has been observed that those fortunate astronauts and cosmonauts who have gone into space and returned to Earth several times (thus repeatedly adapting to weightlessness and readapting to Earth’s gravity) experience progressively less initial perceptual and perceptual interference when they first enter microgravity (or reenter 1 G) and/or are able to regain normal neurovestibular functioning more rapidly (e.g., Bloomberg, Peters, Smith, Heubner, & Reschke, 1997). Laboratory evidence of dual adaptation for both optically and gravitationally rearranged environments has been reported by, among others, Bingham, Muchinsky, and Romack (1991), Cunningham and Welch (1994), Flook and McGonigle, 1977), McGonigle and Flook (1978), and Welch, Bridgeman, Williams, and Semmler (1998). It is important to understand that individuals who have acquired a dual adaptation do not actually remain adapted during the period between exposures to a given rearrangement, but rather maintain a *readiness* to adapt (or readapt). Thus, this proclivity (or “immunity”) becomes manifest only in the presence of the sensory cues that signal entry into or departure from the sensory environment in question.

The importance of dual adaptation for adaptation to VEs is this: If users are systematically alternated between adapting to a VE and readapting to the normal environment (or to another VE), they should eventually be able to shift from one sensory environment to the other with little or no interference of perception, performance, or physical well-being. It is conceivable that, by means of such alternation training, operators can eventually acquire the ability to interact with a given VE without serious initial difficulty and then return to the normal world with little or no aftereffects. Presumably, the ideal dual adaptation-training regimen would use

as its means of eliminating aftereffects the unlearning/relearning procedures advocated in the preceding section. Finally, the brain's "decision" about the form of adaptation to invoke in a given situation clearly requires the presence of one or more discriminative cues that reliably differentiate the two conditions. Therefore, it will be important for investigators to deliberately provide such cues for the observer and to make them both redundant and salient. Evidence that may outwardly appear to contradict the dual adaptation hypothesis has been reported by Gower et al., 1987, whose subjects revealed increasing, rather than the expected decreasing, postural aftereffects (ataxia) from repeated exposures to an aircraft simulator. Before accepting these data as evidence against the notion of dual adaptation, however, it should be determined if, despite the systematic increase in postexposure ataxia, the rate of readaptation to the normal environment changed. An increase in the latter from one simulator exposure to the next would support the dual adaptation hypothesis. Alternatively, the report by Kennedy and Stanney (1986) of progressively increasing aftereffects might signify that subjects' adaptation was accumulating from one adaptation session to the next, thereby causing the aftereffects to increase as well. According to the dual adaptation hypothesis, however, once adaptation has finally reached asymptote such that further exposures provide little or no increment, the size of the postexposure aftereffects should begin to decline on subsequent exposures, and the rate of readaptation should increase.

7. THE ROLE OF INDIVIDUAL DIFFERENCES

As with all measures of human perception and performance, the acquisition rate and magnitude of adaptation to sensory rearrangement vary widely from person to person (e.g., Welch, 1978, chap. 11). Therefore, it is reasonable to assume that VE users will differ reliably from one another with respect to such things as (1) the detectability of a given discordance; (2) the degree of interference the discordance causes them, and (3) how adaptable they are to it. Little is known about the causes or correlates of individual traits of adaptability.

Clearly, however, the existence of such individual differences in the response to current VEs means that some users will require more adaptation training than others to attain a given level of adaptation. Indeed, it is possible that those individuals who are particularly prone to the deleterious behavioral and perceptual effects of VEs will be the most benefited from adaptation training procedures. Furthermore, because of such individual differences it seems likely that, even after the major problems of current VEs have been overcome by engineering advances, at least some users will continue to register and be reactive to the small sensory and sensorimotor rearrangements that will almost certainly remain. Thus, adaptation training procedures of the sort advocated here will continue to have a place in VE use. However, even when all that is left are these idiosyncrasies, the likely response of the human-factors engineer would be to create a device that modified itself to conform to them, rather than employing the adaptive fine tuning suggested here. A potential problem with this solution, however, is that it entails confronting the user with a changing stimulus condition, which might cause problems of its own (M. Draper, personal communication, May 27, 1998).

8. SUMMARY AND CONCLUSIONS

Until the sensory and intersensory rearrangements that characterize many current VEs are corrected by means of improved design and technology, users will continue to experience disruptive perceptual, behavioral, and physiological effects during and after exposure to these devices. One important means of assisting users to deal with these problems is the application

of training procedures based on well-established principles of perceptual and perceptual-motor adaptation to sensory rearrangement. The flipside of maximal adaptation is maximal aftereffects. However, the latter can be quickly, completely, and perhaps permanently abolished by means of the same procedures and conditions used to produce adaptation in the first place and by the induction of dual (or contingent) adaptation from repeated experience with the VE in question.

There is one serious caveat to the whole undertaking of training VE users to overcome the limitations of their devices. Namely, because it is possible for adaptation to inhibit transfer of training to the subsequent real-world task for which it is being used, it is important to balance carefully the benefits and potential disadvantages of adaptation for transfer of training. Even when engineering advances ultimately eliminate the major sensory and sensorimotor limitations of current VEs, it is likely that the adaptation training procedures proposed here will continue to be necessary as a means of accommodating the idiosyncrasies of the individual user. Finally, it should go without saying that many of the arguments and training procedures proposed here are open to question and thus represent topics for empirical investigation with important implications for the VE community.

1. INTRODUCTION

Cybersickness (a form of motion sickness) induced by exposure to virtual environments (VEs) is one of the most important health and safety issues that may influence the advancement of VE technology (Barfield & Weghorst, 1993; Gross, Yang, & Flynn, 1995; Kalawsky, 1993; Pausch, Crea, & Conway, 1992; Stanney et al., 1998). Research on space motion sickness (Oman, Lichtenberg, & Money, 1990; Reschke et al., 1994; Reschke, Kornilova, Harm, Bloomberg, & Paloski, 1996), and simulator sickness has shed light on the nature of cybersickness (Hettinger, Berbaum, Kennedy, Dunlap, & Nolan, 1990; Kennedy, Jones, Lilienthal, & Harm, 1993a; Pausch et al., 1992). As many as 80% to 95% of individuals exposed to VE systems report some sickness symptoms (Cobb, Nichols, Ramsey, & Wilson, 1999; Kennedy & Stanney, 1997), and 5% to 30% have symptoms severe enough to discontinue VE exposure (DiZio & Lackner, 1997; Wilson, Nichold, & Ramsey, 1995).

A brief history of motion sickness research with emphasis on theories developed to explain the symptomatology is presented in the next section. Section 3 focuses on what is known about the neural pathways and physiological mechanisms involved in the expression of motion sickness. It provides a general overview of the vestibular system, central nervous system (CNS), autonomic nervous system (ANS), and neuroendocrine system involvement in the motion sickness syndrome. Because the ANS plays a prominent role in the physiological expression of motion sickness, a brief review of its functions and characteristics is included as background for discussions in later sections.

Section 4 deals with signs, symptoms, and physiological correlates of motion sickness. The emphasis is on the physiology underlying the “cardinal” signs and symptoms and on measurement techniques. The most commonly measured physiological correlates are described within the context of the general “stress” or “alarm” response. Finally, section 5 provides a review of a variety of methods used in the prevention and treatment of motion sickness.

A number of excellent reviews are available in the literature that offer comprehensive descriptions of the signs, symptoms, and physiological correlates of motion sickness, and provide extensive bibliographies of supporting scientific research (Harm, 1990; Kohl, 1985; Money, Lackner, & Cheung, 1996; Money, 1970; Reason & Brand, 1975; Reschke et al., 1994; Reschke et al., 1996).

2. HISTORICAL BACKGROUND AND THEORIES OF ETIOLOGY

Nearly all definitions of motion sickness include a partial list of the signs and symptoms along with some description of the initiating stimulus, for example, “a condition characterized by pallor, cold sweating, nausea and vomiting that follows upon the perception of certain kinds of real or apparent motion” (Reason & Brand, 1975, p. 1).

“Motion sickness is a clinical diagnostic term implying that certain criteria have been met to ensure validity. Thus, a close temporal order of exposure to “motion” generating stressful accelerations and the appearance either of vomiting or some combination of such cardinal symptoms as nausea, pallor, sweating, increased salivation and drowsiness constitutes, respectively, a pathognomonic or valid diagnosis” (Graybiel, 1969, p. 352).

As far back in time as the ancient Greeks, the father of medicine, Hippocrates, recognized the relationship between motion stimuli and physiological responses as evidenced in his assertion that “sailing on the sea proves that motion disorders the body” (Reason & Brand, 1975, p. 2).

Historically, the evolution of theories to explain the etiology of medical disorders begins with postulations targeting the organ system exhibiting the most salient signs and symptoms as the primary site affected by the causal factor. The development of theories concerning the etiology of motion sickness is no exception (Marti Usaney, 1954). Although only a brief description of the assertions of proponents of the major theories is possible here, there are a number of excellent reviews in the literature that offer more detailed historical accounts of motion sickness theories (Money, 1970; Reason & Brand, 1975; Tyler & Bard, 1949).

Theorists in the 19th century agreed that motion was the causal factor in the malady; however, there was considerable disagreement about which system was most disturbed by it. Based on the reasoning that the systems capable of independent movement should be the primary sites affected by external motion, the circulatory and gastrointestinal systems were the logical candidates. The general class of theories derived from this line of reasoning has been referred to as the “blood and guts” theories (Reason & Brand, 1975).

Two other classes of theories in this time period worth noting were the ANS theories and the vestibular theories. There was a strong tendency during this time to attribute the origin of the symptom of a variety of medical problems to the ANS (Marti Usaney, 1954). Hence, theories that suggested that motion resulted in a shock or concussion to the central ANS, paralyzed the sympathetic nervous system (SNS), or caused peripheral vagus nerve irritation enjoyed some acceptance in the medical and scientific community. The earliest theories providing the foundation for contemporary vestibular etiology theories of motion sickness were, however, largely ignored. Interestingly, the first theoretical contributions outlining the etiological role of the vestibular system in motion sickness (Irwin, 1881) were based on sound scientific evidence from neurophysiological studies, which established the function of the semicircular canals and otoliths. On the other hand, the more popular nonvestibular theories were based on little more than conjecture and speculation. More contemporary theories that have been proposed to explain the etiology of motion sickness include the *sensory conflict theory* (Oman,

1982; Reason & Brand, 1975), the *poison theory* (Money et al., 1996; Treisman, 1977), and the ecological theory (Riccio & Stoffregen, 1991).

Sensory conflict is currently the most widely accepted explanation for the initiation of motion sickness symptoms. The sensory conflict theory of motion sickness advanced by Reason and Brand (1975) best explains motion sickness, and is parsimonious. Briefly, the sensory conflict theory of motion sickness assumes that human orientation in three-dimensional space, under normal gravitational conditions, is based on at least four sensory inputs to the central nervous system. The otolith organs provide information about linear accelerations and tilt relative to the gravity vector; information on angular acceleration is furnished by the semicircular canals; the visual system provides information concerning body orientation with respect to the visual scene; and touch, pressure, and kinesthetic systems supply information about limb and body position. When the environment is altered in such a way that information from the sensory systems is not compatible and does not match previously stored neural patterns, motion sickness may result.

Total reliance on this theory, however, may limit our thinking. Sensory conflict explains everything in general, but little in the specific. Shortcomings of the sensory conflict theory include its lack of predictive power, inability to explain those situations where there is conflict but no sickness, inability to quantify conflict, failure to include sensory-motor conflict, inability to explain specific mechanisms by which conflict actually gives rise to vomiting, and failure to address the observation that adaptation is not possible without conflict.

Treisman (1977) suggested that the purpose of mechanisms underlying motion sickness, from an evolutionary perspective, was not to produce vomiting in response to motion but to remove poisons from the stomach. He believed that motion was simply an artificial stimulus that activated these mechanisms or, more specifically, that provocative motions act on mechanisms designed and developed to respond to minimal physiological disturbances produced by absorbed toxins. According to Treisman, neural activity to coordinate inputs from all the sensory systems in order to control limb and eye movements would be disrupted by the central effects of neurotoxins. Therefore, disruption of this activity by unnatural motions is interpreted as an early indication of the absorption of toxins, which then activates a mechanism to produce vomiting. Expanding on this theory, Money et al. (1996) argue that motion sickness is a poison response, initiated by the vestibular system, with two major phenomena: (1) a stomach emptying response (primarily parasympathetic control); and (2) a stress response (primarily sympathetic control). The vestibular system is involved in regulating the ANS, although the precise manner in which it does so is uncertain (Yates, 1992; Yates & Miller, 1996). One criticism of this theory is that the time required for a toxin to affect central vestibular mechanisms is too long for vomiting to be useful in removing toxins from the gastrointestinal tract, and thus would be one of the last lines of defense against poisoning (Yates, Miller, & Lucot, 1998a).

The ecological theorists argue that motion sickness is caused by prolonged postural instability (Riccio & Stoffregen, 1991) and adamantly reject the sensory conflict theory (Riccio & Stoffregen, 1991; Stoffregen & Riccio, 1991). This theory is based on an ecological approach to perception and action, where the interactions between the animal and environment are the critical unit of analysis. Riccio and Stoffregen (1991) acknowledge that there are changes in sensory stimulation in provocative situations, but argue that these changes are determined by changes in how the environment constrains the control of posture. Further, they argue that the length of time you are unstable and the magnitude of the instability are predictive of motion sickness and the intensity of symptoms. Some limitations of this theory include its inability to fully explain why labyrinthine deficient individuals do not get motion sickness, the lack of potential neurologic pathways or mechanisms involved, and lack of a clear explanation of why postural instability causes motion sickness.

It is clear from the broad differences in these theories and the limitations of the theories to explain all aspects of motion sickness that this is a very complex phenomenon. Both the sensory conflict and the ecological theories emphasize the conditions under which motion sickness occurs, but not the reason for sickness, whereas the poison theory attempts to explain the evolutionary causes. Regardless of the theory to which one subscribes, the conditions that provoke motion sickness involve multimodal sensory information, where the information from all the sensory modalities is not in agreement. Exposure to altered or novel sensory conditions can lead to motion sickness as well as sensorimotor disturbances. The incidence, severity, and primary set of symptoms vary with the sensory conditions to which one is exposed (Kennedy et al., 1993a; McCauley & Sharkey, 1992; Reschke et al., 1994). Hence, different labels have been applied to indicate the provocative conditions, for example, terrestrial, space, simulator sickness, and cybersickness.

Some issues concerning susceptibility and prediction of motion sickness are addressed in chapter 30 (this volume), and countermeasures are presented in chapters 31 and 36 (this volume). These problems are covered in a more general sense in this chapter primarily from the perspective of research methodology and strategies, whereas the physiology of motion sickness is reviewed in somewhat greater detail.

3. NEUROPHYSIOLOGY

Despite the large body of literature containing numerous reports on signs, symptoms, and physiologic correlates of motion sickness, knowledge of the physiologic mechanisms and specific neural pathways involved in the manifestations of this syndrome in humans is still somewhat limited. The high degree of variability reported in the number, order, type, severity, and time-course of physiological responses across individuals and across motion sickness stimulus conditions attests to the fact that incredibly complex interactions among neurophysiological structures, pathways, and mechanisms are involved in the expression of motion sickness. As an indication of the complexity involved, Steele (1968, p. 90) offers the following summary from an earlier report (Rapoport, Horvath, Small, & Fox, 1967):

The vestibular ganglia communicate with 14 specific neural structures having about 2 dozen mutual interconnections. These, in turn, communicate through approximately 120 identified channels to the next level consisting of 44 centers. Thus, going no farther than three steps from the sense organ, and without even considering the visual, auditory, proprioceptive, and other inputs, the system becomes quite unwieldy.

It is, however, widely accepted that the vestibular system is required, and both the CNS and ANS play important roles in the expression of motion sickness.

3.1 Autonomic Nervous System

The ANS is activated by brain stem, hypothalamic, and spinal cord centers. In addition, impulses transmitted from the cerebral cortex and, in particular, from the limbic system affect autonomic activities. More important, some information from various components within spatial orientation systems eventually passes through all or most of the central structures that can activate the ANS. Hence, neural inputs from spatial orientation systems can directly or indirectly influence autonomic activities.

Although it is not within the scope of this chapter to describe the ANS in detail, a basic description of its organization and its functions and characteristics is important for understanding motion sickness symptomatology.

3.1.1 General Organization and Description

The ANS consists of two components, the sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS). Sympathetic pathways exit the CNS from the first thoracic to the third lumbar segments of the spinal cord, whereas parasympathetic pathways exit the CNS in the cranium (cranial nerves 3, 7, 9, and 10) and sacral spinal cord segments 2, 3, and 4. Sympathetic and parasympathetic preganglionic neurons exit the CNS and synapse onto postganglionic neurons that innervate visceral tissues. Sympathetic postganglionic neurons are located near the spinal column and project a distance to their targets, whereas parasympathetic postganglionic neurons lie in or near the tissue they innervate and have short projections. These efferent autonomic pathways innervate smooth muscle, cardiac muscle, and glands. Early researchers restricted their definition of the ANS to the peripheral autonomic nerves and their site of origin. Contemporary definitions of the ANS, however, often include visceral afferents and central neural circuitry (Sved & Ruggiero, 1996).

Sympathetic fibers at the effector site are primarily adrenergic, with norepinephrine (NE) being the major neurotransmitter. Parasympathetic fibers at the effector site are primarily cholinergic with acetylcholine (ACh) being the major neurotransmitter. However, a number of other neurotransmitters and peptides may be secreted by autonomic fibers at the effector. These include adenosine 5'-triphosphate, dopamine, 5-hydroxytryptamine, neuropeptide Y, enkephalin, somatostatin, and others (Money et al., 1996; Sved & Ruggiero, 1996).

3.1.2 Functions and Characteristics of the ANS

The principal function of the ANS is to maintain homeostatic conditions in the body, that is, conditions that provide an optimal internal environment for cellular functioning. Smooth muscle of the viscera and blood vessels, cardiac muscle, and glands are innervated by the ANS. Furthermore, most organs and glands receive fibers from both the sympathetic and parasympathetic divisions of the ANS. Examples of exceptions to this dual innervation feature are blood vessels and sweat glands, which receive fibers only from the SNS.

The SNS is responsible for evoking integrated response patterns that serve to mobilize body energy to prepare the organism and sustain it when there is a demand for physical activity; the parasympathetic nervous system evokes responses that promote digestion and conserve energy. In general, stimulation of the SNS tends to have diffuse physiological effects as compared to the more discrete effects of parasympathetic stimulation. Physiologic consequences of SNS stimulation also tend to be sustained for some time after the stimulus is removed. This is due to the fact that activation of the SNS causes the release of sympathetic neurotransmitters (epinephrine and norepinephrine) from the adrenal medulla, which serve to maintain sympathetic activity. The traditional view of ANS function proposed by Cannon (1939) suggested that the SNS functioned as a unit producing diffuse nonspecific responses, and the PNS produced discrete responses. However, depending on the stimulus and the CNS control center(s) called into play, sympathetic activation can produce changes in some parts of the system without affecting others. It is now known that very specific patterns of SNS activation can occur in response to certain stimuli, and that these patterned responses can include both increases and decreases in sympathetic outflow to specific target organs. Similarly, there are situations where PNS activity is more diffuse (Sved & Ruggiero, 1996). A good example of more discrete SNS effects is seen in thermoregulatory processes. When heat reduction is called for, sympathetic impulses to the cutaneous vasculature are inhibited to promote vasodilation and increased blood flow in the skin, causing heat loss by convection and radiation. Concomitantly, SNS outflow to sweat glands increases, promoting evaporative heat loss.

The SNS and PNS often function in a reciprocal fashion to each other. It should be pointed out, however, that one or the other division usually predominates in the control of a particular

organ system or gland. Hence, stimulation, withdrawal, or inhibition of the efferent neural impulses from CNS control centers to the fibers of the predominant ANS branch can accomplish control over a wide range in the level of activity in a particular structure(s). An additional aspect of this feature is the differential stimulus intensity requirements of the two divisions to produce equal and opposite responses. The stimulus intensity from the nondominant division may have to be many times greater than that from the dominant division in order to produce a reciprocal change of a similar level of organ activity. For example, the PNS predominates in modulating the general activity level of the gastrointestinal tract; stimulation increases tone and motility. Intense SNS stimulation is required to inhibit normal tone and motility. Finally, stimulation of the SNS or PNS can produce either excitatory or inhibitory effects on the activities of the structure(s) they innervate. Whether the effector activity is increased or decreased by stimulation of one or the other branch of the ANS is dependent upon the neurotransmitter-receptor relationship. Most sympathetic postganglionic fibers release norepinephrine onto either alpha or beta adrenergic receptors, whereas parasympathetic postganglionic fibers release acetylcholine (ACh) onto muscarinic cholinergic receptors. An example of differential receptor responses to SNS activation is the regional vasomotor changes that occur in preparation for exercise. Blood vessels dilate in the skeletal muscles, and constrict in the skin and in organs not needed for the increase in physical activity.

The various features or characteristics of the ANS highlight the need to ask certain questions when attempting to interpret physiological responses to motion sickness provocation. Two questions come to mind immediately. The first derives from the characteristic predominance of one division over the other: Is an observed change in some parameter primarily due to modulation of activity within the predominant branch of the ANS or to strong stimulation in the nondominant branch? For example, inhibition of gastrointestinal (G-I) tone and motility could be due to either intense SNS stimulation or to inhibition of normal parasympathetic tone. The second question is related to the reciprocal nature of the two ANS divisions: Does the absence of a change in a physiological parameter indicate no change in autonomic activity, or is it the case, for example, that a reciprocal response in the parasympathetic branch is sufficient to override or resist an increase in the activity of the SNS? In other words, a stimulus activates some mechanism or control system that is effective in maintaining the parameter constant. The arguable point that recurs throughout this chapter is that these kinds of questions cannot be answered on the basis of observations of a single parameter or by examining responses independent of one another.

In summary, various ANS activities are controlled and/or modulated at all levels of the CNS. The specific type and intensity of the demand (stimulus) dictates the level or location of CNS control, which, in turn, dictates the mechanisms activated to accomplish the required physiological adjustments. Mechanisms called into play can range from relatively simple reflexes involving discrete effector sites, to a more complex set of reflex mechanisms involving multiple sites within a system, to incredibly complex patterns of responses involving virtually the entire organism. Given the many levels of neural control and the vast range of potential responses, it should not be surprising that physiological responses and response patterns during motion sickness provocation vary within and across individuals, as well as within and across different motion stimulus conditions.

3.2 Vestibular System and CNS Structures and Pathways

The sensory and CNS structures and pathways involved in motion sickness are described in detail in several recent publications (Kucharczyk, Stewart, & Miller, 1991; Tache & Wingate, 1991; Yates & Miller, 1996). Therefore, only a brief overview of structures and their neural connections involved in the production of motion sickness is presented here.

An intact vestibular system is required for motion sickness to occur. The vestibular end organs (semicircular canals and otoliths) project fibers, differentially, to four vestibular nuclei located in the brain stem approximately at the junction of the medulla and pons: lateral, medial, superior and inferior nuclei. Neural pathways from the vestibular nuclei project to areas in the medulla, the cerebellum (to oculomotor and spinal-motor control systems) and to the cerebral cortex. The vestibular nuclei and the vestibulo-cerebellum receive inputs from other sensory systems (visual, somatic, and proprioceptive) concerned with head-body orientation and movement.

In the 1950s it was believed that certain structures in the vestibulo-cerebellum, the uvula and nodulus, as well as the area postrema (chemoreceptor trigger zone), located in the dorsomedial medulla, were essential for motion induced vomiting. Although more recent work has shown that these areas are not essential (Borison & Borison, 1986; Miller, Nonaka, & Jakus, 1994; Miller & Wilson, 1983), structures in the vestibulo-cerebellum may still be involved in motion-induced vomiting. More recent work indicates that neurons involved in coordinating vomiting are distributed in an arc extending from the area postrema and nucleus tractus solitarius (NTS) through the lateral tegmental field of the reticular formation (RF) to the ventrolateral medulla (Miller & Ruggiero, 1994). Current research suggests that the NTS may serve as the final common pathway for all forms of emetic responses (Sved & Ruggiero, 1996; Yates et al., 1994). Although the NTS receives almost all types of visceral inputs and influences many output systems, the following discussion focuses on those inputs and outputs most relevant to vomiting and motion sickness.

Because most of the signs and symptoms of motion sickness are autonomically mediated, understanding the role of the vestibular system in autonomic regulation is essential to understanding motion sickness. The most direct pathway for vestibular modulation of autonomic responses involved in motion sickness is via projections from the medial and inferior vestibular nuclei to the NTS and the dorsal motor nucleus of the vagus (Sved & Ruggiero, 1996). In addition to vestibular inputs, the NTS receives inputs from other areas that can trigger vomiting, such as the area postrema and abdominal vagal afferents (Sved & Ruggiero, 1996; Yates et al., 1994). Gastrointestinal changes associated with vomiting are probably mediated by projections from the NTS to the dorsal motor nucleus of the vagus and the nucleus ambiguus (Miller & Grelot, 1996). Other motion sickness symptoms may be mediated, in part, through NTS projections to the parabrachial nucleus, which has extensive connections with other autonomic nuclei (Sved & Ruggiero, 1996).

The nucleus tractus solitarius plays an integral role in both gastric motility and emesis related to motion sickness (Ito & Honjo, 1990), and in cardiovascular regulation (Barron & Chokroverty, 1993; Onai, Takayama, & Miura, 1987). The NTS receives ascending carotid, aortic, and cardiopulmonary parasympathetic afferent fibers (Barron & Chokroverty, 1993), as well as fibers from the medial and inferior vestibular nuclei, the cerebellar fastigial nuclei, and certain reticular formation (RF) nuclei (Ito & Honjo, 1990; Onai et al., 1987). The NTS in turn influences (1) vagal efferent output to the stomach and heart (Barron & Chokroverty, 1993; Ito & Honjo, 1990) and (2) the output of certain brain stem RF nuclei that control the peripheral sympathetic nervous system via the intermediolateral cell column of the spinal cord (Barron & Chokroverty, 1993; Previc, 1993; Yates, 1992; Yates, Goto, & Bolton, 1993; Yates & Miller, 1996). Direct connections between the medial vestibular nuclei and brain stem cardiovascular output areas (such as the dorsolateral medullary RF and subretrofacial nuclei—a term mainly used to identify a part of the rostral ventrolateral medulla of the cat) also exist in experimental animals (Yates, 1992) as do otolith-subretrofacial connections (Previc, 1993; Yates et al., 1993). Otolithic inputs into the subretrofacial nucleus are seven times more plentiful than semicircular canal inputs (Previc, 1993; Yates et al., 1993).

Other pathways that may be involved include vestibular projections to the lateral tegmental field of the RF or to the caudal ventrolateral medulla (Yates, 1996). Finally, the cerebellum may be another route through which vestibular inputs may modulate autonomic activity (Balaban, 1996; Wood et al., 1994).

4. SIGNS, SYMPTOMS, AND PHYSIOLOGICAL CORRELATES

Individual reactions to real or apparent motion stimuli are as varied in number and complexity, as are the stimulus conditions that can produce them. With the exception of labyrinthine-defective individuals, anyone can be made sick given an appropriate stimulus of sufficient intensity and duration. Nonetheless, there are some signs and symptoms that occur with a high degree of regularity as part of the syndrome, which are commonly referred to as "cardinal" signs and symptoms, and are considered pathognomonic. These include pallor, cold sweating, nausea, and vomiting. Other reactions to motion stimuli, often referred to as associated or additional signs and symptoms, are much more variable in their occurrence and time course. A partial list includes such things as salivation, headache, drowsiness, dizziness, sensation of increased body temperature, general malaise, apathy and depression, and decreased motor coordination (Harm, 1990; Reason & Brand, 1975). Finally, changes in a wide range of physiological parameters in nearly every major system of the body have been observed during motion sickness provocation.

The following section offers some brief general comments and observations regarding each of the cardinal signs and symptoms, a review of the basic physiology underlying the responses, and techniques used to measure and record signs and symptoms. Physiological correlates are outlined as well. However, the number and variety of physiological parameters that have been examined in motion sickness research precludes reviewing the specific underlying physiology and measurement techniques for individual physiological variables.

4.1 Pallor and Cold Sweating

4.1.1 *General Comments and Observations*

Pallor and cold sweating are generally accepted as antecedents to nausea and often occur in close temporal relationship to early stomach symptoms of epigastric awareness/discomfort. In some motion sick subjects, a brief flushing of the face precedes pallor, and then pallor persists throughout the remainder of the period of motion sickness. Reports concerning the temporal relationships between the onset of cold sweating and subjective reports of stomach awareness or nausea are somewhat more equivocal than those concerning pallor. Some investigators have observed that cold sweating consistently preceded nausea, whereas others found the appearance of cold sweating to be quite variable in time (Reason & Brand, 1975), if it occurred at all. Differences in measurement techniques, ambient temperature and humidity conditions during testing, and the particular motion stimulus account, in part, for the equivocal nature of these findings.

4.1.2 *Physiology of Pallor*

Pallor is defined as a white or whitish-greenish hue to the skin. In motion sickness studies, it is most readily observed in the face; first it appears around the eyes, nose, and mouth (Reason & Brand, 1975) progressing in some individuals to the severe pallor associated with circulatory collapse. Skin color changes, such as pallor or flushing arise from altered vasomotor activity in the cutaneous circulation. Pallor is the result of vasoconstriction, whereas vasodilation produces flushing or reddening of the skin. Neural control of the skin vasculature is exclusively

of sympathetic adrenergic origin; increased sympathetic activity causes vasoconstriction and inhibition or withdrawal of sympathetic activity results in vasodilation. CNS vasomotor control centers are located primarily in the ventral medulla and are in turn controlled by hypothalamic centers. In addition, the hypothalamic centers receive modulating inputs from limbic structures as well as from the cerebral cortex. Facial pallor may also be due, in part, to the increased levels of vasopressin (AVP) during motion sickness (Money et al., 1996). High levels of AVP produce vasoconstriction in the skin (Gilman, Rall, Nies, & Taylor, 1990). Finally, depending upon the type of stimulus, the vasoconstrictor response may be generalized, segmental, or regional (Brobeck, 1979).

4.1.3 Pallor Measurement Techniques

Visual observation techniques (i. e. color photographs; Crampton, 1955) or subjective impressions of discrete levels of pallor (Graybiel, Wood, Miller, & Cramer, 1968) are by far the most common methods of measuring changes in skin color during motion sickness. Three techniques that offer quantitative physiological indices of skin color have been employed in motion sickness provocation studies. Oman and Cook (1983) developed and employed an infrared reflectance plethysmographic technique that provided an index of blood volume in the skin, and Harm et al. (1987a) used transcutaneous oxygen ($P_{tc}O_2$), which provided an index of blood flow as indirect measures of skin color changes. In both studies, these quantitative measures of skin color showed a fairly close temporal relationship with increasing intensity of epigastric/stomach symptoms. However, the investigators observed differences in individual response patterns of skin color changes. Over repeated trials, some subjects consistently showed a transient blush/flush prior to pallor onset, whereas others responded exclusively with either blush or pallor (Oman & Cook, 1983). Harm and colleagues observed similar individual differences in $P_{tc}O_2$; however, the direction of the response depended, to a great extent, on the level of susceptibility in the subjects. Individuals categorized as susceptible exhibited increases in skin oxygen (flushing), whereas those categorized as insusceptible showed decreases in skin oxygen (pallor) throughout the motion test period. A third technique used to measure changes in skin circulation during motion sickness is with a laser Doppler flowmeter (Kolev, Moller, Nilsson, & Tibbling, 1997), which directly measures blood flow, as compared to the indirect measure ($P_{tc}O_2$) used by Harm et al. (1987a).

These techniques share several advantages over visual observation/detection techniques. First, they both offer means for continuous measurement that allows for greater precision in characterizing the time course of physiological changes associated with motion sickness. Second, skin color changes are likely to be detected earlier and more consistently during the development of the motion sickness syndrome than is possible with visual observation. Finally, they have greater potential for yielding physiologically relevant evidence of the underlying mechanisms responsible for motion sickness symptoms.

4.1.4 Physiology of Sweating

“Cold sweating is defined as that which occurs in the absence of an adequate thermal stimulus” (Reason & Brand, 1975, pp. 41–42). The sweat glands activated during cold sweating are termed *eccrine*. Eccrine sweat glands are located in large numbers on the palmar and plantar surfaces, as well as over most of the body. These glands are innervated exclusively by the sympathetic division of the ANS. They receive predominantly cholinergic innervation (the postganglionic synaptic neurotransmitter is ACh, but some adrenergic fibers are also in close proximity (Shields, MacDowell, Fairchild, & Campbell, 1987). Sweating is sometimes considered a parasympathetic response because it is mediated by cholinergic receptors, and because stimulation of CNS structures (premotor cortex and anterior regions of the hypothalamus)

known to produce responses associated with generalized parasympathetic activation also elicit sweating.

Electrodermal or sweating responses measured on the palmar and plantar surfaces are primarily due to psychological stimuli or acute changes in sensory input, whereas responses from other sites (e.g., dorsal hand, forearm, and forehead) are generally due to thermal stimuli. The timing characteristics of responses, such as between palmar and dorsal surfaces, support this notion. Electrodermal responses from the palm usually have a short latency and rapid rise and recovery times indicative of reflexive orienting responses, compared to the longer latency and slow rise and recovery times observed from the dorsal surfaces. In fact, this is precisely what McClure Fregly, Molina, & Greybrel (1971) found in a study using cross-coupled angular accelerations to provoke motion sickness. The palmar response, that is, skin resistance, peaked on the first or second head movement and rapidly declined; the sweat response from the dorsal hand and forearm began later and increased more gradually. The observation that the responses were independent of one another and exhibited different timing characteristics implies activation of different control systems.

A variety of control systems are responsible for modulating electrodermal or sweat gland activity, including the premotor corticospinal system, the hypothalamic-limbic system, and the basal ganglia. Supportive evidence for the existence of multiple control systems having some shared and some independent neural pathways is comprehensively outlined elsewhere (Dawson, Schell, & Filion, 1990; Wang, 1964). More importantly, recognition of the various control systems and their independent neural pathways may provide some information concerning the neural pathways and mechanisms involved in cold sweating manifested as part of the motion sickness syndrome.

4.1.5 Sweat Measurement Techniques

A wide variety of techniques, both subjective and objective, have been used to measure and record cold sweating. Qualitative scores of sweating are derived from either subjective reports offered by the subject or visual observations made by the experimenter (Graybiel et al., 1968). Quantitative assessments of sweat gland activity (or electrodermal activity) include measurements of skin resistance, skin conductance, and skin potential. The most strongly recommended of the three measures is skin conductance (Dawson et al., 1990). Dawson et al. (1990) have suggested that skin conductance level (SCL) and skin conductance responses (SCRs) are the two most sensitive and useful measures. SCL is defined as the tonic level of electrical conductivity of the skin (measurement unit is μmho or μS). SCRs are phasic waves superimposed on the tidal drifts in SCL. Skin conductance responses may occur spontaneously (usually 1–3 per minute in the resting subject), or in response to a specific stimulus. Such things as body movements and sighs also can elicit SCRs. These responses are typically evaluated in terms of their amplitude, frequency, and temporal characteristics (e.g., latency, rise and recovery time, and duration).

The technique used for recording skin conductance uses two electrodes placed on active sites (bipolar), and involves passing a small constant voltage (less than 0.05v) across the skin segment of interest. A resistor is placed in series with this circuit, and the voltage drop across the resistor is equal to the conductance in the segment of interest. The common measurement sites on the hand are between the first and second fingers at the distal or medial segments (volar surface) and between the thenar eminences of the palm.

Interpretation and characterization of electrodermal responses (i.e., latency, amplitude, rise and recovery time, duration, and polarity) depend upon a whole host of factors. These include the measurement site, type of electrode paste, stimulus characteristics, measurement technique selected, environmental conditions, and subject factors. Careful review of the methodological

issues and measurement technique should be carried out before one undertakes recording of sweat responses in motion sickness research (see Dawson et al., 1990; Venables & Christie, 1980, for reviews).

4.2 Nausea and Vomiting

4.2.1 General Comments and Observations

Nausea is undoubtedly the most frequently occurring, and probably the most profoundly unpleasant, symptom of motion sickness. Although the time course and progression of nausea and vomiting varies somewhat with the stimulus conditions, it usually begins with awareness of mild epigastric queasiness and steadily increases in intensity to severe nausea culminating in vomiting. Some individuals, however, will vomit without premonitory nausea, whereas others may experience severe nausea but are unable to vomit. Therefore, the person who vomits during motion provocation tests should not necessarily be considered "sicker" than one who becomes extremely nauseated without vomiting. In motion sickness provocation tests, nausea usually begins to subside immediately upon removal of the stimulus. Depending upon the stimulus intensity and duration, however, stomach symptoms may be completely absent within several minutes or may continue for several hours. A prolonged recovery is often characterized by waxing and waning in the intensity of nausea.

4.2.2 Physiology of Nausea and Vomiting

Nausea is thought to be the awareness of unusual activity in the CNS circuitry involved in vomiting. At least two areas in the cerebral cortex are probably necessary for the sensation of nausea: the inferior frontal gyrus (Roberts, Miller, Rowley, & Kucharczyk, 1994) and the temporofrontal region (Chelen, Kabrisky, & Rogers, 1993). Autonomic visceral afferent inputs to the CNS may contribute to the sensation of nausea but are not required (Miller & Grelot, 1996). In fact, patients with total gastrectomy can still experience nausea (Cummins, 1958), and patients with bulimia can induce vomiting without experiencing nausea. Given that there are situations where nausea occurs without vomiting and vice versa, it seems likely that the two are mediated by different mechanisms. Finally, high levels of AVP also may contribute to nausea. During motion sickness, plasma levels of AVP can increase by as much as 20 to 30 times the baseline levels (Eversmann et al., 1978; Koch, Summy-Long, Bingaman, Sperry, & Stern, 1990; Kohl, Leach, Homick, & LaRochelle, 1983). Administration of AVP to humans is often accompanied by nausea and vomiting (Thomford & Sirinek, 1975), and administration of an AVP antagonist abolished motion-induced vomiting in squirrel monkeys (Cheung, Kohl, Money, & Kinter, 1994). It should be noted, however, that nausea and vomiting can occur in the absence of increased levels of AVP. For example, nausea and vomiting following ingestion of syrup of ipecac (Nussey, Hawthorn, Page, Ang, & Jenking, 1988) and self-induced vomiting in patients with bulimia (Kaye, Gwirtsman, & George, 1989) are not accompanied by increases in AVP.

Vomiting is described as the forceful expulsion of stomach contents through the mouth, and is produced by complex, highly coordinated smooth and somatic motor responses. Visceral smooth muscle changes precede the somatic motor components and include decreased motility of the stomach and small intestine, a retrograde giant contraction (RGC) followed by phasic contractions of the stomach, and small intestine. The RGC moves the contents of the upper small intestine into the stomach, and the phasic contractions move the contents of the lower small intestine into the colon. Neural pathways from the NTS to the dorsal motor nucleus of the vagus and the nucleus ambiguus probably mediate the smooth muscle changes. Somatic motor components of vomiting begin with relaxation of the lower esophagus and movement of the

upper stomach into the thorax, followed by coordinated contraction of the major respiratory muscles (abdominal, diaphragm, external and internal intercostal muscles). The respiratory motor components of vomiting are probably mediated, at least in part, via projections from the NTS to the ventrolateral medulla (see Miller & Grelot, 1996; Money et al., 1996, for reviews). More recent animal research provides strong evidence that the midline medulla plays an essential role in mediating the coordinated respiratory pattern involved in the vomiting process (Billig, Foris, Card, & Yates, 1999; Miller, Nonaka, Jakus, & Yates, 1996; Yates, Smail, Stocker, & Card, 1999).

4.2.3 G-I Response Measurement Techniques

Measurement of gastric symptoms is usually accomplished by having the subject report subjective estimates of stomach upset. One of the most commonly employed rating scales used in laboratory studies is the one incorporated in the Pensacola Diagnostic Criteria for motion sickness susceptibility (Graybiel et al., 1968), where each symptom level is assigned incremental point values. The first level of the scale is epigastric awareness, followed by epigastric discomfort, Nausea 1, 2, and finally Nausea 3 (vomiting). Subjective rating scales for simulator sickness have also been developed (Kennedy, Lane, Berbaum, & Lilenthal, 1993b) and have been used to measure cybersickness (Kennedy et al., 1993a). The simulator sickness questionnaire is described in more detail in chapter 30 (this volume). Other techniques employed in examining changes in gastrointestinal activity associated with motion sickness include radiographic and nuclear medicine techniques (Reid, Grundy, Khan, & Read, 1995; Stewart, Wood, Wood, & Mims, 1994), gastric balloon and intraluminal transducers (Crampton, 1955; Kolev & Altaparmakov, 1996), breath hydrogen to measure mouth to cecal transit time (MCTT) (Muth, Stern, & Koch, 1996), and electrogastrography (EGG); Andre, Muth, Stern, & Leibowitz, 1996; Harm, Sandoz, Stern, Koch, & Koslovskya, 1997; Harm, Stern, & Koch, 1987b; Muth et al., 1996; Stern, Koch, Stewart, & Lindbald, 1987; Stewart et al., 1994). The insertion of gastric balloons, intraluminal transducers, serosal electrodes, and radiographic techniques are not practical for routine use in motion sickness research, whereas EGG has the advantage of being a noninvasive technique, which greatly enhances its practical value. A brief description of EGG is provided below. For the history and a complete review of EGG, the interested reader is directed to the recent text by Chen and McCallum (1994) on the topic.

Electrogastrography is a technique for recording myoelectric activity of the stomach using surface electrodes and was first identified by Alvarez (1922). In humans, gastric smooth muscle pacemaker potentials oscillate around a frequency of 3 cpm (0.05 Hz), with an amplitude of 100 to 500 μ V. Pacemaker potentials are propagated across the stomach from the antrum toward the pylorus. Gastric myoelectric activity is generally referred to as the basic electrical rhythm (BER) (Harm et al., 1987b; Rague & Oman, 1987) or electrical control activity (Harm et al., 1987b; Rague & Oman, 1987). Gastric myoelectric activity is responsible for coordinating stomach contractions and regulating gastric emptying. Gastric arrhythmias, including tachygastria (fast frequency waves), bradystimulation (slow frequency waves), and dysrhythmias (no clear frequency peak) also can be detected accurately by EGG (Familoni, Abell, & Bowes, 1995). Gastric motility is mediated by both the sympathetic and parasympathetic branches of the ANS. Increased vagal (parasympathetic) activity augments gastric motility (Fujii & Mukai, 1985), whereas increased sympathetic activity or vagal withdrawal decreases gastric motility (Hall, El-Sharkawy, & Diamant, 1986).

The frequency and amplitude of the EGG have been studied in conjunction with measures of gastric motility. Chen et al. (1994) simultaneously recorded EGG and manometric activities of the distal stomach and upper small bowel in healthy subjects under fasted and fed conditions.

They observed that peak EGG power during the postprandial period was significantly greater than during motor quiescence in the fasted period, the dominant frequency was significantly higher during the postprandial period compared to periods of motor activity in the fasted state, and the instability coefficient of EGG power (ratio of the standard deviation to the mean value) was significantly higher during motor activity in the fasted state versus motor quiescence in the fasted state. Interestingly, a 1 cpm wave superimposed on the normal 3 cpm rhythm was noted in the power spectrum of the postprandial EGG. This low-frequency component was highly associated with intestinal contractions (Chen, McCallum, & Richards, 1993).

The EGG has been employed in studies of motion sickness induced by circularvection (Muth et al., 1996; Muth, Thayer, Stern, Friedman, & Drake, 1998; Stern et al., 1987), linearvection (Harm & Parker, 1994), cross-coupled Coriolis stimulation (Rague & Oman, 1987; Stewart, Wood, & Wood, 1989; Stewart et al., 1994), parabolic flight maneuvers (Harm et al., 1987b) and space flight (Harm et al., 1997). In these studies, gastric motion sickness symptoms were associated with the appearance of tachygastria and/or a decrease in the amplitude of the BER. In many instances of reduced amplitude, the reduction emerged before subjects reported awareness of any level of stomach symptoms. In a recent motion sickness adaptation study, tachygastria was associated with a subject's reports of stomach symptoms. This subject's gastric electrical rhythms gradually returned to the normal BER over several days of adaptation to the stimulus conditions (Harm & Parker, 1994).

4.3 Physiological Correlates

Physiological reactions to motion sickness provocation stimuli can, and often do, occur in nearly every system of the body. Most of the research in this area has been directed toward either identifying parameters that can be used to discriminate among susceptible and insusceptible individuals, or characterizing changes in physiological response variables. Although there are reports of statistically significant differences in a variety of physiological parameters as a function of susceptibility, investigators tend to interpret their findings with some caution because considerable variability is often observed within susceptibility categories. The reliability of physiologic correlates across repeated motion sickness tests was recently examined (Stout, Toscano, & Cowings, 1995). The results of this study suggested that autonomic responses measured during the last minute of the motion sickness test were moderately stable across repeated tests. A large number of physiological parameters in the cardiovascular, respiratory, gastrointestinal, and neuroendocrine systems have been examined during a variety of motion sickness provocation testing conditions. The most frequently measured parameters in each of these physiological systems, along with a few interesting but less common parameters, are outlined in Table 32.1.

At present there is no unifying hypothesis that explains all of the physiological manifestations of motion sickness. Most researchers would probably agree, however, that the motion sickness syndrome has many of the components characteristic of "stress" or "alarm" response patterns described in medical physiology textbooks. Most would also agree that this characterization of motion sickness is limited and should be viewed with some caution. It is applicable primarily to acute (short-duration) forms of laboratory-induced motion sickness or to the early stages of chronic (long-duration) forms before adaptive processes begin to exert their influence on physiological activities (see chap. 31, this volume). Moreover, it does not explain individual differences in specific physiological responses, nor does it explain some interesting paradoxical findings in the neuroendocrine literature. Before describing this research, some of the primary components of the "stress" response are presented.

The "stress" response consists of a generalized activation of the sympathetic nervous system that includes: (1) stimulation of the adrenal medulla to increase secretion of epinephrine and

TABLE 32.1
Physiological Correlates of Motion Sickness

Physiological System	Parameters
Cardiovascular	Electrocardiogram, heart rate, cardiac interbeat interval, blood pressure, blood volume pulse, muscle blood flow, and skin blood flow, volume, and oxygen
Respiratory	Volume, rate and carbon dioxide
Gastrointestinal	Tonus, motility, and electrogastrogram, and mouth to cecal transit time
Neuroendocrine	<i>Adrenal factors:</i> steroid hormones and catecholamines. <i>Anterior pituitary factors:</i> GH, TSH, ACTH, FSH, LH, and prolactin. <i>Posterior pituitary factors:</i> ADH/AVP
Other	Skin conductance, dark focus, and pupil responses

norepinephrine; (2) stimulation of the posterior and anterior pituitary gland (via hypothalamic input) to increase secretion of antidiuretic hormone or vasopressin (ADH or AVP, respectively), and adrenocorticotropin (ACTH), respectively (ACTH subsequently causes release of adrenocortical hormones such as cortisol); (3) redistribution of blood away from peripheral tissues and nonparticipating organs to skeletal muscle; and (4) stimulation of respiration to increase oxygen delivery and carbon dioxide removal. Admittedly, this is an oversimplified description of the “stress” response, but it should be adequate background for understanding the physiological stress responses already described (pallor, cold sweating, and neuroendocrine responses) and those presented next.

Real or apparent stressful motion activates the neuroendocrine system. Neurohumoral substances released by some CNS structures and subsequently by the various endocrine glands are responsible for regulating metabolic activity to meet the demands placed on the body. Observations of elevated levels of stress-related neuroendocrine hormones (Eversmann et al., 1978; Kohl, 1985) indicate the hypothalamus-pituitary-adrenal cortex (H-P-A) axis plays a role in the expression of motion sickness. The general neuroendocrine response to stressful motion and sensory-rearrangements includes elevated levels of ACTH, cortisol, prolactin, growth hormone, ADH or AVP, thyroid hormone, epinephrine, and norepinephrine (see Reschke et al., 1994; Reschke et al., 1996, for reviews). Stimulation of the hypothalamus initiates the release of pituitary hormones via its hormonal and neural connections with the pituitary gland. The anterior pituitary gland releases ACTH, prolactin, and growth hormone, as well as others. The posterior pituitary gland releases ADH. ACTH, in turn, stimulates the release of a variety of hormonal substances from the adrenal cortex (e.g., cortisol). More detailed descriptions of the H-P-A axis and endocrine responses to stress are available in standard medical physiology texts.

A number of investigators have found correlations between susceptibility to motion sickness and endogenous levels of neurohumoral substances. Differences between susceptibility subgroups and neuroendocrine responses to motion sickness stimulus conditions have also been observed. Kohl (1985) found those individuals resistant to motion sickness had higher endogenous levels of ACTH and exhibited higher levels of ACTH, epinephrine, and norepinephrine in response to motion sickness provocation. This finding led to the hypothesis that less susceptible individuals are better able to resolve sensory conflicts because the

higher endogenous levels and higher responsivity of their endocrine systems make them more adaptable. In contrast, Eversmann et al. (1978) noted that subjects with additional symptoms (e.g., sweating, pallor) exhibited higher hormonal levels than those with vomiting/retching alone and proposed that increased hormonal secretion could be related to symptom severity. Grigoriev et al. (1988) found that hormonal levels in moderately susceptible subjects peaked immediately after rotation ceased, and those of more susceptible subjects peaked later. This group proposed that the stress of rotation stimulates an adequate hormonal response in moderately susceptible individuals (resulting in adaptation), whereas highly susceptible subjects experience a delayed adaptation response, CNS excitation, or both after the stimulus is terminated.

Generally, cardiovascular responses during motion sickness are consistent with a stress response. Decreased peripheral circulation is manifested in the cardinal sign of facial pallor, which was described in detail earlier. Increased skeletal muscle blood flow has been observed in cases of moderate to severe motion sickness. Skeletal muscle blood flow is most often measured in the forearm using a technique called venous occlusion plethysmography. In this technique, a pressure cuff blocks venous return, and the rate of swelling in the arm is the measure used to estimate blood flow. The rate of blood flow through the arm can increase two to three times in motion sick subjects and is generally correlated with symptom severity (Sunahara, Farewell, Mintz, & Johnson, 1987; Sunahara, Johnson, & Taylor, 1964).

The most commonly measured cardiovascular correlates of motion sickness are heart rate (HR), blood pressure (BP) and cardiac interbeat interval (R-R interval). Heart rate and blood pressure responses associated with motion sickness are, however, typically smaller than those seen in other conditions that produce a stress response, and they can increase, decrease, or stay the same (see Harm, 1990; Money et al., 1996, for reviews). The high levels of plasma AVP produced during motion sickness may partially counteract HR and BP increases normally exhibited as part of the stress response. Intravenous administration of high doses of AVP causes decreases in heart rate and blood pressure (Thomford & Sirinek, 1975). Also, the decrease in cutaneous blood flow and the increase in skeletal muscle blood flow that occurs with motion sickness may serve to stabilize or minimize BP changes during motion sickness (Money et al., 1996). The variability reported in the direction of changes in HR and BP can be due to a number of factors, including individual differences in responses to motion sickness, the specific stimulus conditions (duration, intensity, type of sensory conflict), and/or the severity of motion sickness at test termination.

Beat-by-beat variations in heart rate are mediated by both branches of the ANS. Spectral analyses of the frequency components of R-R interval data have identified three frequency bands that contribute to these variations. The higher of the three frequency bands is related to respiratory frequency. Respiratory frequency oscillations, often referred to as respiratory sinus arrhythmia (RSA), reflect parasympathetic vagal activity (Berger & Cohen, 1987; Chen, Berger, Saul, Stevenson, & Cohen, 1987). These changes in parasympathetic activity cause increases in the spectral power of the respiratory frequency band, which increases the overall R-R interval variability. The potential utility of cardiac variability as a measure of motion sickness severity was demonstrated in squirrel monkeys (Ishii, Igarashi, Patel, Himi, & Kulecz, 1987), where increased cardiac variability was related positively to symptom severity. In studies using a circularvection drum to induce motion sickness symptoms, Uijtdehaage, Stern, and Koch (1992) observed decreases in RSA during drum exposure. In addition, they found that higher levels of vagal tone (higher levels of RSA) prior to drum rotation predicted a low incidence of motion sickness symptoms and were associated positively with normal 3 cpm gastric BER. In a subsequent study, these investigators found that RSA level prior to drum rotation correctly predicted sickness level during the test in 76.7% of the subjects (significantly better than chance) with higher levels of vagal tone predicting fewer symptoms (Uijtdehaage,

Stern, & Koch, 1993). Other investigators also have found decreases in R-R interval responses during motion sickness (Doweck et al., 1997; Hu, Grant, Stern, & Koch, 1991), whereas another group found no change in heart rate variability during motion sickness (Mullen, Berger, Oman, & Cohen, 1998).

Directional differences in HR variability reported across the studies just described may be due to differences in: individual responses, stimulus conditions, severity of motion sickness, the specific measure of variability employed, and/or the methodology used for measuring and analyzing HR variability. Respiratory rate and volume contribute to HR variability. Studies that control respiratory rate and volume during HR measurement periods may show different results than those that do not control these respiratory factors. In addition, different measures of HR variability are used including the coefficient of variance ($CV = \text{standard deviation}/\text{mean}$), spectral power of the high-frequency band (RSA), total spectral power, or the ratio of low- to high-frequency power. Several reviews of R-R interval neurophysiology and measurement and analysis techniques are available (see Gottman, 1990; Kitney & Rompelman, 1980; Papillo & Shapiro, 1990; Porges & Bohrer, 1990).

Intuitively, one would expect a susceptible individual to exhibit the various signs, symptoms, and autonomic manifestations as well as higher levels of catecholamines and adrenocortical hormones than an insusceptible person. Although limited, the current findings indicate that while insusceptible individuals do not exhibit the usual symptom complex, their baseline values of neuroendocrine measures and the increase in these values during motion stimulation are higher than susceptible subjects. Kohl (1985, p. 1162) argues that "individuals possessing lower susceptibilities to stressful motion are more adaptive to environmental stressors or sensory conflicts by virtue of their higher baseline levels or activity of certain specific endocrine components, and particularly by the greater responsivity of these endocrine systems." Findings in studies concerned with physiological correlates, although limited, also indicate that insusceptibles show evidence of higher levels of sympathetic activation (elevated heart rate, cutaneous vasoconstriction), and earlier onset during motion sickness provocation than susceptibles (Cowings, Suter, Toscano, Kamiya, & Naifeh, 1986; Harm et al., 1987a). The neuropharmacological research concerned with motion sickness indicates that a combination of sympathomimetic and anticholinergic agents is more effective in preventing or reducing motion sickness symptomatology than either type of agent alone. These findings tend to support the notion that SNS activation provides some protection against motion sickness.

5. PREVENTION AND TREATMENT

By far, the most common method of preventing and treating motion sickness is the administration of medications. Other methods include biofeedback training, acupressure and acustimulation, and adaptation procedures. Adaptation and other techniques for managing cybersickness are dealt with in more detail in chapters 30, 31, and 36 (this volume).

5.1 Pharmacologic Agents

Many drugs have been tested for their effectiveness against motion sickness. Although some drugs have proven somewhat effective, no drug or drug combination has been identified that protects all individuals. In ranking drugs with respect to their effectiveness in preventing symptoms of motion sickness, Wood and Graybiel (1970) found that the drugs tended to be grouped according to their principal pharmacological action. The major classes of drugs that have been used in the treatment of motion sickness are anticholinergics (parasympatholytics), antihistamines, sympathomimetics, and sympatholytics. Medications from these classes have

been evaluated for their effectiveness when given alone and when given together in various combinations. Antimotion sickness drug research has been reviewed extensively by Reschke et al. (1994), Wood (1979, 1990), and Yates, Miller, & Lucot (1998b).

Currently, the most effective antimotion sickness medications are scopolamine and promethazine, and both of these in combination with sympathomimetics (e.g., ephedrine and D-amphetamine). The most effective over-the-counter medication is Dramamine (Miller & Grelot, 1996). Numerous studies have found scopolamine, an anticholinergic (parasympatholytic) drug, to be effective in treating motion sickness (Graybiel & Lackner, 1987; Wood, 1990; Wood & Graybiel, 1968). Although most of the antihistamines tested for antimotion sickness properties have had some benefit, they generally provide less protection than scopolamine. Promethazine, the most effective of the antihistamines (that has the strongest central anticholinergic action of the antihistamines), approaches scopolamine in efficacy (Graybiel & Lackner, 1987), and is currently the drug of choice for treating space motion sickness (Davis, Jennings, Beck, & Bagian, 1993b; Miller & Grelot, 1996). The few sympatholytic drugs that are effective against motion sickness were found to have only marginal benefit and had less effect than the least effective antihistamine (Wood & Graybiel, 1970).

The ability of sympathomimetic drugs to prevent motion sickness was first discovered when amphetamine was combined with scopolamine to counteract the sedation caused by the latter. Experimental control subjects taking amphetamine alone also exhibited increased tolerance to motion (Wood & Graybiel, 1970). Wood and Graybiel (1970) found that combining a parasympatholytic drug (scopolamine) with a sympathomimetic produced either an additive effect (ephedrine) or a synergistic effect (amphetamine). These combinations were far more effective than any single drug. The combination of promethazine and ephedrine has also been found to be very effective in treating motion sickness (Wood, 1979).

Two newer classes of antiemetic drugs, 5HT3 and NK1 receptor antagonists, may be promising candidates for the treatment of motion sickness (Gardner et al., 1995; Koch, Xu, Bingaman, et al., 1994). The 5HT3 receptor antagonist drugs have been shown to be effective in treating nausea and vomiting associated with chemotherapy, anesthesia, and radiation (Fujii, Toyooka, & Tanaka, 1996; Kovac et al., 1996; Lehoczky, 1999). One drug in this class, ondansetron, was found ineffective in preventing motion sickness in humans in one study (Stott, Barnes, Wright, & Ruddock, 1989) but produced a small but significant improvement in resistance to motion sickness in another study (Koch et al., 1994). The drug was administered orally in the first study and intravenously in the second study. Additional research is needed to evaluate other medications in this class and to determine if higher dosages will be effective in treating motion sickness. The NK1 receptor antagonist drugs produce more broad-spectrum antiemetic activity than the 5HT3 antagonists do. Thus far, most of the research using this class of drugs has been done with animal models with one exception (Diemunsch et al., 1999). Although no studies have examined the effectiveness of NK1 receptor antagonists in preventing motion sickness in humans, Gardner et al. (1995) found an NK1 receptor antagonist was effective in preventing motion sickness in monkeys. A major advantage of these two classes of drugs is that they do not produce central nervous system depressant effects or degraded cognitive and psychomotor performance (Benline, French, & Poole, 1997).

5.1.1 *Mechanisms of Action*

Given that the neural circuitry involved in motion sickness is not known, it is not surprising that the specific mechanism(s) of action of the effective antimotion sickness drugs is also unknown. However, a number of investigators have offered some general explanations, particularly for the effectiveness of the drug combinations. Motion sickness symptoms include both parasympathetic and sympathetic reactions (Money et al., 1996; Wood & Graybiel, 1972).

Wood and Graybiel (1972) postulated that exposure to stressful motion activates neurons in the central nervous system that respond to acetylcholine while simultaneously activating norepinephrine neurons. The enhanced effect of anticholinergic/sympathomimetic combinations would stem from paired cholinergic-blocking activity and norepinephrine activation. This explanation suggests a general nonspecific drug action on the ANS. Alternatively, the site of action of antimotion sickness medications may be in the vestibular nuclei (Yates et al., 1998b). The vestibular nuclei contain a number of the types of receptors acted on by antimotion sickness medications (Yates et al., 1998b). The site of action of broad-spectrum antiemetics is presumed to be somewhere in the final common pathway for vomiting. If this is the case, these drugs may not be effective against the nausea and autonomic symptoms of motion sickness.

In addition to the lack of knowledge of the neural circuitry involved in motion sickness, mechanisms of action of antimotion sickness medications are difficult to determine for several reasons. First, much of the research in this area is carried out on animals. There are considerable interspecies differences in responsiveness to different medications, and hence, results from this work may not generalize to humans. In addition, some drugs in a given class are effective, whereas others are not. Similarly, different drug combinations from the same two drug classes have varying degrees of effectiveness. For the interested reader, Yates et al. (1998b) recently published an excellent review of the pharmacology of motion sickness.

5.1.2 Routes of Administration

The vast majority of antimotion sickness drugs have been administered orally. Because the duration of action of these drugs is typically brief, frequent dosing is needed if the motion is expected to last for extended periods. An additional complication of oral medications is the reduction in gastric motility characteristic of acute motion sickness (Wood, Wood, Manno, Manno, & Redetzki, 1987); drugs must be given prophylactically to avoid decreases in drug absorption. For this reason, alternate routes of administration, such as transdermal application (Homick, Kohl, Reschke, Degioanni, & Cintron-Trevino, 1983; Levy & Rapaport, 1985; McCauley, Royal, Shaw, & Schmitt, 1979), suppositories (Davis et al., 1993a), and intramuscular injections (Davis et al., 1993b; Graybiel & Lackner, 1987) have been investigated. Another factor complicating the search for motion sickness remedies is the occurrence of side effects, which can preclude using the most effective dose or dosing schedule.

5.2 Biofeedback and Autogenic Feedback Training

In biofeedback training, instrumental information about selected autonomic activities is provided to the subject with a visual or auditory “reward” presented for producing the desired response (e.g., decreased heart rate). Autogenic training employs a collection of cognitive imagery techniques to produce the desired change in autonomic activity. Self-suggestion exercises are utilized to produce certain body sensations that correspond to the desired changes in physical parameters. Autogenic feedback training (AFT) combines the above techniques. Cognitive imagery is used to produce the desired changes with immediate sensory feedback on success via instrumental readouts (Cowings, 1990).

The basic rationale underlying the use of biofeedback or autogenic feedback training is that since the symptoms of motion sickness are autonomically mediated, self-regulation of ANS responses should lead to reduced symptoms during motion sickness-provoking situations. Cowings argues that nausea and vomiting are parasympathetic reactions to sympathetic activation. If so, then motion sickness symptoms should be prevented by training an individual to maintain his or her autonomic responses at baseline levels. Furthermore, since the perception of vestibular stimulation is unchanged by AFT, this type of training must interrupt the

autonomic response after the sensory conflict has already occurred (Cowings, 1990). Raising the threshold for autonomic activation may inhibit development of motion sickness symptoms induced by sensory conflict (Cowings & Toscano, 1982).

More recent investigations, however, have found that autogenic feedback training is ineffective in reducing motion sickness symptoms (Dobie, May, Fischer, Elder, & Kubitz, 1987; Jozsvai & Pigeau, 1996). Jozsvai and Pigeau (1996) examined Coriolis-induced motion sickness severity and motion tolerance in three groups of subjects: (1) autogenic training plus true feedback; (2) autogenic training plus false feedback; and (3) a control group that received no treatment. These investigators found no differences between the two treatment groups in self-regulation of autonomic responses and no relationship between self-regulation ability and sickness severity or motion tolerance. Moreover, these authors suggest that treatment gains reported by others may result from placebo effect. The issue of biofeedback versus placebo effects is discussed in greater detail elsewhere (Furedy, 1985).

5.3 Electrostimulation and Acupressure

The use of electrical currents in the treatment of motion sickness has also been explored. Electroanalgesia or electrotranquilization uses two electrodes, one placed on the forehead and the other in the area of the mastoid process. Melnik et al. (1986) increased the current until the subject reported a sensation of warmth in the area of the electrodes with a session length of 30 to 60 minutes. Nekhayev, Vlasov, & Ivanov (1986) and Polyakov (1987) used a pulsed current during sessions lasting an hour. Electroanalgesia did not increase resistance to experimentally induced motion sickness when sessions were performed before stressful motion (Melnik et al., 1986; Polyakov, 1987). However, sessions conducted between two motion stressor tests reduced or eliminated the residual motion sickness symptoms from the first test (Melnik et al., 1986; Nekhayev et al., 1986) and increased tolerance to the motion sickness test performed following the electroanalgesia session (Melnik et al., 1986; Nekhayev et al., 1986; Polyakov, 1987). A second session of electroanalgesia following the second motion stressor test also improved recovery from symptoms induced by that test.

Ivanov and Smitko (1985) observed that motion sickness affected the conductivity along the standard acupuncture pathways regardless of symptom severity. Electroacupuncture was used successfully by this group to treat seasickness. Others have found electrical acustimulation and acupressure to be effective in reducingvection-induced nausea (Hu, Stern, & Koch, 1992; Hu, Stritzel, Chandler, & Stern, 1995). Acustimulation may work by enhancing the normal slow wave myoelectrical activity of the stomach (Lin et al., 1997). Subthreshold multichannel electrical stimulation of the antigravity group of cervical muscles has also been reported to achieve promising results as a countermeasure against motion sickness (Matveyev, 1987). Although electrical devices are reported to be an effective countermeasure to several forms of terrestrial motion sickness, they have not been tested as a countermeasure for cybersickness.

6. SUMMARY

Motion sickness induced by exposure to virtual environments may be a key factor in limiting widespread use of VE technology. As many as 30% of individuals exposed to VE systems have symptoms severe enough to discontinue use. Several theories have been proposed to explain the etiology of motion sickness; however, none can fully account for this complex malady. One reason for the lack of a more comprehensive theory is that the neural circuitry and mechanisms involved in motion sickness in humans is unknown. It is accepted that an intact vestibular system is required for motion sickness to occur and that there are both direct and

indirect pathways from the vestibular nuclei to ANS centers that mediate many of the signs, symptoms, and physiologic correlates of motion sickness. Certain areas in the cerebral cortex are probably necessary for the sensation of nausea, and the NTS is believed to be the final common pathway for the vomiting response, regardless of its cause.

The most common method of preventing and treating motion sickness is the administration of medications. There are a number of drugs and drug combinations that are effective in treating motion sickness, although the specific mechanisms of action are unknown. Many of the more effective medications have a sedative effect, which raises concerns about safety and performance. Newer classes of drugs that hold promise in preventing and treating motion sickness without sedative effects still need to be evaluated more extensively in clinical trials. Other methods of preventing and treating motion sickness include biofeedback, acupressure and acustimulation, and adaptation techniques.

7. ACKNOWLEDGMENTS

I would like to thank all the reviewers for their thoughtful comments and suggestions, and express a special thanks to Dr. Bill Yates for his critical inputs to the neuroanatomy and neurophysiology sections.

1. INTRODUCTION

Alan Alda, an actor, throws a ball for Silas, the dog. Silas chases the ball and returns it to Alda who throws it for him again. Alda shifts his attention to the pet hamster, and Silas acts jealous. Alda scolds Silas and sends him to the other room for punishment. Silas then slinks away.

—(Calvert, 1999a, p. 236)

Although Silas acts just like every other dog, he is not real. Silas is a virtual dog, programmed by Dr. Bruce Blumberg at the MIT Media Lab. Blumberg has been careful to program Silas to have the needs that other dogs have. Silas has about a dozen goals and motivations that he tries to satisfy (Blumberg, 1996). Autonomous agents like Silas T. Dog bring us one step closer in the quest for realistic, three-dimensional (3-D) virtual environments (VEs).

How will time spent in such VEs impact social skills? Will people better understand their real pets? Will something innately human be changed if people choose a virtual pet rather than a real one? Silas does not have to be walked (unless you feel like walking him), nor does he chew up your favorite shoes. He can provide company during the user's free time. But he is not a real dog either. Can Silas ever become man's best friend? Would watching Silas on television be any different from interacting with him in a virtual environment?

How will virtual experiences affect social relationships and social behaviors with people both inside virtual reality (VR) and outside in real life? Online spouses and friends are already part of the changing landscape of representational experiences (Turkle, 1995), and televised depictions of families have long been a staple of entertainment programming. Can virtual relationships substitute for, or supplement, face-to-face relationships, or will people feel lonely and isolated?

Who will people be in the information age? What will identities be like when people are no longer constrained by a physical body, when they are free to embody themselves in diverse

characters and develop multiple facets of their identities? How will virtual actions impact real behavior?

Currently, there is limited empirical literature in the VE area to address these questions. Because media issues tend to recur (Calvert, 1999a), three primary sources of information will be examined in this chapter: (1) studies in virtual environments; (2) studies about the Internet; and (3) studies about television. Because VEs will be delivered across the Internet in the future (see chap. 16, this volume), current and future Internet social interactions are particularly germane to this review. Even so, answers to questions about the social impact of VE are preliminary and require additional empirical investigations.

2. THE FORM AND CONTENT OF INFORMATION TECHNOLOGIES

Knowledge is transmitted and must be decoded in all media experiences, including virtual environments. Like other technologies before it, VE simulations are comprised of both content and form. Content has to do with domains such as aggression, sexuality, prosocial behavior, and fantasy. Form has to do with the unique representational codes that are used to present content (Huston & Wright, 1998). More specifically, form refers to audiovisual production features, such as action, sound effects, and dialogue, that structure, mark, and represent various kinds of content (Calvert, 1999a). Virtual environments add interactive capabilities and a first-person perspective to early media experiences such as television.

2.1 The Form of Information Technologies

The world is a rich stream of changing visual, auditory, tactile, and olfactory sensations. The form of VE simulations reflects an ongoing evolution in the symbolic codes that are used to represent media experiences. More specifically, there has been a shift from the auditory spoken and written codes of the telephone, radio, and books to the audiovisual codes of television and the World Wide Web. With the Internet, particularly the World Wide Web, users can interact with visual and audio messages. Although embodied VE simulations will expand these representational experiences into olfactory and tactile modes of expression, VE currently relies on the visual system more than other sensory systems (Schroeder, 1996). Auditory dimensions are not that different from previous applications in the film, television, and video game areas. Virtual environments are unique in allowing users a first-person interaction with 3-D visual images in immersive environments.

In examining the impact of media on man, McLuhan (1964) argued that television was unique in its form, not its content. This statement is true of other media as well. Take, for instance, the incident where two Colorado adolescent boys killed their classmates, teachers, and themselves. Playing the video game Doom was implicated as one source of their antisocial acts. Apparently they learned a particular style of killing by playing this game. Perhaps they could have learned similar behaviors from reading books, newspapers, or watching television programs or films, but *how* the behavior was displayed as they pulled the triggers of their guns was similar to the form of how they fired the guns of their video game.

Embodiment, interactivity, perceptually salient production features, and immersion combine to make some VE simulations seem realistic. Embodiment involves the sensation that you are the character. In VE simulations, a player looks out of the eyes of a character, and the world looks similar to how it looks when a person looks out of their own body. Embodiment leads to a sensation known as *presence*, which occurs when a person suspends reality and feels like they are physically in a computer-generated environment (Barfield, Zeltzer, Sheridan,

& Slater, 1995; Stuart, 1996; see chap. 40, this volume). Virtual embodiment lends a first-person perspective to media experiences.

Presence is augmented by interactivity. In VE games, people interact with and control images much more so than when they are spectators viewing a prepackaged television program or even when they control a video game player but are not embodied in it (Calvert & Tan, 1994). When a person directly experiences a media form and is able to control it, there is a one-to-one correspondence between what is done and what happens. This increased sense of personal involvement and presence in the VE game may also increase player identification with characters, their perceptions of the vividness of events, and their perceptions of self-efficacy.

The realism of virtual images may be augmented further by the use of perceptually salient formal features. *Perceptual salience*, a term coined by Berlyne (1960), involves features that contain high levels of movement, contrast, incongruity, surprise, complexity, novelty, and the like. Perceptually salient television and computer features involve action (movement), sound effects (surprise, incongruity), and loud music (contrast, surprise). Immersion uses perceptual cues to trick the senses into feelings of presence in a computer-generated environment (Stuart, 1996). Because of primitive orienting responses that ensure our survival, salient features are likely to draw attention to information, thereby increasing the probability that the content will be processed (Calvert, 1999a).

When perceptually salient images are combined with interactivity, an embodied user feels immersed in these symbolic worlds, often making the virtual world very compelling. This personal experience of interacting with 3-D moving images is why some users want to run away when they are attacked in a VE game. The player personally feels attacked. As virtual interfaces are improved, these audio-visual representational interactions will provide a lifelike quality that is unparalleled in media experiences (Calvert, 1999a). This evolution of technology means that users can create and construct shared realities that are limited only by their imaginations and by the latest technological breakthroughs (Schroeder, 1994b).

Form and content are theoretically separate dimensions, but production practices link perceptually salient formal features with certain kinds of content. For instance, rapid action, sound effects, and loud music are often associated with action-adventure television programs containing high levels of violent content (Huston & Wright, 1998). These same perceptually salient features are used extensively in VE games (Calvert, 1999b), making these experiences attention getting and arousing to players. Even so, perceptually salient forms can be used to present prosocial content. When interaction, embodiment, and perceptual salience are used to present content, the potential for that content to be attention getting and acted on increases, be it antisocial or prosocial.

2.2 Content of Information Technologies

Formal features deliver content. Virtual environments offer the opportunity for users to experience any type of content that interests them. Content can range from realistic simulations where surgeons practice heart catheterizations to fantasy simulations such as slink world. Slinks are yellow-faced characters with cylindrical bodies and distinct personalities who autonomously move, avoid collisions with other objects, and react to other slinks, the latter activity being based upon the slink's happy, angry, or uncaring moods (Green & Sun, 1995). Virtual environment games, models of buildings, artistic environments, visualization models, and training environments are the most commonly portrayed content in virtual worlds (Schroeder, 1996; see chaps. 42–55, this volume).

Obviously, the applications of VE are diverse, and the content of various applications varies to suit the particular goal of the simulation. Nonetheless, VE content reflects market trends, making games one of the most widespread applications for consumer use (Schroeder, 1996;

see chap. 55, this volume). The content of VE games partly reflects earlier media content, though its roots are in military simulation (Herz, 1997). Just as the entertainment industry relies on action and violence to attract viewers to television, film, and video game content, so too do many VE games (Calvert, 1999a). In fact, games are now spearheading VE development (Schroeder, 1996). Because the most common experience of people is currently VE games, games are a focal point here for understanding the social impact of VE technology.

Game content involves a player or players who at times assume various identities and perform certain activities within a virtual simulation. On the one hand, these games provide an avenue for aggressive interactions with other real or imaginary characters. On the other hand, these games provide an avenue for characters to create cognitive strategies and to work together collaboratively to win the game (Pearce, 1998). Therefore, both aggressive and prosocial interactions can occur within these imaginary scenarios.

The company Virtuality was one of the first producers of commercially available VE systems (Schroeder, 1996). They created adventure games such as Dactyl Nightmare and Legend Quest. Legend Quest uses archetypal fantasy images, such as the wizard, the warrior, and the elf. Narrative elements, comparable to that found in film, are central to this game (Schroeder, 1996). In Dactyl Nightmare, two cartoonlike characters gain points by shooting each other and a pterodactyl as they move through a maze of platforms suspended in space (Calvert & Tan, 1994). The goal is to get as many points as possible. Virtual Worlds Battle Tech Center, Magic Edge, and Fighter Town also provided early combat-based entertainment. Currently mainstream commercial virtual entertainment programs are offered by Disney Quest, which creates mostly nonviolent programs, and by Sony Metreon.

Immersive VE often connotes a space that arises when a person interacts with a computer with particular hardware, such as gloves and helmets, or in a CAVE (Cave Automatic Virtual Environment), where users move through a shared virtual space. MUDs (Multiuser domains, dungeons, or dimensions) are yet another type of virtual environment. MUDs, originally constructed around the idea of a real-life game called Dungeons and Dragons (Schroeder, 1997), are now found on the Internet. In time, MUDs will be delivered as VE simulations over the Internet (see chap. 16, this volume).

One current form of MUD is a text-based social virtual environment (Turkle, 1995). There are no particular goals or tasks that participants are expected to do in this MUD. Instead, MUD participants assume complex personae, such as a wizard or a warrior, and embark on various adventures in relatively unstructured situations. MOOs (multiuser object oriented environments) and MUSEs (multiuser simulated environments) are similar to MUDs except they are based on different kinds of software (Turkle, 1995).

MUDs have now evolved into visual, rather than solely textual, virtual spaces (Calvert, 1999c). These MUD applications, which are more sophisticated than text-based MUDs but less sophisticated than truly immersive VE simulations, include desktop VE and second person VE systems (Schroeder, 1997). In desktop VE systems, a person can look out of a character's perspective into a virtual world, but they are not immersed, as they would be when using head-mounted displays (HMDs) or in a CAVE. Second-person VE systems are even less immersive than desktop VE systems. In second person VE systems, the player is represented by an on-screen avatar (i.e., a figure or character). Users communicate through written text that appears on the screen. The player sees a computer-generated environment, but not through their own eyes (Schroeder, 1997). The experience is much like playing a video game, but it is often much less structured than a game.

In second-person VE systems, players represented through avatars roam visual spaces such as Alphaworld and Cybergate (Schroeder, 1997). Social interactions change substantially when visual images and personal characters are included in the simulation, rather than having to rely solely on text for communication. For example, verbal aggression expressed in words

becomes physical aggression directed at avatars, sexual language becomes sexual interactions between avatars, and belonging to the group via text-based exchanges is expressed by physical proximity to other avatars (Schroeder, 1997). The additional visual information provided in these newer virtual spaces represents a fundamental leap in the experiences of players. Within the next decade, another leap will occur as computer networks allow truly immersive virtual interactions on the Internet (Adam, Awerbuch, Slonim, Wegner, & Yesha, 1997).

At present, however, social interactions with other users on the Internet are more common in these low-end VE applications than in immersive VE (Schroeder, 1997). Currently, MUDs include visual adventure games on the Internet where players slay beasts and triumph over evil (Sleek, 1998b) as well as social MUDs where players interact in relatively open spaces to construct whatever is of interest to them (Schroder, 1997; Turkle, 1995). The hundreds of thousands of current MUD users are primarily adolescent and adult males in their 20s, but there are also children playing Barbie and the Power Rangers online (Turkle, 1995). More than 250,000 people have visited Alphaworld alone (Schroeder, 1997). Through MUDs, players can recreate themselves, their identities, and be anyone that they want to be (Turkle, 1995).

Immersion influences the relative power of people who interact in virtual environments. For instance, small groups of young adults solved problems in a VE followed by a continuation of the task in the real world. Only one person was actually immersed. The immersed person was consistently the leader in the virtual environment, but this role did not generalize to the real world (Slater, Sadagic, Usoh, & Schroeder, 1999).

3. THEORETICAL PERSPECTIVES AND PREDICTIONS IN RELATION TO VIRTUAL ENVIRONMENT CONTENT

Virtual environments allow people to engage in various kinds of representational experiences in both realistic and imaginary simulations (Calvert, 1999b). Representational thought allows individuals to transcend the present reality, thereby extending the perceptual field in both time and space. Through representational experiences, memories of the past and fantasies about the future become part of current reality.

The impact of media on peoples' lives has been examined from various theories in the fields of psychology and communication. Various predictions are made about the impact of these experiences, depending on the particular theoretical perspective brought to bear on the information. These predictions are summarized in Table 33.1.

3.1 Social Cognitive Theory

Social cognitive theory (Bandura, 1997) focuses on the role that models play as influences on social behaviors. These models can be real people, or they can be symbolic media characters.

As a model displays behaviors, observers attend to and encode relevant information. If rewards are available for imitating the behavior, the observer will often do so. Imitation can occur for all kinds of behaviors, be they prosocial or antisocial (Calvert, 1999a). Models can also increase the probability that another person will exhibit antisocial actions through a process called disinhibition. People often inhibit behaviors that they would like to do because the behaviors are not socially acceptable. However, if a model performs antisocial behaviors and gets rewarded for them (or at least not punished), then the observer's internal controls are undermined or disinhibited (Bandura, 1997). Models can also increase the probability of socially desirable behaviors through a process called response facilitation. In response facilitation, infrequent yet desirable behaviors, such as buying breast cancer stamps at the post office, can be increased when a person observes a model perform them.

TABLE 33.1
Theoretical Predictions About the Impact of Information Technologies on Social Behavior

<i>Theory</i>	<i>Predictions</i>
Social Cognitive Theory	After observing social models, observers will imitate the behaviors that they have observed others perform; they will be disinhibited from controlling antisocial and inappropriate behaviors; and response facilitation will increase the probability that they will enact socially desirable behaviors. <i>Self-efficacy</i> , the belief that you can control events, can be promoted by observing and participating in rewarding symbolic experiences. Media expose people to various social models.
Arousal Theory	Observing or interacting with exciting media gets a person pumped up. The behavior that follows is a function of what the environment cues. The personally felt experiences of VE increase a user's arousal levels.
Psychoanalytic Theory Freud	Sex and aggression are two major drives that people experience. If these drives cannot be satisfied directly, they can be harmlessly released via catharsis: when one uses fantasy to reduce a drive state. Sex and aggression are two content areas that are systematically used in media portrayals.
	The personality, called the <i>psyche</i> , is constructed by developing various <i>archetypes</i> that are embedded in the <i>collective unconscious</i> . The self-archetype integrates information from the various archetypes, including the persona, the anima and animus, and the shadow. Archetypes, such as those of heroes and warriors, are regularly experienced in television, film, Internet, video game, and VE encounters, providing information that can be used in constructing the self-archetype.
Cultivation Theory	People construct a world view based upon the media experiences they encounter through processes of <i>mainstreaming</i> and <i>resonance</i> . In mainstreaming, people come to believe the dominant cultural messages they encounter. In resonance, effects are amplified because they parallel one's own unique experiences. Virtual environment players, particularly in MUDs, will create a shared reality that they construct together.
Information Processing Theory	People take in information through sensory systems and interpret it based on prior expectancies, or <i>schemas</i> . Virtual environments build on processing activities, such as perception, attention, and memory, in creating user-friendly interfaces.
Ethology	<i>Ethology</i> focuses on behaviors that have evolutionary significance, such as finding a mate and avoiding predators. Media allow people to experience these challenges of nature without experiencing real danger.
Perceptual Developmental Theory	Humans evolved in a perceptual world rich with meaning. As humans, one learns to perceive what is really there. Information technologies, such as virtual environments, can trick one's perceptual systems into believing some things are real when they are not.
Uses and Gratification Theory	Information technologies are used to fulfill various needs that people have, such as the need for entertainment, the need for companionship, or the need to escape from the demands of life.

Over time, Bandura (1997) increasingly focused on the concept of self-efficacy, the belief in personal control over life events. The subprocesses of attention, retention, production, and motivation occur as a person observes and later imitates a behavior. Self-efficacy regulates these subprocesses, particularly when a person fails and motivation to continue a task is weakened. If a person perceives that they have control over events, then they are more likely to continue to attend to, retain, and produce a behavior.

Virtual environments allow user control, a component of self-efficacy, via interaction. Experienced VE users take control of these environments more than inexperienced, novice users. For instance, novices observe more in simulations, whereas experts are more likely to act (Schroeder, 1997). Also, role playing, an important rehearsal mechanism for performing a behavior, is integrated into VE simulations through interaction. This means that the behaviors enacted (e.g., pulling the trigger of a gun) will be readily accessible to players after the VE interaction is over.

3.2 Arousal Theory

Autonomic arousal is often measured by heart rate, skin conductance, and blood pressure, whereas an electroencephalogram measures cortical arousal. Both kinds of arousal are related, but researchers in the media area typically study autonomic arousal (Calvert, 1999a). People who are exposed to aggressive, sexual, or scary content typically become more aroused and then direct that arousal in diverse ways, depending on what is cued by the environment. That is, arousal can be channeled into aggressive, sexual, or prosocial behaviors, regardless of the content, depending upon situational cues. After repeated exposure to aggressive or sexual content, the individual may become desensitized to that content and to the plights of others.

Certainly VE content is not always meant to be arousing. For instance, therapeutic applications (see chaps. 49–51, this volume) utilizing systematic desensitization procedures, such as a program to help a person overcome a fear of heights, focuses on how to get a person to relax in what is typically an arousing, stressful situation. By contrast, entertainment games (see chap. 55, this volume) focus on getting users to be excited, much like an amusement park ride. The arousing qualities of entertainment-driven VEs may increase attentiveness. Interaction and presence should increase users' heart rate and other indices of physiological arousal. The content that is being experienced in VE will be the immediate trigger for releasing arousal, but real-life events just after VE interactions can also trigger behavior. With repeated interaction, users should habituate to the content, as they have done in other exciting media experiences. That means that the content will have to be more vivid for arousal levels to return to prior levels (Calvert, 1999a).

3.3 Psychoanalytic Theory

Psychoanalytic theory focuses on human drives, particularly sex and aggression, as the reasons for our behaviors (Thomas, 1996). Most of the reasons for actions occur at an unconscious level, reflecting these basic drives. Although drives are a normal part of human experience, society often disapproves of, and therefore regulates, their expression. Consequently, drive reduction is accomplished in indirect ways. One example is catharsis. Instead of killing someone or having sex with someone, drives are released vicariously through a fantasy experience. Theoretically, VE games should yield the same cathartic releases that television, film, and video game experiences were expected to offer viewers or players.

In an extension of Freud's ideas, Jung (1959) proposed that humans share a collective unconscious, a repository of shared racial experiences that have been inherited. Archetypes, or primordial images, reside in the collective unconscious and are developed by individual

experiences. These archetypes include mother, father, hero, trickster, persona, anima, animus, shadow, and self (Hall & Nordby, 1973). On the Internet, the persona, or mask, is a term that is used to describe a character's identity (Turkle, 1995). Moreover, men sometimes create and play a female persona online, thereby developing their anima or feminine side of the self, whereas women often create and play a male persona online, thereby developing their animus, or male side of the self. The shadow, or primitive side of human nature, protects the self but can overreact in very aggressive ways when threatened. The developmental task is to synthesize the various archetypes into ones self, the overarching archetype.

Most fantasies, including virtual ones, include many archetypal images. Playing out personae, or the archetypes, in VE games should lead to the development and differentiation of that archetype and the inclusion of it in the self-archetype. Put another way, virtual fantasy interactions may provide experiences that players can use to construct their identities.

3.4 Cultivation Theory

In cultivation theory, media present messages that form the basis for a shared, constructed reality (Calvert, 1999a). One cultivation effect, called mainstreaming, focuses on the dominant media images that people share, and therefore, come to believe to be true. For example, those who frequently view aggressive content on television come to believe that the world is a more aggressive place than it really is. These heavy viewers buy more guns, watchdogs, and locks than light viewers do (Gerbner, Gross, Morgan, & Signorielli, 1994). Another cultivation effect, called resonance, amplifies real-life experiences that overlap with media experiences.

Mainstreaming effects should become common for those who share the same virtual spaces day after day because they create a reality based on shared experiences. Resonance will occur when these experiences occur in real-life as well as in the virtual world. The implication is that experiences in the virtual world will influence people's views of reality, just as television viewing has.

3.5 Information Processing Theory

Information processing theory focuses on humans as information processing devices. Based on their experiences, people construct schemas, that is, cognitive structures that influence perception, attention, and memory. These schemas are then used to interpret future incoming information, thereby influencing what will be learned. In VE, input devices, such as helmets and goggles, alter the perceptual reality that is available for processing.

3.6 Ethology

Ethology focuses on behavior that has evolutionary significance for the species (Thomas, 1996). Activities such as finding food, avoiding predators, finding a mate, mating, protecting the young, and finding shelter are behaviors that ensure the survival of the species. Programs that build on basic human and animal needs, such as the program for Silas the dog, use ethology as a framework. These kinds of applications may be particularly useful in creating Abots, the robots who may eventually become indistinguishable from real users in simulated environments.

3.7 Perceptual Developmental Theory

In perceptual developmental theory, the focus is on how perceptual systems evolved to ensure survival (Thomas, 1996). People are active perceivers whose sensory systems evolved to pick

out the salient and important environmental stimuli. The visual system is particularly important in evolution. Perceptually salient stimuli such as movement, contrast, incongruity, complexity, surprise, and novelty are features that are likely to elicit attention as well as improve the odds of survival (Berlyne, 1960).

In VE simulations, users are tricked into perceiving and seeing events that are not really there. Virtual environments accomplish this task, in part, by creating natural interactions where characters move and interact with each other without the use of artificial keyboards or textual commands (Bricken & Coco, 1995; see chaps. 11 and 13, this volume). Perceptual laws are obeyed in many of these simulations. For instance, in Slink World, slinks are programmed to avoid collisions with other moving objects. When rapidly approached, slinks pull back and act scared. But when slowly approached, slinks are likely to stay in their current position (Green & Sun, 1995).

3.8 Uses and Gratification Theory

Communication media are used by people to satisfy or gratify their needs (Rubin, 1994). Needs are diverse, ranging from sexual stimulation to relaxing to information seeking. In VE, users may play games to entertain themselves (see chap. 55, this volume), or they may interact with a clinical simulation to reduce phobias (see chaps. 50 and 51, this volume). Even so, many people use VE to satisfy entertainment needs, just like they used other media before it.

4. COGNITIVE AND BEHAVIORAL IMPACT OF VIRTUAL ENVIRONMENTS

According to uses and gratification theory, media fulfill certain needs that people have. Freud theorized that those needs involve sex and aggression, and the Nielsen ratings attest to the popularity of violent content. However, people have diverse needs for entertainment and for learning about others that extend well beyond violence and sex. Social interactions provide opportunities for constructive prosocial activity as well as for antisocial activity. Both antisocial and prosocial interactions are explored in this section.

4.1 Aggressive Interactions

Since 1953, violent crime has risen 600% in the United States, and homicide is the main cause of death for U.S. urban males who are 15 to 24 years of age (Coie & Dodge, 1998). American teenagers are at least four times more likely to be murdered than teenagers in 21 other industrialized nations; not surprisingly, Americans rank crime and violence as the most important problem being faced in this country. Media content, specifically violent television viewing, has been implicated as one reason for aggressiveness by American youth, in particular, and American society, in general (Coie & Dodge, 1998; Huston & Wright, 1998).

In an early examination of VE and aggression, Calvert and Tan (1994) examined the arousal levels and aggressive thoughts of college students in one of three conditions: (1) an immersive VE condition where they interacted in an aggressive game; (2) an observational condition where they viewed another person's aggressive VE game; and (3) a simulation experience where the players moved as if they were in a VE game, but in which no aggression was displayed (the control group). The game, Dactyl Nightmare, involved shooting an opponent and a pterodactyl that both periodically attack the player.

The results best supported arousal theory. Participants who played the game were more aroused, as measured by pulse rate, than those who observed another play the game or those

who simulated game movements. Social cognitive theory received mixed support. Specifically, game players reported more aggressive thoughts than those who observed another person play the game or who simulated game movements; however, contrary to prediction, the observers reported no more aggressive thoughts than the game simulators. The psychoanalytic view that catharsis would release aggressive impulses safely via fantasy was not supported because players were more aroused and had more aggressive thoughts, not less. The results suggest that interactive VE experiences lead to stronger effects than simply observing another person perform an antisocial act.

According to Pearce (1998), the visceral kill or be killed formula created by game makers plays on primitive human instincts that are necessary for survival. Violence, as part of the human psyche, has been prevalent throughout time. War is expressed in simulations that were originally board games that became computer games as technology evolved. Thus, VE and video games, more generally, had their roots in military operations. In fact, the first VE games were designed to train military personnel. Through role playing, war strategies could be perfected. Virtual environment entertainment platforms adopted these earlier military game simulations.

A key question is the extent to which these aggressive encounters will generalize to real-life experiences. Those who view aggressive television content tend to be more aggressive in real life, and research in video games and initial VE games find similar results for aggressive behavior and aggressive thoughts, respectively (Calvert, 1999a). Estimates of 3% to 9% of unique variance are found in studies that link children's aggressive conduct to their exposure to television violence (Huston & Wright, 1998). Millions of dollars were invested in virtual and video game military simulations to impact real fighting skills, not just pretend ones (Herz, 1997).

There are also those who argue that violent media impact people in different ways. That is correct. Some people become more aggressive, but those who see themselves as victims become more afraid (Gerbner et al., 1994). Moreover, everyone who sees violent media learns about aggressive behavior, even if they don't act on it immediately, and they can act on it later if motivational incentives are provided (Bandura, 1965). If only a small percent of individuals spontaneously act more aggressively after exposure to media violence, the quality of life is impacted for all. The evidence suggests that a portion of the population does become more aggressive after viewing or interacting with violent media content (Huston & Wright, 1998).

4.2 Identity Construction

Constructing a personal identity is a life-long experience accomplished by day-to-day encounters, particularly those involving other people. Virtual environments will become a source of experiences for creating parts of identity. As individuals move between virtual worlds and real worlds, their sense of identity may become increasingly malleable. They can be a male, a female, or both, moving fluidly across varying MUDs. How will virtual construction impact the real-life construction of the self? Who will people be?

Historically, a debate involves whether identity is comprised of a single entity or multiple entities (Turkle, 1995). That is, does each individual have one and only one true self, or do individuals display multiple selves, depending upon the situation? Physical embodiment is a defining characteristic of the self (Harre, 1983), but people are free to use different bodies in virtual environments. What implication does the lack of real-life embodiment have for self-construction? Will people develop alternate and multiple selves that express hidden aspects of their character?

When children identify with other people, they selectively take in information about them and incorporate that person's characteristics and qualities into their own sense of self (Calvert, 1999c). Identification with televised and filmed models is one reason that viewers imitate

certain characters: They are making that character's behaviors their own. The VE genre allows players to be, not just to observe, the characters in these narratives. Being an embodied character may allow players to incorporate personality characteristics and behaviors directly into their own personal repertoire (Calvert & Tan, 1994).

The opportunity to create different selves expands greatly in virtual environments. People are not constrained by their physical body in defining who they are. They can construct the specific body that they want, and they can be as many people as they want to be. They can also be animals, robots, or other nonhuman entities. Although they no longer have to use their own physical body in these virtual worlds, they do have a virtual body. Moreover, presence (see chap. 40, this volume) should increase their beliefs about the realism of these embodied entities. These personae may then become incorporated into their self-constructions.

For children, the role playing that takes place in imaginative play episodes is one way that they try out various perspectives, thereby coming to understand how and why others feel and act as they do (Calvert, 1999c). Similarly, VE immersions provide opportunities for both children and adults to take on different roles in a fantasy context, thereby mastering a role and understanding the perspective of that person in a safe environment.

In Jungian psychoanalytic theory, key archetypal images recur throughout history. Many of these images, embedded in the collective unconscious and displayed in fiction, involve the roles of hero, father, mother, child, wizard, sorceress, sorcerer, king, queen, emperor, princess, prince, wise old man, wise old woman (or crone), innocent, healer, trickster, witch, magician, persona, anima or animus, shadow, and self (Hall & Nordby, 1973). The self is a meeting place where various archetypes are integrated into one's personality (Turkle, 1995).

Archetypal images are passed from one generation to the next through the collective unconscious, a shared repository of ancestral images that are like negatives on a roll of undeveloped film (Hall & Nordby, 1973). Individual experiences then develop those latent images. The specific image that emerges is a function of a person's unique experiences. These experiences can be real, or they can be realistic or even imaginary, as is the case of VE immersions.

The persona is the public display, or the mask, of the self that is presented in public. The Internet is a place where personae are already being constructed in MUDs (Turkle, 1995; see chap. 16, this volume). Acting on information makes it your own (Calvert, 1999c). Thus, as people act on these archetypal images, they should be integrated within their own identities, thereby making their own sense of self much richer and more complex. The implication is that identity can potentially be altered as players enact various roles via these Internet personae, allowing the real person to integrate the archetypes that are being played out into his or her real personality. Personal views of a hero, or of any other archetypal image, should be influenced by role playing heroes in VE encounters. The role of hero, which has often been reserved for men, may become more available to women through VE games. One problem with these immersive identities is that an individual may lose track of who he or she really is. Fantasy can sometimes be compelling and even more appealing than reality. The person may choose to withdraw from real life to a more controlled imaginary persona and reality (Turkle, 1995). A person can be important in fantasy, a Walter Mitty so to speak, with all the embellishments made possible by being present in an electronically generated environment of that person's choosing. The virtual identity option may be particularly appealing to young adolescents who are struggling with an identity crisis. Negative identities can also be constructed. If a person chooses to play a mobster or other antisocial characters in virtual environments, antisocial behaviors are being practiced. Having such images and behaviors readily available can potentially increase antisocial behaviors and accentuate character flaws as seen in Littleton, Colorado.

In online symbolic encounters, people can also deceive others about who they really are (Calvert, 1999c). The use of temporary and fictitious identities, known as handles, are widespread in electronic communities (Mantovani, 1995). Is it ethical for a man to present

himself as a woman, thereby gaining access to information that would not ordinarily be available to him? One man did, assuming an Internet persona of a woman who was helping other women with their emotional problems. Many women were upset that he deceived them (Turkle, 1995). Men also present themselves as women because they are more likely to be approached, and women present themselves as men to avoid being approached (Turkle, 1995). These gender switches are not uncommon online and will certainly be possible in VE as well.

Players can also confuse bots, which are online robots, with a real person. Or players can create a persona where they appear to be a bot, thereby gaining access to private conversations as cyberspace voyeurs (Turkle, 1995). One player created a passive character called Nibbet who was a rabbit. Others forgot he was there or assumed he was a bot, allowing him to listen to conversations where he would probably not be welcome.

In summary, virtual environments allow people to try out different facets of their identities and to rehearse behaviors in a safe place. Because players can be anyone they want to be, they can try out new ways of being in cyberspace. However, they can deceive others and themselves about their real selves. Identities can be enacted that are negative and that reinforce character flaws.

4.3 Sexual Interactions

Ongoing interest continues to be expressed in having virtual sex, particularly by men (Epley, 1993). Currently, these possibilities are limited because of tactile interface issues. However, once these telehaptic issues are resolved (see chaps. 5 and 6, this volume), there is clearly a paying audience for sexual virtual experiences. Computer software and Internet interfaces are already widely used for pornography, particularly by boys and men (Calvert, 1999a).

Opportunities for sexual enjoyment via VE offer positive as well as negative experiences for users. In text-based Internet MUD applications, many characters meet online and engage in virtual sex. Some even get married in virtual ceremonies (Turkle, 1995). These fantasy relationships provide an opportunity for safe sex because there is no danger of contracting or spreading a sexually transmitted disease. Users also are engaged in an experience with another person, allowing them to participate within the boundaries of a shared sexual fantasy rather than an individual one. By knowing how a partner feels and what a partner enjoys, a player may become better able to interact with real partners by understanding their needs. Players may even meet future real-life partners by exploring intimate experiences on the Internet. Sometimes people really marry a person that they were initially involved with in an Internet relationship, but other times real meetings are disappointing (Turkle, 1995).

On the other hand, sexual deviance and violations of another person's rights can also occur in virtual sexual experiences. For instance, some Internet sites are policed to prevent users from acting in sexually deviant ways on sites that are not meant to be sexual. MUD administrators for the Palace Internet site deal with issues such as pornography and profanity (Sleek, 1998b). Reports of cyber-rape have also occurred (Wallace, 1999). In one instance, a more sophisticated MUD user took control of another person's character, and he forced that character to have a violent sexual encounter (Turkle, 1995). As these sexual encounters become more realistic with the addition of immersive technology, how will the law deal with such verbal actions and symbolic violations? Words are deeds in virtual experiences (Turkle, 1995), making ethical issues a pressing concern. The anonymity afforded by cyberspace currently allows sexual deviants to act out with impunity (Wallace, 1999). Issues of imitation, disinhibition, and desensitization may become serious issues as sexual activity becomes an immersive, online option.

Ethical issues, such as marital fidelity, will also be experienced in virtual spaces. How will a person feel if their partner has virtual sex with an imaginary character, or with a character

who is a real person in another location? Will betrayal and infidelity be experienced? *Mad About You*, a television program, played out the scenario of a fantasy partner a few years ago. Marital distress occurred when the husband had a virtual sexual encounter with the model Cindy Crawford, suggesting that these enacted fantasies are not harmless entertainment.

What will happen when a man pretends to be a woman or a woman pretends to be a man? Do partners have a right to know the real sex of that person, particularly if they are seeking an online sexual encounter? Is this kind of deception permissible, or is it unethical? Will the online partner care if they are being deceived? Bots, that is, cyberspace robots, are also mistaken for real people. In one instance, a man made repeated sexual advances toward Julia, an intelligent computer agent (Turkle, 1995). As these agents become more humanlike in their interactions with people, the line between the robot and the real person will be increasingly difficult for people to discern.

Finally, sexual predators may find a new home to prey on unsuspecting people, particularly children. Parents are particularly worried about these potential online dangers as Internet interactions can be used to create avenues for real-life meetings or for virtual online meetings (Turow, 1999).

4.4 Social Interaction or Social Isolation?

Humans are social beings who often seek the contact of others. Will computer simulations and online interactions promote friendships and close ties with others, or will simulations lead to social isolation and addiction? Although many parents are concerned that Internet interactions will lead to social isolation and potentially disrupt family interactions (Turow, 1999), the impact of online Internet interactions is mixed.

Kraut et al. (1998) examined the social and psychological impact of initial Internet use for 73 households. People used the Internet primarily to communicate. As Internet use increased, people reported that they interacted less with their families, had fewer people in their social circles, and felt more depressed and lonely. Similarly, Slater et al. (1999) found that young adults enjoyed working in groups, felt less isolated, felt more comfortable, and felt other group members were more cooperative after participating in a real, rather than a virtual environment, interaction; however, the design was flawed in that the real interaction always occurred after the virtual one. Sleek (1998a) argues that too much reliance on impersonal, weak, online interactions through e-mail correspondence and chat groups cannot replace the social support of real-life face-to-face interactions with family members and friends. As computer use increases through VE simulations, real face-to-face interactions may diminish even more.

The impersonal world of computers and business, coupled with the loss of social networks, has resulted in a loss of social skills and an increase in shyness for many users (Cooper, 1997). Part of this problem may also reflect the displacement of other activities. As one spends more time in virtual interactions, less time is available to participate in, and to practice, face-to-face social interactions. Thus, feelings of isolation and loneliness may increase as VE interactions become more commonplace. But if people do become too shy, they can then interact with a VE therapist in a systematic desensitization simulation. For instance, therapeutic interventions allow students with behavioral disorders to practice social skills (e.g., Muscott & Gifford, 1994).

As a participant observer, Schroeder (1997) explored two virtual worlds, Alphaworld and Cybegate, as a human and a cartoon avatar, respectively. Schroeder found that players created social stratification within these worlds. Insiders often developed a distinctive persona such as being a prankster, a bully, or a helpful guide, whereas outsiders acted more like a tourist. In fact, in Alphaworld, visitors or tourists literally wear a camera around their avatar's neck so that they are readily identifiable as outsiders. In these virtual worlds, insiders tend to explore and to create spaces with their friends in the far reaches of these worlds, whereas outsiders are

less engaged with others, observe more, and stay in central locations where most of the avatars tend to be located. Overall, these two different groups had a different social status, marked by the distinctive roles and behaviors that separated them, and differential status emerged with varying levels of involvement and expertise in the virtual world.

Online VE interactions can eliminate the geographical constraints that disrupt human interactions by making friends and family members in far away places accessible in everyday social life. Players can meet and interact in virtual simulations, enacting fantasies when their real worlds impede actual physical contact. The loneliness associated with a move to a new place can be lessened by bringing close friends into one's symbolic space, even if it is not one's real space. While the experience is not the same as being face-to-face in the real world, having your characters face-to-face in an imaginary setting can also strengthen ties. Instant messaging allows ongoing online interactions with one's "buddies."

Online relationships can also lead to new friendships. For example, Parks and Roberts (1998) reported that 94% of a sample of 235 MOO participants, ranging in age from 13 to 74, had developed an ongoing personal relationship on a MOO. These included close friendships, friendships, and romantic relationships. Although offline relationships were better developed than MOO relationships, MOO relationships offered the possibility of creating new face-to-face friendships. One third of these MOO relationships had led to real-life meetings.

In a survey of 2,500 respondents, Katz and Aspden (1997) found that the Internet complements social connections. Friendships cultivated online often led to real-life meetings, family contact was enhanced, and a sense of community was fostered. There was no evidence that Internet users dropped out of real-life activities, such as religious, leisure, and community organizations. Eighty-eight percent of the respondents reported no change in the amount of time spent in face-to-face interactions or phone conversations with family and friends. Six percent of respondents spent more time interacting with or talking to family members, and 6% spent less time. Only 14% of the sample reported friendships created online, and 60% of those people had met at least one of their online friends. The authors estimate that about two million face-to-face meetings have taken place because of initial Internet interactions.

Addiction to computer interaction is one reason that people may have fewer face-to-face interactions (Turkle, 1995). For example, some players choose to interact with text-based VEs from the time that they wake up until they fall asleep (Turkle, 1995). Windows on computers allow them to participate in work and in fantasy text-based MUD worlds simultaneously, moving between various applications throughout the day.

In certain instances, however, online experiences may be engaging, not addictive. Consider a lesson from television. Addiction has often been used to describe those who cannot seem to quit looking at the television screen. Anderson and Lorch (1983), however, documented that such experiences actually involve an easy and engaged attentional state, known as attentional inertia, in which users get increasingly involved in the activity that they are doing. These activities can range from watching television to playing to reading a book. Moreover, attentional inertia has been documented from childhood through adulthood, making it a skill that all age groups use to sustain attention in an activity. Therefore, while some may describe rapt attention as addictive, it may just be a normal facet of attention: people become involved in interesting, responsive activities and environments. Virtual environments are certainly one kind of intrinsically interesting environment for many users.

The answer to the complex questions about social isolation and addiction ultimately depends on how a player treats online experiences (Turkle, 1995). The most extreme case involves those who spend most of their time in computer simulations. If those computer simulations

become a permanent substitute for real life and the person pursues dysfunctional behaviors, then addiction to the computer world and isolation from real social relationships can become serious issues. By contrast, if computer simulations are a temporary working space to deal with adverse circumstances, the person may emerge healthier and more functional (Turkle, 1995).

In summary, while some studies find that users feel more lonely and isolated after engaging in Internet interactions, others find that the Internet does not substantially alter the amount of time spent in face-to-face interactions. In many instances, real face-to-face interactions occur because of initial Internet contact. For most people, virtual environment simulations will probably become a recreational activity, taking up part, but not all, of their leisure time experiences. In the latter situation, virtual environments have the potential to satisfy needs by supplementing the everyday social experiences of real life, just as other media experiences have done in the past. Nevertheless, heavy use of online computer technologies has the potential to disrupt social relationships, just as heavy television use can.

4.5 Prosocial Interactions

Just as media exposure can lead to antisocial activity, so too can exposure lead to constructive prosocial responses. Prosocial behavior involves socially constructive activities such as helping, sharing, cooperating, and creativity (Calvert, 1999a). There are numerous television studies demonstrating that prosocial television can enhance children's helpfulness, cooperation, empathic responsiveness, and delay of gratification (Huston & Wright, 1998). The same impact may occur for VE interactions, but studies in this area are rare at present.

Many VE games provide opportunities for players to interact with virtual actors, who can be either real or imaginary players. These games are often fantasies where the player assumes an archetypal role (e.g., hero or wizard) and then enters a VE simulation where other players assume the identities of other game characters. These games provide the opportunity for players to share an adventure where they work together and cooperate to overcome evil forces. Characters can talk to each other and plan group strategies to win the game. Prosocial and antisocial (e.g., aggressive) behaviors coexist in these VEs as they sometimes do in real life. Through role-play, characters enact the behaviors of others, thereby helping the player to control and to incorporate those qualities into their own identities (Calvert, 1999c). Self-efficacy, the belief in personal control, should increase as users role-play these ancient and powerful images.

Pearce (1998), who finds that women enjoy social interaction in computer games, created a nonviolent, story-based VE game called Virtual Adventures. Players compete against other teams and cooperate within teams. Prosocial actions, such as rescuing the Loch Ness Monster's eggs from bounty hunters, were incorporated in the game. The players became story characters that worked together to solve a common pressing goal. Women rated this software more favorably than men did. Her findings suggest that prosocial immersive programs can be entertaining to certain users.

A potential problem for VE players is that they may come to rely on others' fantasies rather than constructing their own. A constructed reality leaves little room for imagination (Mantovani, 1995). Heavy television viewing is associated with a decline in imaginative play and in creativity, but with increases in daydreaming (Valkenberg & van der Voort, 1994; van der Voort & Valkenberg, 1994). However, the kind of program being viewed is crucial in understanding how television impacts fantasy, imagination, and creativity. For instance, television programs that encourage imaginative activities lead to increases in creativity (Schmitt et al., 1997).

Interactive VE experiences may impact a player's imaginative world differently than observational media have, with daydreams taking on a new life as they are developed and enacted in online computer experiences. Unstructured situations also tend to enhance imaginative play more so than structured situations (Carpenter, Huston, & Holt, 1986). Therefore, there may be a difference in imaginative outcomes for those who enter relatively unstructured virtual spaces and create parts of that site when compared to those who just visit an unstructured site or for those who play structured VE games.

5. LIMITATIONS OF VIRTUAL ENVIRONMENTS

There are always limitations to any innovation, and VE is no exception. Recurring media concerns such as the displacement of other activities are already being documented. For example, some players spend 40 or more hours each week in text-based MUDs, an experience known as simulation overdose (Turkle, 1995). People who spend too much time in VE may head back to real life because they decide that the real world offers more than a simulated one. For instance, a real pet may ultimately be more fulfilling than a virtual one. Media research in other areas indicates that displacement usually occurs when a new technology is introduced, and is sustained only for activities that fill a similar need for people, such as entertaining them (Calvert, 1999a). Thus, it is likely that a novelty effect for VE experiences will eventually give way to a balanced use of the technology in daily life.

The distinction between what is real and what is pretend is another issue that will be faced. In the everyday world, children already have difficulty in telling the difference between a realistic, but fictional, event versus a real event portrayed on television (Huston & Wright, 1998). These issues are partly resolved through developmental changes in the way that children think, but the roles that television characters play can even confuse adults. For instance, people often expected actors like John Wayne to really be like the characters that he played. Perceptions of fantasy and reality should be explored, particularly as virtual simulations become more realistic in the future.

6. SOCIAL IMPLICATIONS FOR THE FUTURE OF VIRTUAL ENVIRONMENTS

The information age continues to hold new options and challenges for the people who participate. What will social life be like in this coming age of realistic VE immersions where virtually any behavior will be possible? The literature on this topic is very limited at present, and this issue requires additional study. However, when other media research from the Internet and television areas is included, the following observations can be made.

In virtual environments, the social behaviors that are played out in real life simply move to a new symbolic plane. The long history of media research can be used to predict that people will use VE to meet their needs, including their social ones, as they do with television and the Internet already. Virtual experiences will become integrated into the daily fabric of life, just as the technologies before it were. People will imitate the characters that they play and become desensitized to situations in which they overindulge themselves. But each new technology also adds its own unique imprint to how those representational experiences will affect users.

Virtual environments will allow people to participate in, and to exercise control over, online social interactions. In the future, friends will be virtual as well as real. People will assume alternate personae, both realistic and fantasy-driven. From the privacy of home, people will travel to and experience any place that they desire. They will experience intimacy. They will

create and live out fantasies with real and imaginary people in virtual worlds. As is true of the technologies that came before it, people can use VE to enhance their real social lives, or they can use it to escape or to act out antisocial tendencies, augmenting the problems that they already have.

McLuhan (1964) told us that the medium was the message. Virtual environments represent a major step forward, bringing people one step closer to a social world where the lines between the symbolic and the real are merged.

PART V: Evaluation

34

Usability Engineering of Virtual Environments

Deborah Hix and Joseph L. Gabbard

hix@vt.edu, jgabbard@vt.edu

1. INTRODUCTION

Usability engineering, described rather simplistically, is the process by which usability is ensured for an interactive application at all phases in the development process. These phases include user task analysis, design of the user interaction, rapid prototyping, user-centered evaluation, and iterative redesign based on evaluation results. Usability engineering includes both design and evaluations with users; it is not just applicable at the evaluation phase. Usability engineering is not typically hypothesis-testing-based experimentation, but instead structured, iterative user-centered design and evaluation applied to all phases of the software development life cycle.

Until recently, the terms *usability engineering* and *virtual environments* were rarely, if ever, used in the same sentence or context. Virtual environment (VE) developers have focused largely on producing the next new “gee whiz” gadget and “way cool” interaction technique with too little attention given to how users will benefit (or not) from those gadgets and techniques. Admittedly, “gee whiz, way cool” exploration in a new realm such as VEs is necessary. However, VEs have been rather mature for nearly a decade now, with an ever expanding variety of possible applications.

Most extant usability engineering methods widely in current use were spawned by the development of traditional desktop graphical user interface (GUIs). Even when VE developers attempt to apply usability engineering methods, most VE user interfaces are so radically different that well-proven techniques that have produced usable GUIs may be neither particularly appropriate nor effective for virtual environments. Few principles for design of VE user interfaces exist, and almost none are empirically derived or validated. Use of usability engineering methods often results in VE designs that produce very unexpected reactions and performance of users, reaffirming the need for exactly such methods. Ultimately, researchers and developers

of VEs should seek to improve VE applications *from a user's perspective*—ensuring their usability—by following a systematic approach to VE development such as offered from usability engineering methods.

To this end, we present several usability engineering methods, mostly adapted from GUI development, which have been successfully applied to VE development. These methods include *user task analysis*, *expert guidelines-based evaluation* (also sometimes called *heuristic evaluation* or *usability inspection*), and *formative usability evaluation*. Summative evaluation is also discussed because it is an important aspect of making comparative assessments of VEs from a user's perspective. Further, we postulate that, like GUI development, there is no single method for VE usability engineering. Thus, this chapter addresses how each of these methodologies supports focused, specialized design, measurement, management, and assessment techniques such as those presented in other chapters (see chaps. 11, 13, 16, 17, 21, 25, and 35, this volume). Our experiences with usability engineering of three different VEs are included in this discussion: a CAVETM (Cave Automatic Virtual Environment)-based medical volume-imaging system; a Responsive Workbench-based military command and control application; and a new interaction technique for desktop virtual environments.

2. SETTING THE CONTEXT FOR VE USABILITY ENGINEERING

Before specific usability engineering methods are presented and examples of their application are given, it is important to set the context for usability engineering. Developers of interactive systems—systems with user interfaces—often confuse the boundaries between the software engineering process and the usability engineering process. This is due at least in part to a lack of understanding of techniques for usability engineering, as well as which of these techniques is appropriate for use at which stages in the development process. Software engineering has as a goal to improve software quality, but this goal, in and of itself, has little impact on the usability of the resulting interactive system, in this case, a virtual environment. For example, well-established “v&v” (validation and verification) techniques focus on software correctness, robustness, and so on, from a software developer’s view, with little or no consideration of whether that software serves its users’ needs. Thus, quality of the *user interface*—the usability—of an interactive system is largely independent of quality of the software for that system. Usability of the user interface is ensured by a user-centered focus on developing the *user interaction component*—the look, feel, and behavior as a user interacts with an application. The user interaction component includes all icons, text, graphics, audio, video, and devices through which a user communicates with an interactive system. Interaction designers and evaluators develop the user interaction component (see chaps. 11–13, this volume). Usability is unaffected by the *software component*, including that for both the user interface and the rest of the application (i.e., the non-user-interface software). Software engineers and systems engineers develop the software component of an interactive system.

Cooperation between usability engineers and software engineers is essential if VEs are to mature toward a truly user-centric work and entertainment experience. Thus, both the interaction component and the software component are necessary for producing any interactive system, including a VE, but the component that *ensures usability* is the user interaction component.

3. CURRENT USABILITY ENGINEERING METHODS

Current research at Virginia Tech aims to address the applicability of established usability engineering methods in conjunction with development of new usability engineering methods.

Simply put, our goal is to provide a methodology, or set of methodologies, to ensure usable and useful VE interfaces.

Usability engineering methods typically consist of one or more usability evaluation, or inspection, methods. Usability inspection is a process that aims to identify usability problems in user interaction design, and hence, end use (Nielsen & Mack, 1994).

As already mentioned, many of the techniques presented have been derived from usability engineering methods for GUIs. But from our own studies, as well as from collaboration with and experiences of other VE researchers and developers, GUI methods have been adapted, producing new methods for usability engineering of VE user interaction design. Adaptations and enhancements to existing methods have been made at two levels to evolve a usability engineering methodology applicable to virtual environments. Specific methods themselves had to be altered and extended to account for the complex interactions inherent in multimodal VEs (see chaps. 21–22, this volume), and various methods had to be applied in a meaningful sequence to both streamline the usability engineering process as well as provide sufficient coverage of the usability space.

To better understand the strengths and applicability of each individual GUI usability engineering method, we present a basic discussion of each method, to provide a brief overview of each. Following the discussion of individual methods, we discuss benefits and insights gained from sequential application of these adapted methods for VE user interaction development.

3.1 User Task Analysis

A *user task analysis* is the process of identifying a complete description of tasks, subtasks, and actions required to use a system as well as other resources necessary for user(s) and the system to cooperatively perform tasks (Hix & Hartson, 1993).

User task analyses follow a formal methodology, describing and assessing performance demands of user interaction and application objects. These demands are, in turn, compared with known human cognitive and physical capabilities and limitations, resulting in an understanding of the performance requirements of end users. User task analysis (Hackos & Redish, 1998) may be derived from several components of early systems analysis, and at the highest level, rely on an understanding of several physical and cognitive components. User task analyses are the culmination of insights gained through an understanding of user, organizational, and social work flow, needs analysis, and user modeling.

There are four generally accepted techniques for performing user task analysis: documentation review, questionnaire survey, interviewing, and observation (Eberts, 1999). Documentation review seeks to identify task characteristics as derived from technical specifications, existing components, or previous legacy systems. Questionnaire surveys are generally used to help evaluate interfaces that are already in use or have some operational component. In these cases, task-related information can be obtained by having domain experts such as existing users, trainers, or designers complete carefully designed surveys. Interviewing an existing or identified user base, along with domain experts and application “visionaries,” provides very useful insight into what users need and expect from an application. Observation-based analysis, on the other hand, requires a user interaction prototype, resembling more the formative evaluation process than development of user task analysis, and as such, is used as a last resort. A combination of early analysis of application documentation and domain-expert and user interviewing typically provides the most useful and rich task analysis.

While user task analyses are typically performed early in the development process, it should be noted that, like all aspects of user interaction development, task analyses also need to be flexible and potentially iterative, allowing for modifications to performance and user interaction

requirements during any stage of development. However, major changes to user task analysis during late stages of development can derail an otherwise effective development effort, and as such should only be considered under dire circumstances.

User task analysis generates critical information used throughout all stages of the application development life cycle. One such result is a top-down decomposition of detailed task descriptions. These descriptions serve, among other things, as an enumeration of desired functionality for designers and evaluators. Equally revealing results of task analysis include an understanding of required task sequences as well as sequence semantics. Thus, results of task analysis include not only identification and description of tasks, but ordering, relationships, and interdependencies among user tasks. These structured analytical results set the stage for other products of task analysis, including an understanding of information flow as users work through various task structures.

User task analysis also provides indications of where and how users contribute information to, and are required to make decisions that influence, user task sequencing. This information, in turn, can help designers identify which part(s) of the tasking process can be automated by computer (one of the original and still popular services a computer may provide), affording a more productive and useful work environment.

Without a clear understanding of user task requirements, both evaluators and developers are forced to “best guess” or interpret desired functionality, which inevitably leads to poor interaction design. Indeed, both user interaction developers and user interface software developers claim that poor, incomplete, or missing task analysis is one of the most common causes of both poor software and product design.

3.2 Expert Guidelines-based Evaluation

Expert guidelines-based evaluation, or *heuristic evaluation*, or *usability inspection* aims to identify potential usability problems by comparing a user interaction design, either existing or evolving, to established usability design guidelines. The identified problems are then used to derive recommendations for improving interaction design. This method is used by usability experts to identify critical usability problems early in the development cycle so that design issues can be addressed as part of the iterative design process (Nielsen, 1994b).

Expert guidelines-based evaluations rely on established usability guidelines to determine whether a user interaction design supports intuitive user-task performance (i.e., usability). Nielsen (1994a) recommends three to five evaluators for an expert guidelines-based evaluation because fewer evaluators generally cannot identify enough problems to warrant the expense, and more evaluators produce diminishing results at higher costs. It is not clear whether this recommendation is cost-effective for VEs, because more complex VE interaction designs may require more evaluators than GUIs. Each evaluator first inspects the design alone, independently of other evaluators’ findings. Results are then combined, documented, and assessed as evaluators communicate and analyze both common and conflicting usability findings.

An expert guidelines-based evaluation session may last one to two hours or more, depending on the complexity of the design. Again, VE interaction designs may require more time for full exploration. Furthermore, expert guidelines-based evaluation can be done using a simple pencil and paper design (assuming that the design is mature enough to represent a reasonable amount of interaction components and interactions). This allows assessment to begin very early in the application development life cycle.

The output from an expert guidelines-based evaluation should not only identify problematic interaction components and interaction techniques, but should also indicate why a particular component or technique is problematic. Results from expert guidelines-based evaluation are subsequently used to remedy obvious and critical usability problems as well as to shape the design of subsequent formative evaluations (see section 3.3). Evaluation results further serve as

both a working instructional document for user-interface software developers, and more importantly, as fundamentally sound, research-backed, design rationale.

Given that expert guidelines-based evaluations are based largely on a set of usability heuristics, it can be argued that these evaluations are only as effective and reliable as the guidelines themselves. Nielsen and Molich (1990) and Nielsen (1994a), respectively, present the original and revised set of usability heuristics for traditional GUIs. While these heuristics are considered to be the de facto standard for GUIs, they are too general, ambiguous, and high-level for effective and practical expert guidelines-based evaluation of virtual environments. Effectiveness is questioned on the simple fact that three-dimensional (3-D), immersive, VE interfaces are much more complex than traditional GUIs. The original heuristics (implicitly) assume traditional input–output devices such as keyboard, mouse, and monitor, and do not address the appropriateness of VE devices such as CAVEs, head-mounted displays (HMDs), haptic and tactile gloves, and various force feedback devices. Determining appropriate VE devices for a specific application and its user tasks is critical to designing usable virtual environments. Practicality is questioned due to the abstractness of the heuristics; VE evaluators need specific, concrete guidelines to apply in rapid and reliable evaluations.

It is well recognized that VE interfaces and VE user interaction are immature and currently emerging technologies for which standard sets of design, much less usability guidelines, do not yet exist. However, our recent research at Virginia Tech has produced a set of VE usability design guidelines, contained within a framework of usability characteristics (Gabbard, 1997). This framework document (see <http://csgrad.sc.vt.edu/~jgabbard/ve/framework>) provides a reasonable starting point for expert guidelines-based evaluation of virtual environments. The complete document contains several associated usability resources including specific usability guidelines, detailed context-driven discussion of the numerous guidelines, and citations of additional references.

The framework organizes VE user interaction design guidelines and the related context-driven discussion into four major areas: users and user tasks, input mechanisms, virtual model, and presentation mechanisms. The framework categorizes 195 guidelines covering many aspects of VEs that affect usability including navigation, object selection and manipulation, user goals, fidelity of imagery, input device modes and usage, interaction metaphors, and much more. The guidelines presented within the framework document are well suited for performing expert guidelines-based evaluation of VE user interaction because they provide both broad coverage of VE interaction/interfaces and are specific enough for practical application. For example, with respect to navigation within VEs, one guideline reads “provide information so that users can always answer the questions: Where am I now? What is my current attitude and orientation? Where do I want to go? How do I travel there?” Another guideline addresses methods to aid in usable object selection techniques stating “use transparency to avoid occlusion during selection.”

These guidelines have been successfully used within context as a basis for expert guidelines-based evaluation of several VEs ranging from medical visualization to command and control situational awareness applications (see sections 4.1–4.3 for details).

3.3 Formative Usability Evaluation

The term *formative evaluation* was coined by Scriven (1967) to define a type of evaluation that is applied during evolving or formative stages of design. Scriven used this in the educational domain for instructional design. Williges (1984) and Hix and Hartson (1993) extended and refined the concept of formative evaluation for the human–computer interaction (HCI) domain.

The goal of formative evaluation is to assess, refine, and improve user interaction by iteratively placing representative users in task-based scenarios in order to identify usability problems, as well as to assess the design’s ability to support user exploration, learning, and

task performance (Hix & Hartson, 1993). Formative usability evaluation is an observational evaluation method that ensures usability of interactive systems by including users early and continually throughout user interface development. The method relies heavily on usage context (e.g., user task, user motivation) as well as a solid understanding of human-computer interaction (and in the case of VEs, human-VE interaction) and, as such, requires the use of usability experts (Hix & Hartson, 1993).

While the formative evaluation process was initially intended to support iterative development of instructional materials, it has proven itself to be a useful tool for evaluation of traditional GUI interfaces. Moreover, in the past few years, we have seen firsthand evidence indicating that the formative evaluation process is also an efficient and effective method of improving the usability of VE interfaces (Hix et al., 1999a).

The steps of a typical formative evaluation cycle begin with development of user task scenarios that are specifically designed to exploit and explore all identified tasks, information, and work flows. Representative users perform these tasks as evaluators collect both qualitative and quantitative data. These data are then analyzed to identify user interaction components or features that both support and detract from user task performance. These observations are in turn used to suggest user interaction design changes as well as formative evaluation scenarios and observation (re)design.

The formative evaluation process itself is iterative, allowing evaluators to continually refine user task scenarios in order to fine-tune both the user interaction and the evaluation process. Contrary to popular belief, the formative evolution process produces both qualitative and quantitative results collected from representative users during their performance of task scenarios (del Galdo, Williges, Williges, & Wixon, 1986). One type of qualitative data collected is termed *critical incidents* (del Galdo et al., 1986; Hix & Hartson, 1993). A critical incident is a user event that has a significant impact, either positive or negative, on users' task performance and/or satisfaction (e.g., a system crash or error, being unable to complete a task scenario, user confusion). Critical incidents that have a negative effect on users' work flow can drastically impede usability and may even have a dramatic effect on users' perceptions of application quality, usefulness, and reputation. As such, any obvious critical incidents are best discovered during formative evaluation phases as opposed to during consumer desktop use.

Equally important are the quantitative data collected during formative evaluation. These data include measures such as how long it takes a user to perform a given task, the number of errors encountered during task performance, and others. Collected quantitative data are then compared to appropriate baseline metrics, sometimes initially redefining or altering evaluators' perceptions of what should be considered baseline. Both qualitative and quantitative data are equally important because they each provide unique insight into an interaction design's strengths and weaknesses.

3.4 Summative Evaluation

Summative evaluation, in contrast to formative evaluation, is typically performed after a product or design is more or less complete. Its purpose is to statistically compare several different systems, for example, to determine which one is "better," where better is defined in advance. Another goal of summative evaluation is to measure and subsequently compare the productivity and cost benefits associated with various designs. In this fashion, evaluators are simply comparing the best of a few refined designs to determine which of the "finalists" is best-suited for delivery.

The term *summative evaluation* was also coined by Scriven (1967) for use in the instructional design field. As with the formative evaluation process, HCI researchers (e.g.,

Williges, 1984) have applied the theory and practice of summative evaluation to interaction design with surpassingly successful results.

In practice, summative evaluation can take on many forms. The most common are the comparative, field trial, and more recently, the expert review (Stevens, Frances, & Sharp, 1997). While both the field trial and expert review methods are well-suited for instructional content and design assessment, they typically involve assessment of single prototypes or field-delivered designs. In the context of VE design, we are mostly interested in assessing the quality of two or more user interaction designs, and as such, have focused on the comparative approach. Our experiences have found that this approach is very effective for analyzing the strengths and weaknesses of various well-formed, completed designs using representative user scenarios.

Stevens et al. (1997) present a short list of questions that summative evaluation should address. These questions have been modified to address summative, comparative evaluation of VE user interfaces. The questions include:

- What are the strengths and weaknesses associated with each user interaction design?
- To what extent does each user interaction design support overall user and system goal(s)?
- Did users perceive increased utility and benefit from each design? In what ways?
- What components of each design were most effective?
- Was the user interaction evaluation effort successful? That is, did it provide a cost-effective means of improving design and usability?
- Were the results worth the program's cost?

3.5 A Cost-effective Progression

As previously mentioned, one of our long-term research goals is to produce methodologies to improve the usability of VE user interaction designs. More specifically, the goal is to develop, modify, and fine-tune usability engineering techniques specifically for virtual environments. Techniques to aid in usability engineering of VEs will mature, and as such, the potential for conducting effective evaluations and delivering subsequent usable and useful VEs will increase.

Our current efforts are focusing on the combination of usability evaluation techniques described in sections 3.1 to 3.4. As depicted in Fig. 34.1, our applied research over the past several years has shown that, at a high level, progressing from user task analysis to expert guidelines-based evaluation to formative evaluation to summative evaluations is an efficient and cost-effective strategy for designing, assessing, and improving the user interaction—usability engineering—of a virtual environment (Gabbard, Hix, & Swan, 1999).

One of the strengths of this progression is the fact that it exploits a natural ordering or evolution of interaction design and prototyping, with each method generating a streamlined set of information that the next method utilizes. In this sense, each method is able to generate a much better starting point for subsequent methods than when applied in a stand-alone fashion. Moreover, simply applying more than one usability engineering method ensures more complete coverage of an interaction design's "usability space," each revealing its niche of particular usability problems and collectively shaping a more usable virtual environment. Finally, the progression of methods also produces a "paper trail" of persistent documentation that may serve as documented design rationale.

This progression is very cost-effective for assessing and improving virtual environments. For example, summative studies are often performed on VE interaction designs that have had little or no task analysis or expert guidelines-based or formative evaluation. This may result in a

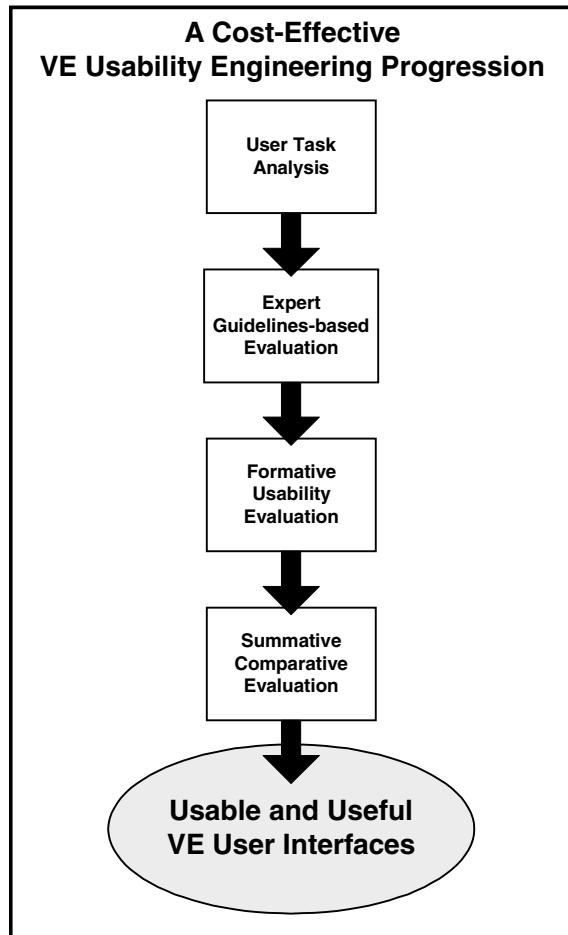

FIG. 34.1. A cost-effective progression of usability engineering methods.

situation where the expensive summative evaluation is essentially comparing “good apples” to “bad oranges” (Hix, Swan, Gabbard, McGee, Durbin, & King, 1999a). Specifically, a summative study of two different VEs may be comparing one design that is inherently better, in terms of usability, than the other one. When all designs in a summative study have been developed following the suggested progression of usability engineering, then the comparison is more valid. Experimenters will then know that the interaction designs are basically equivalent in terms of their usability, and any differences found among compared designs are, in fact, due to variations in the fundamental nature of the designs and not their usability.

4. APPLICATION OF USABILITY ENGINEERING METHODS

The following case studies present the application of usability engineering methods to interaction design of three different VE applications. The first, called Crumbs, is a medical imaging system developed to run in the CAVE. The next, called Dragon, is a military command and control application developed for the Responsive Workbench. The third, called pre-screen projection, is a new interaction technique developed for desktop virtual environment. The first two VE applications and their user interaction design are at different phases in their development

and assessment. Specifically, Crumbs is in the formative evaluation phase and Dragon is in the summative evaluation phase. The discussion of pre-screen projection is the most detailed, because that work is essentially complete at the time of this writing. The important point is that for each of these VE applications, the usability engineering methods described above have been followed with great success in evolving the interaction design.

4.1 Crumbs

Crumbs is a VE application used as a tracking tool for biological and medical images, developed by the NCSA Biological Imaging Group at the University of Illinois (Brady et al., 1995). A goal of Crumbs is to facilitate identification of complex biological structures in images by allowing users to visualize dense volumetric data sets in an immersive VE, namely, the CAVE. Users can also mark (using a “bread crumb” metaphor) and measure individual structures in the data set they are viewing and manipulating. Magnetic resonance images and laser scanning confocal microscope images were predominantly used in Crumbs during the usability engineering activities herein described.

Crumbs was developed at NCSA, and Virginia Tech personnel were not involved from the beginning. The first collaboration between NCSA and Virginia Tech researchers was to conduct an expert guidelines-based evaluation of a fairly well-developed version of Crumbs. The framework of usability characteristics of VEs (Gabbard, 1997) discussed in section 3.2 was the basis for this evaluation. Proceeding methodically through the framework, a syntactic analysis of the Crumbs’ user interaction design was performed. Evaluation was primarily focused on those features that could be determined by an expert inspection and comparison to the guidelines in the framework. The evaluators were not expert Crumbs users, so could not effectively perform an in-depth semantic analysis that would have determined more details about whether Crumbs’ interaction design supported all appropriate user tasks that were needed. However, the syntactic analysis revealed numerous usability issues that were then addressed by evaluators collaboratively with the Crumbs developers.

Specifically, following the four main areas of the framework, VE users and user tasks as supported in Crumbs, the virtual model of Crumbs, the VE user interface input mechanisms, and the VE user interface presentation mechanisms were assessed. For example, in VE user interface presentation mechanisms, usability issues with objects including the color map, a slice plane, and a trashcan icon, particularly inconsistencies across these different objects and their manipulation were found. In VE user interface input mechanisms, pop-up menus were attached to the current location of the cursor and therefore often appeared very near the bottom of the front wall of the CAVE. This made it very difficult for users to make a selection. Further, numerous problems were uncovered with the wand device used to manipulate and navigate through the Crumbs application. The final report to Crumbs developers included more than a dozen suggestions for substantial changes to the Crumbs user interaction design (Swartz, 1998). This report included the framework usability design guideline that was violated, the potential usability problem therefore resulting, and one or more specific recommendations for fixing the usability problem. Most recommendations were incorporated before moving on to the current state of Crumbs development, which is the formative evaluation phase (Gabbard et al., 1999b; Swartz, Thakkar, Hix, & Brady, 2000).

Formative evaluations thus far have been performed in the NCSA CAVE; future ones will also be conducted in the Virginia Tech CAVE. In the first formative evaluation, users with a priori knowledge of Crumbs were chosen. This was, in part, to determine whether the changes made from the expert guidelines-based evaluation resulted in an improvement of the user interaction design. This assessment was largely anecdotal, because there were no metrics from use of the original Crumbs interaction design. A second reason for choosing participants

already familiar with Crumbs was to avoid the fairly long learning curve needed to become familiar with a very complicated, very specialized application. Someone who knows nothing about magnetic resonance images or confocal microscope images would not be a representative user of Crumbs. The choice of effective participants was somewhat limited because of the complexity of the application domain and resulting scarcity of appropriate users. Although participants varied in their individual experience with Crumbs, their familiarity with it and related appropriate tasks provided adequate consistency across the participants chosen. Of the five participants in the first formative evaluation, two had largely used Crumbs to give demonstrations, whereas the other three had used Crumbs for "real work."

The first formative evaluation session was actually a pilot session to make sure the evaluation protocol was effective and reasonable. Some problems were found with the original protocol, which were amended in subsequent sessions. In particular, the plan was to have two evaluators present for each session, because of the large amount of data that are generated during a session. One evaluator was intended to be in the CAVE near the participant to serve as a facilitator and to keep the session moving along. The second evaluator was to be outside the CAVE, taking timings, counting errors, and collecting critical incidents that occurred and other qualitative data as a participant attempted to perform tasks with Crumbs. However, we quickly found that having an evaluator in the CAVE with the participant was very distracting for the participant. The evaluator often unintentionally got in the way as the participant moved around during task performance despite the evaluator's best efforts to stay out of the way. The evaluator also sometimes accidentally got tangled in wires across the floor of the CAVE, which further distracted the participant, who did not seem to get entangled. Perhaps the major problem was that the evaluator's presence was found to reduce the participant's sense of presence and immersion in the environment (see chap. 40, this volume), and therefore reduced the participant's productivity and focus on the Crumbs tasks. Modifications to the evaluation protocol were made so that all evaluators were located outside the CAVE, with the one serving as mediator nearest its open edge. For some sessions there were three evaluators, all of whom were kept busy collecting timing, error, and critical incident data in the complex Crumbs application.

Results from both guidelines-based and formative evaluations indicated numerous usability problems. For example, users encountered difficulties with use of buttons on the CAVE wand for various modes in Crumbs, especially a scale and mark mode. Several inconsistencies in the Crumbs interaction design also caused problems, including inconsistent use of directly manipulating various types of objects, and inconsistent ways of selecting objects. Users also had difficulty knowing where they were in Crumbs at any point in time, especially on task completion. A major usability issue was occlusion of 3-D objects by other objects, which contributed to multiple user errors and long task completion times. Further, some audio cues that were intended to help users actually annoyed them. For each usability issue, one or more redesign suggestions were made based on the framework of usability characteristics of virtual environments. Many of these redesign recommendations were incorporated into Crumbs by its developers at NCSA.

4.2 Dragon

Personnel at the Naval Research Laboratory's Virtual Reality Laboratory, again in collaboration with Virginia Tech researchers, have developed a VE for battlefield visualization, called Dragon (Hix et al., 1999a). Implemented on a Responsive Workbench, Dragon's metaphor for visualizing and interacting with 3-D computer-generated scenery uses a familiar tabletop environment. Applications in which several users collaborate around a work area, such as a table, are excellent candidates for the Workbench. This metaphor is especially familiar to Naval

personnel and Marines, who have, for decades, accomplished traditional battlefield visualization on a tabletop. Paper maps of a battlespace are placed under sheets of acetate. As intelligence reports arrive from the field, technicians use grease pencils to mark new information on the acetate. Commanders then draw on the acetate to plan and direct various battlefield situations. Historically, before high-resolution paper maps, these operations were performed on a sandtable, literally a box filled with sand shaped to replicate battlespace terrain. Commanders moved around small physical replicas of battlefield objects to direct battlefield maneuvers. The fast-changing modern battlefield produces so much time-critical information that these cumbersome, time-consuming methods are inadequate for effectively visualizing and commanding a modern-day battlespace.

Dragon was developed on the Responsive Workbench to give a 3-D display for observing and managing battlefield information shared among technicians and commanders. Visualized information includes a high-resolution terrain map; entities representing friendly, enemy, unknown, and neutral units; and symbology representing other features such as obstructions or key map points. Users can navigate to observe the map and entities from any angle and orientation around the Workbench.

Dragon's early development was based on an admittedly cursory user task analysis, which drove early design. This was followed, however, by numerous cycles of expert guidelines-based evaluation as well as formative evaluations. Early in Dragon design, three general interaction methods for the Workbench were produced and assessed, any of which could have been used to interact with Dragon: hand gestures using a pinch glove (Obeysekare et al., 1996), speech recognition, and a handheld flightstick. Although it was an interesting possibility for VE interaction, formative evaluations found that speech recognition is still too immature for battlefield visualization. Further, the pinch glove was found to be too fragile and time-consuming to pass from user to user around the Workbench. It also worked best for right-handed users whose hands were approximately the same size. In contrast, formative evaluations revealed that the flightstick was robust, easily handed from user to user, and worked for both right- and left-handed users.

Based on these formative evaluations, a three-button game flightstick was modified by removing its base and placing a 6-degree-of-freedom position sensor inside. Initial designs used a laser pointer metaphor in which a laser beam appeared to come out the "head" of the flightstick as a user pointed it toward the VE map. When a beam intersected terrain or an object, a highlight marker appeared.

In early demonstrations of initial versions of Dragon in real military exercises for battlefield planning, users indicated they found Dragon's accurate and current visualization of the battlespace to be more effective and efficient than the traditional method of maps, acetate, and grease pencils. Following these successful demonstrations and positive feedback, we began intensive usability engineering of Dragon's user interaction design.

During early demonstrations and evaluations, user observation indicated that navigation (how users manipulate their viewpoint to move from place to place in a virtual world, in this case, the battlefield map), profoundly affects all other user tasks (see chap. 24, this volume). If a user cannot successfully navigate to move about in a virtual world, then other user tasks such as selecting an object or grouping objects cannot be performed. A user cannot query an object if the user cannot navigate through the virtual world to get to that object. Although a user task analysis was performed before guidelines-based and formative evaluations, these evaluations supported expectations of the importance of navigation.

Expert guidelines-based evaluation was done extensively for Dragon, prior to much formative evaluation. However, the framework of usability characteristics of VEs were being developed at the same time the guidelines-based evaluation was performed, and so the guidelines used were much more ad hoc and less structured than those that eventually became the framework.

Nonetheless, even informal inspection of the evolving Dragon interaction design provided tremendous feedback in what worked and what did not, especially for use of the wand and other aspects of navigation in Workbench VE applications in general, and Dragon in particular. During these evaluations, VE user interaction design experts worked alone or collectively to assess the Dragon interaction design. In the earliest evaluations, the experts did not follow specific user task scenarios per se, but engaged simply in “free play” with Dragon using the wand. All experts knew enough about the purpose of Dragon as a battlefield visualization VE to explore the kinds of tasks that would be more important for Dragon users. During each session, one person was typically “the driver,” holding the flightstick and generally deciding what and how to explore in the application. One and sometimes two other experts were observing and commenting as the “driver” worked, with much discussion during each session. Major design problems that were uncovered in the expert guidelines-based evaluation of Dragon included: poor mapping of navigation tasks (i.e., pan, zoom, pitch, heading) to flightstick buttons; missing functionality (e.g., exocentric rotate, terrain following); problems with damping of map movement in response to flightstick movement; and graphical and textual feedback to the user about the current navigation task. After these evaluations had revealed and remedied as many design flaws as possible, we moved on to formative evaluation.

The basic Dragon application was used to perform extensive formative evaluations, using anywhere from one to three users for each cycle of evaluation. A single evaluation session often uncovered design problems so serious that it was pointless to have a different user attempt to perform scenarios with the same design. The design was iterated, based on these observations, and then a new cycle of evaluation was commenced, undergoing four major cycles of iteration in all.

In designing scenarios for formative evaluation, coverage of specific usability issues related to navigation was carefully considered. For example, some of the tasks exploited an egocentric (user moves through the virtual world) navigation metaphor, whereas others exploited an exocentric (user moves the world) navigation metaphor. Some scenarios exercised various navigation tasks (e.g., degrees of freedom: pan, zoom, rotate, heading, pitch, roll) in the virtual map world. Other scenarios served as primed exploration or nontargeted searches for specific features or objects in the virtual world. Still others were designed to evaluate rate controlled interaction techniques versus position controlled interaction techniques (see chap. 13, this volume).

During each of six formative evaluation sessions, the participant was first asked to play with the flightstick to figure out which button activated which navigation task. Each user was timed as they attempted to determine this, and notes were taken on comments and any critical incidents that occurred. Once a user had successfully figured out how to use the flightstick, they formally performed the task scenarios. Only one user was unable to figure out the flightstick in less than 15 minutes; this user was told details they had not yet discovered and proceeded with the scenarios.

Time to perform the set of scenarios ranged from about 20 minutes to more than 1 hour. User performance of individual tasks and scenarios was timed and errors made during task performance were counted. A typical error was moving the flightstick in the wrong direction for the particular navigation metaphor (exocentric or egocentric) that was currently in use. Other errors involved simply not being able to maneuver the map (e.g., to rotate it) and persistent problems with mapping navigation tasks (degrees of freedom) to flightstick buttons, despite extensive prior evaluations to minimize this issue. During each formative evaluation session, at least two and often three evaluators were present. One served as the facilitator to interact with the participant and keep the session moving; the other one or two evaluators recorded times, counted errors, and collected critical incidents and other qualitative data. While these sessions (like those of Crumbs in the CAVE) seem personnel-intensive, with two or three evaluators involved, the quality and quantity of data collected by multiple evaluators was found to greatly

outweigh the cost of those evaluators. A surprising amount of effort was spent on mapping flightstick buttons to navigation tasks (pan, zoom, rotate, heading, pitch, roll), but it was found to pay off with more effective, intuitive mappings.

As mentioned earlier, we went through four major iterations of the Dragon interaction design, based on our evaluations. The first iteration, the Virtual Sandtable, was an egocentric navigation metaphor based on the sandtable concept briefly described earlier. This was the version demonstrated in the military exercises also mentioned previously. A key finding of this iteration was that users wanted a terrain-following capability, allowing them to “fly” over the map, an egocentric design. Map-based navigation worked well when globally manipulating the environment and conducting operations on large-scale units. However, for small-scale operations, users wanted this “fly” capability to visually size up terrain features, entity placement, fields of fire, lines of sight, and other characteristics.

The second iteration, Point and Go, used the framework of usability characteristics of VEs to suggest various possibilities for an egocentric navigation metaphor design. This metaphor attempted to avoid having different modes (and flightstick buttons) for different navigation tasks because of known usability problems with moded interaction. Further, this decision was based on how a person often navigates to an object or location in the real world; namely, they point (or look) and then go (move) there. Our reasoning was that adopting this same idea to egocentric navigation would simplify the design and at least loosely mimic the real world. In this design, a user simply pointed the flightstick toward a location or object of interest and pressed the trigger to fly there. The single gesture to move about was not powerful enough to support the diverse, complicated variety of navigation tasks inherent in Dragon. Furthermore, a single gesture meant that all degrees of freedom were controlled by that single gesture. This resulted in, for example, unintentional rolling when a user only wanted to pan or zoom. Essentially, this presented a control versus convenience trade-off. Many navigation tasks (modes) were active simultaneously, which was convenient, but difficult to physically control for a user. With separate tasks (modes) there was less convenience, but physical control was easier because degrees of freedom were more limited in each mode. In addition to these serious problems, users wanted to rotate around an object, such as to move completely around a tank. This indicated that Dragon needed an exocentric rotation ability, which was added. This interesting finding showed that neither a pure egocentric nor a pure exocentric metaphor was desirable; each metaphor has aspects that are more or less useful depending on user goals. While this may seem obvious, it was confirmed by users through the formative evaluation approach. Further, the somewhat poor performance of what we thought was the natural “point and go” metaphor was rather counterintuitive, and further demonstrates that mimicking VE design after the real world is not always successful from the VE user’s perspective.

The third iteration, Modal, went from the extreme of all navigation tasks coupled on a single button, as in the previous iteration, to a rather opposite design in which each navigation task was a separate mode. Specifically, as a user clicked the left or right flightstick button, Dragon cycled successively through the tasks of pan, zoom, pitch, heading, and exocentric rotate. A small textual indicator was displayed on the Workbench to show the current mode. Once a user had cycled to the desired task, the user simply moved the flightstick and that task was enabled with no need to push any flightstick button. As expected, it was very cumbersome for users to always have to cycle between modes, and it was obvious that a compromise between convenience and control still had not been achieved.

In the fourth iteration of the Dragon interaction design, Integrated Navigation, based on the framework of usability characteristics of VEs and user observations of what degrees of freedom could be logically coupled in the Dragon application, a hybrid design of the modeless/moded designs of prior iterations was produced. Specifically, pan and zoom were coupled onto the flightstick trigger, pitch, and heading onto the left flightstick button, and exocentric

* Adapted from Gabbard (1997).

rotate and zoom onto the right flightstick button. This fourth generation interaction design for Dragon finally achieved the desired convenience versus control compromise. Final formative evaluation studies revealed that this was a design for navigation that seemed to work well. The only usability problem observed was minor: Damping of map movement was too great and needed some adjustment, which was made.

As the formative evaluation cycles neared completion for Dragon, summative studies for the navigation design were planned. Design parameters that affect usability of the VE navigation metaphor to be studied in summative evaluations are those that, in general, could not be decided from the formative evaluations. Twenty-eight such design parameters were identified, as shown in Table 34.1, that potentially affect the usability of user navigation. The organization of these parameters is based on the framework of usability characteristics of virtual environments. The four main areas of this framework are the headings in Table 34.1, and design parameters for navigation are grouped based on these areas.

Based on observations during evaluations, extensive literature review, and our expertise in VE interaction design, the numerous variables have been narrowed to five that we feel are most critical for navigation, and therefore most important for the first cycle of summative evaluations. These five variables and their level of treatment in our summative study are:

- Navigation metaphor (ego- versus exo-centric)
- Gesture mapping (rate vs. position of hand movement)
- Visual presentation device (Workbench, desktop, CAVETM)
- Head tracking (present vs. absent)
- Stereopsis (present vs. absent)

This summative study has been performed on four presentation devices (i.e., Workbench, desktop, CAVE, one wall of CAVE) and we are analyzing results at the time of this printing. It is, we believe, one of the first formal studies to directly compare four different VE devices using the same application and the same user tasks.

4.3 Pre-screen Projection

Pre-screen projection is a new interaction technique (described below) developed at the Naval Research Laboratory's Human-Computer Interaction Laboratory (Hix, Templeman, & Jacob, 1995; Hix et al., 1999b), with strong collaboration by Virginia Tech researchers beginning very early in the development process and continuing throughout. An *interaction technique* is a way in which a human uses a physical input-output device to perform a task during human-computer interaction (Foley et al., 1990; see chap. 13, this volume). It abstracts a class of generic interactive tasks, for example, selecting an object on a screen by pointing and clicking with a mouse. A pop-up menu is an interaction technique. Interaction techniques are a useful research topic because they are specific enough to be studied, yet general enough to have practical applicability to a broad variety of interactive systems. But, like VEs, research specifically in interaction techniques often emphasizes technological creativity, while user-based evaluation of techniques is either cursory or nonexistent. Thus, over the years, a plethora of interaction techniques, both for GUIs and for VEs, have been developed, but to date too little is known about their impact on the usability of interactive systems. There is scant empirical evidence of whether they improve human performance and satisfaction.

Creating the new interaction technique of pre-screen projection involved many steps, beginning with its conceptualization, for example, the idea, the real-world metaphor, or whatever forms a technique's underlying motivation. User task analysis followed conceptualization to drive the design of the technique, going from general abstractions to specific details. Next came prototyping and extensive formative evaluation to determine what use of the technique "feels like." Eventually the technique was implemented in the context of user tasks and an application, on which summative evaluation was performed.

Pre-screen projection allows a user to pan and zoom integrally through a scene simply by moving the head relative to the screen. Its conceptualization is based on real-world visual perception (Gibson, 1986), namely, the fact that a person's view changes as the head moves. Pre-screen projection tracks a user's head in three dimensions and alters the display on the screen relative to head position, giving a natural perspective effect in response to a user's head movements. Further, projection of a virtual scene is calculated as if that scene were in front of the screen. As a result, the visible scene displayed on the physical screen expands (zooms) dramatically as a user moves closer. This is analogous to the real world, where the nearer an object is, the more rapidly it visually expands as a person moves toward it. Using pre-screen projection, a user wears a lightweight helmet or headband with a 3-D motion tracker mounted on the front. As the user moves from side to side, the display smoothly pans over the world view. As the user moves closer to or further from the screen, the display smoothly zooms in and out, respectively. The virtual scene is calculated to appear as if it were 20 inches *in front* of the physical screen. Thus, the scene is displayed on the physical screen, but its dynamic perspective from the user's viewpoint reacts to head movements as if the scene were in front of the screen. This causes the scene to enlarge more rapidly than the screen as a user moves toward it and therefore produces a dramatic zoom.

Having developed this concept to underlie pre-screen projection, we began the challenge of designing and instantiating the interaction technique, which included the usability engineering methods of user task analysis, detailed design, and formative evaluation followed by iterative refinement. The intent was to incorporate pre-screen projection into an application that would

provide a realistic situation for its evaluation. Panning and zooming, which pre-screen projection supports, are inherently spatial, navigational information-seeking activities; that is, a user navigates through an information space. To design and evaluate pre-screen projection, we wanted to have user tasks that would place heavy demands on a user's ability to pan and zoom. Thus, a critical aspect of this research was the co-evolution of appropriate user tasks along with the interaction technique, to produce tasks for evaluating pre-screen projection, rather than for producing the best possible application. This approach reemphasizes the definition of an interaction technique as a means of performing tasks. Prior research at the Naval Research Laboratory's Human-Computer Interaction Laboratory (Jacob & Sibert, 1992) used rather simplistic, nonmilitary, low-fidelity domains and tasks. Because we wanted our work to be relevant to specific naval applications, we chose Naval command and control systems (C^2 systems) as a rich, realistic application domain for usability engineering of pre-screen projection. These systems, simply explained, support the planning, coordination, and execution of a military mission. Pre-screen projection was incorporated into a C^2 -like testbed and task scenarios were created for evaluation.

C^2 is a highly diverse, extremely rich and demanding application area with a breadth and depth of tasks that its users perform. Based on interviews with appropriate military personnel, a detailed literature review, and other resources, a detailed user task analysis of such systems was performed to determine the design space from which to select possible tasks. Participants to whom access was available for evaluation were, in general, civilians with little or no military background. Thus, selecting and designing specific tasks to evaluate pre-screen projection that were rich enough, yet were unbiased and simple enough for users to learn quickly, was a crucial issue. The interaction technique and goals for its evaluation should drive task development, but in reality they are very closely coupled. Simple user tasks were often found to work best for evaluation because they tended not to confound learnability and other issues of the application itself with the issues of evaluation of the interaction technique.

From user task analysis, a subset of defensive engagement tasks were chosen, in which friendly, enemy, unknown, and neutral military objects are displayed on a map. Several scenarios were developed in which groups of friendly ships and planes remain constant from the start of the scenario, but additional enemies, unknowns, and neutrals appear during the course of the scenario. Using the testbed application, the user's goals (tasks) were to acquire and maintain an awareness of an evolving situational picture, and to appropriately allocate weapons from friendly ships to encroaching enemy planes. Specifically, a user monitored the scene, largely by panning, looking for threats. When one was observed, the user then determined the number of planes in that threat (by zooming in on textual details that were progressively disclosed as the user's head moved closer to the screen) and the number of missiles the friendly had available to fire at the enemy. The user then used a slider (not pre-screen projection) to enter the number of missiles to shoot at the enemy and fire those missiles.

As we proceeded with the design of pre-screen projection and specific tasks, we began to see its large design space of possible attributes. Each attribute could have several (and sometimes many) values, so combinatorics of the numerous design decisions quickly became very large. This meant that early design decisions must be made based on very rapid prototyping and a quick formative evaluation cycle, rather than on fuller experimental evaluation. Especially interesting design challenges were provided by two attributes, scaling and fade in/out. These were applied to three types of objects in a scene: a map, icons, and text. *Scaling* is an attribute that specifies which objects in the scene appear larger or smaller as a user moves the head toward or away from the screen. In all design iterations the map scaled, because it is the predominant spatial context for icons and text. In early designs icons did not scale (to remove any implication that icon size has meaning, which it does not in the application studied). Somewhat

surprisingly, users found it difficult to zoom in on nonscaling icons, so the design was changed so that icons scaled. Also, text associated with the icons was not scaled to maximize the amount of readable text presented at any time. After several cycles of formative evaluation, users were comfortable with a final design in which the map and icons scaled, but text did not. *Fade in/out* is an attribute that specifies the gradual appearance and disappearance (progressive disclosure) of objects in a scene as a user moves the head. In all design iterations, the map and icons scaled but did not fade in/out, because of their role in maintaining spatial context. Text was fading in/out at several different levels of disclosure, based on the distance of the user's head from the physical screen, in order to display as much detailed information (in the text) as possible. In early designs, text at one level faded out completely as different text from the next level replaced it. However, users found it hard to determine which level they were in as they looked for specific information. Therefore, the design was changed to fade in only additional text, beneath (rather than on top of the location of) text displayed at prior levels. *Fade-in/out* of text provided some other surprises. At first, text was too densely packed, even after a user had zoomed quite far into the scene. What was thought to be a reasonable adjustment to that problem resulted in the text being too spread out. Text at first was displayed 75% opaque, but this proved to be too low contrast to read easily and also led to incomprehensible clutter when icons were close enough together so that their associated text overlapped. Again, the combinatorics of alternative designs at low levels of detail (e.g., color, font, spacing, and icon shape) was huge.

Many final detailed design decisions (e.g., distance for amplified zooming, distances for levels of disclosure) were based on trial and error, again supporting the need for a fast, highly iterative development usability engineering methodology. Thus, as pre-screen projection evolved over about a 12-month period, numerous cycles of formative evaluation were performed, some as short as 5 minutes, others lasting nearly an hour. Evolution of the design of scaling and fade in/out of text and graphics, for example, as well as virtually all other decisions about design details, came from many rounds of formative evaluation.

Once formative evaluations had identified a good design for pre-screen projection, summative evaluations began, comparing user performance and satisfaction using pre-screen projection to other interaction techniques for panning and zooming, using the defensive engagement tasks. Our study compared pre-screen projection with panning and zooming using a mouse-based interaction technique and also a Spaceball-based interaction technique. Results (Hix et al., 1999b) showed that pre-screen projection led to superior performance for more difficult tasks and, very importantly, also led users to learn a more effective strategy for panning and zooming.

Our best guesses about the design of pre-screen projection and other interaction techniques we have developed over the years were substantiated or refuted by many tight, short cycles of formative evaluation with users performing realistic tasks in the C² testbed application. The many unexpected and difficult usability issues and resulting design decisions could only have been encountered and resolved using a usability engineering methodology, such as that described, that supports this kind of fast, effective iteration.

5. CONCLUSION

Despite improvement in efforts to improve usability engineering of VEs, there is not nearly enough usability engineering applied during development of virtual environments. There is still a need for more cost-effective, high-impact methods. Four usability engineering techniques have been presented that have traditionally been used for GUI development and more recently

modified for usability engineering of virtual environments. We have presented how these techniques may be used together, as well as given descriptions of our experiences applying these techniques to real-world and research-based development efforts.

As VEs become more mature, established interaction techniques and generic tasks for VEs will emerge, and have the potential, as they did with GUIs, to improve usability. The design space and options for VEs is enormously greater than that for GUIs, and VE applications tend to be much more complex than many GUIs. Even "standard" interaction techniques, devices, and generic tasks for VEs will help improve usability only by a small fraction. Usability engineering will continue to be a necessary process if new and exciting VEs that are, in fact, usable and useful for their users are to be created.

6. ACKNOWLEDGMENTS

Dr. Rudy Darken, at the Naval Postgraduate School in Monterey, California, has been a strong proponent of our work for several years; his support and encouragement are greatly appreciated. At the VR Lab of the Naval Research Lab in Washington, D.C., Dr. J. Edward Swan has led efforts on the Dragon project. The VR Lab at NRL is directed by Dr. Larry Rosenblum. Dr. Helen Gigley, of the Office of Naval Research, has funded the pre-screen projection and Dragon work described herein, as well as development of the framework of usability characteristics of VEs. Brian Amento, of AT&T, performed much of the evaluation work on pre-screen projection, which was invented by Dr. Jim Templeman, of NRL's HCI Lab. Kent Swartz and Mike McGee while Students at Virginia Tech contributed to Crumbs and Dragon, respectively. We are grateful to all these contributors, without whom this large body of work would not have been possible.

1. INTRODUCTION

"When description gives way to measurement, calculation replaces debate."

—S. S. Stevens (1951), *Handbook of Experimental Psychology*

In this chapter, challenges to human performance measurement in general are briefly described and potential advantages and disadvantages unique to performance measurement in virtual environments (VE) are identified. Next, basic issues concerning the why, what, and how of VE performance measurement are discussed and then integrated into recommendations for when to perform various aspects of performance measurement. Emphasis is placed on psychophysiological measures because of their potential to provide a valuable complement to other measures of performance in virtual environments. Finally, properties of measurements as they relate to psychometric criteria and data integrity are presented.

The American National Standards Institute (ANSI) 1993 guide to human performance measurement lists several problems that underlie human performance measurement in the context of scientific research, and test and evaluation:

- Lack of a general theory to guide performance measurement
- The inverse relationship between operational control and realism
- The multiple dimensions of behavior
- The ambiguous relationship between objective and subjective data
- Difficulty of measuring cognitive tasks

- Lack of objective performance criteria for most tasks
- Difficulty of generalizing results to the real world

All of these problems apply to human performance measurement in VEs. In particular, the question of generalization to the real world is a critical question for measuring performance in many VE applications. Does the VE sufficiently represent the real world? Conversely, does the VE system interface allow an individual recognized as an expert in the “real world” to demonstrate that expertise in a corresponding VE?

There are several potential advantages of measuring performance in VEs. One example is the capability to precisely recreate situations or environments across different sessions at different times or places. This capability to make sure that important parameters are held constant should be of great value in training, skill-level certification, and personnel selection applications. Another advantage is the capability to record precisely, and in great detail, the user’s actions in the VE system. The record can support performance analysis by expert raters or automated scoring systems.

2. WHY MEASURE PERFORMANCE IN VIRTUAL ENVIRONMENTS?

To facilitate effective, efficient, and safe operation of any VE system, the measurement of human performance should be a consideration during the initial design and throughout the life cycle of the system.

Performance measurement provides a basis to make meaningful comparisons involving the VE system. A systematic approach to performance measurement is necessary to allow comparisons of performance with a VE system to performance with non-VE approaches for similar applications. Along with cost-effectiveness (see chap. 28, this volume) and safety (see chaps. 29–33, 41, this volume), human performance measurement should be an integral part of an overall evaluation of a VE system.

Performance measurement is needed to support comparisons across different system configurations, or changes within a VE system. Performance measures provide a way to determine that system changes and upgrades produce desired effects. In cases where budgetary concerns mandate tradeoff decisions, performance measurement may be used to support the selection of particular hardware or software alternatives. When components of a system are upgraded, experienced users of the previous configuration may believe that their performance was better with the old system. For example, objective measurement provides a way to address claims from individuals that they preferred system performance with the old visual display system (or tracking system, rendering system, etc.) after an expensive upgrade has been implemented.

Performance measures are the foundation for objective comparisons of an individual with other individuals, norms specific to a defined group, and predetermined performance criteria. Objective measurement is a critical requirement for testing, skill-level certification, and personnel selection and assignment applications.

One of the most important reasons to measure performance is to provide meaningful feedback and knowledge of results to individual users. Holding (1965) pointed out that knowledge of results could guide users as they perform a task and could improve subsequent task performance. In addition, knowledge of results can increase motivation to perform a task. Such feedback influences motivation by allowing learners to evaluate their progress, to understand their level of competence, and to sustain their efforts to reach realistic goals.

For some VE applications in which there is not an obvious need to measure user performance, (e.g., entertainment, see chap. 55, this volume) it is possible that performance measures will

assist in identifying causes of cybersickness (see chap. 30, this volume). Therefore, for almost all situations involving immersion in VEs, there would be safety (see chaps. 29–33, 41, this volume), and probably legal (see chap. 27, this volume) reasons to measure performance.

3. WHAT TO MEASURE

3.1 Overview

The National Research Council identified several areas of VE applications: design, manufacturing, and marketing; medicine and health care; teleoperation for hazardous tasks; training; education; information visualization; telecommunications and teletravel; art; and entertainment (Durlach & Mavor, 1995). Obviously, the performance measures of primary interest may differ greatly across these applications.

When devising the performance measurement system for any VE application, two levels of measures should be considered. The primary level will be determined by the specific application that the VE system is designed to address. The second level of measures will support the interpretation of the primary measures. The primary measures focus on outcome, indicating what the user accomplished in the VE system. The secondary measures help us interpret and elaborate on why performance was successful or not.

For some applications areas there will exist well-established primary measures. For these areas, the challenge will be to develop comparable measures within the VE system. For other application areas, the need to compare traditional approaches to VE-based applications may uncover inadequacies in the traditional measures. Some new VE technologies may lead to new tasks for which there are no established measures or new tasks that can be performed only in virtual environments.

For example, some aspects of architectural design performed with a VE system could be much easier to measure than real-world performance. Interim processes could be more easily observed and recreated in virtual environments. Time to complete a design or time to complete a number of alternative designs could be easily and precisely determined. Raters or judges of interim designs and the final design could walk through and interact with the designed structure. However, the ultimate performance measure of utility, style, and the multitude of other relevant measures will still be defined and judged by highly trained and experienced human observers, and applied to the real-world construction.

Although the primary performance measures of most interest will vary as a function of the specific VE application, the performance measures will share several considerations. For example, there are certain statistical or psychometric properties desirable for all measures. In addition, many of the methods of performance measurement described in this chapter can be applied to a wide range of VE applications.

Task taxonomies may provide a starting place in the identification of categories and dimensions of performance measures relevant to a specific VE application. Fleishman and Quaintance (1984) presented a comprehensive task taxonomy. Companion and Corso (1982) offered a general review of approaches to task taxonomies. Fineberg (1995) described a taxonomy specifically designed to address performance in virtual environments. An ANSI (1993) guide presented a ten-category taxonomy of performance measures. The categories were:

- Time
- Accuracy
- Amount achieved or accomplished
- Frequency of occurrence

- Behavior categorization by observers
- Consumption or quantity used
- Workload
- Probability
- Space/distance
- Errors

Many widely used global measures (such as task success rate, assembly sequence errors, or magnitude of production) have at their basis speed or accuracy. For most areas of human performance it is possible to trade off speed and accuracy. As in defining performance criteria for real-world tasks, instructions to the VE user to “perform as fast and accurate as possible” leave it to the user to decide the relative importance of those two dimensions of performance. Setting a time limit has the advantage of keeping a constant duration of immersion, a consideration in controlling or measuring the incidence and severity of cybersickness (see chap. 30, this volume).

Regardless of the VE application, interpretation of the primary measures and identification of ways to improve performance may be facilitated by a set of secondary measures. Secondary measures include performance on the subtasks and processes needed to complete the primary task, user characteristics, and conditions under which performance was measured.

Process measures include lower level processes or functions, such as sensory acuity or basic locomotion, which underlie the primary measures. Process measures are not limited to simple divisions or subtasks of the primary task. Cannon-Bowers and Salas (1997) extend the concept of process measures to include measures such as assertiveness and flexibility. The distinction between outcome measures and process measures is a function of context; that which is an outcome measure in one context can be a process measure in a larger context.

There are many candidate measures of user characteristics that may aid in interpreting performance measures. Examples are: user age, gender, handedness, previous subject matter expertise, and prior experience with computers in general and VE systems in particular. Relevant measures will vary across applications. Finally, measures of the conditions under which performance occurred might aid in the interpretation of primary measures. Examples are personal threat or environmental stress such as temperature extremes.

3.2 Sensation/Psychomotor Measures

Lower level performance measures, which may facilitate interpretation of higher level performance measures, include measures of sensation and perception in the appropriate sensory modalities (see chaps. 3–6, this volume), various levels of consideration of movement through the VE (locomotion, travel, and navigation, see chaps. 11 and 13, this volume), and interaction with objects (interrogation, selection, and manipulation). Gabbard and Hix (1997) presented a useful taxonomy of these VE functions. Lampton et al. (1994) developed a VE test battery that assessed several of these measures. Many of these measures should be addressed during usability testing of a VE system (see chap. 34, this volume). For some VE systems it may be advisable to maintain the ability to collect “usability” measures throughout the life cycle of the VE system.

3.3 Critical Incidents

The very nature of emergency situations is counterproductive to the careful documentation of what happened and why. Therefore, a structured data collection instrument should be available to document what happened and the context in which the incident occurred. For example,

any incident during the use of the VE system in which the safety of individuals is placed in jeopardy should be carefully documented. For measuring performance in VE, the term critical incident should not be limited to indicating an unwanted event, but any out of the ordinary performance, whether good or bad, with the VE system.

3.4 Knowledge Tests

As part of the effort to differentiate the effects of the VE system per se on performance, knowledge tests can be administered to users. The tests can tap procedural and declarative knowledge. Knowledge tests can determine if the intended user has the prerequisite knowledge for worthwhile training on, or use of, the VE system.

3.5 Error Analyses

Error analysis should be an important part of performance measurement for most VE applications. Norman (1988) identifies two fundamental categories of errors: slips and mistakes. Slips are errors in the execution of otherwise correct plans. A mistake involves the execution of a plan as intended, but the plan was inappropriate to accomplish the overall goal. Comprehensive approaches to error analysis are presented by Reason (1990) and Senders and Moray (1991).

As VE user interfaces improve, error analysis may assume more importance relative to simpler measures of speed and accuracy. Additional measures of the judgment exhibited by the VE system user include calculated risks and intentional violations of rules or procedures. For better or worse, VE medium may encourage greater risk taking by users. Some performance measures involving judgment within VE may completely defy clear-cut scoring as right or wrong, but rather will involve evaluating idioms, which are styles of artistic expression typical of a particular medium.

4. PSYCHOPHYSIOLOGICAL MEASUREMENT IN VIRTUAL ENVIRONMENTS

Psychophysiological measurement has great potential to bolster measurement of human performance in VEs and can provide insight to the underlying mechanisms of performance. Psychophysiological measurement conducted while the participant is immersed does not require the participant to provide conscious feedback. Therefore, distracting self-report procedures and after-the-fact reports of questionable reliability can be avoided.

4.1 Psychophysiological Approaches to Measurement

Baseline measurement refers to the psychophysiological data collected before any experimental stimulus is introduced. It is the initial assessment of the physical and psychological state and traits of the individual including daily changing psychophysiological characteristics such as fatigue, concentration, and anxiety as well as long-term psychopathologies and medical problems. Both state and trait variables are interwoven in the mass of psychophysiological data and are essential to recognize for two main purposes: to separate the state and trait characteristics from the performance variables related to the virtual environment and to categorize the participant.

In the categorical approach, the purpose is to separate individuals according to a performance variable of interest. Current advances in technology and research have provided the ability for

researchers to use psychophysiological baseline data to predict individuals' performance in areas such as task functional state, task performance, workload, adaptability, accuracy, and anxiety. This approach is not only used to predict future performance but also used to separate performance related variables after the experiment over and above self-report indices.

A correlation approach is often used to determine the specific psychophysiology markers characteristic of human-system variables assessed by subjective measures. The measures of interest here would be those that measure human-system variables such as sense of presence (see chap. 40, this volume) or simulator sickness (see chap. 30, this volume). When correlating these measures with psychophysiological data, one can more clearly define the human characteristics underlying the reports and use them in subsequent analyses to identify desired and relevant evoked responses to various virtual stimuli.

Measuring evoked responses is an approach used when an experimenter wishes to determine information about the system. The experimenter can separate and analyze various aspects of a condition or system that may induce immediate psychophysiological change. In VE research there is interest in determining the aspects of the experience that produce states such as arousal, attention, and distractibility, which contribute to overall performance. As researchers seek to produce an effective virtual environment, importance is placed on human responses to stimuli that are real in appearance and those virtual components that produce meaningfulness, or arousal.

Adaptation is the focus of the feedback approach (see chaps. 37–39, this volume). Adaptation is the main concept in feedback and the results of conditional change in performance are expressed through the electrophysiology of the nervous system. During real-time psychophysiological monitoring, researchers are able to identify unwanted cognitive or physiological states and then either provide indicators such as tones, or alter the environment and virtual stimuli to return the operator's psychophysiological performance to its desired state. For example, therapists are using VEs and psychophysiological monitoring with biofeedback to reduce acrophobia or agoraphobia (see chaps. 50 and 51, this volume). Also, feedback techniques have been used with pilots in order for them to maintain a necessary cognitive state of awareness (see chap. 43, this volume). Level of arousal or cognitive functioning is constantly monitored and either the task is modified, or the operators alter their own psychophysiological levels to adapt to optimal functioning.

4.2 Types of Measures and Performance Indicators

Most current psychophysiological techniques involve placing and securing electrodes over the areas of the body appropriate to the types of performance indicators (e.g., concentration, anxiety, and workload) to be measured.

Electroencephalography is the recording of electrocortical brainwaves using an electroencephalograph (EEG). This area of applied psychophysiology has rapidly become the most advanced psychophysiological tool for assessing human performance primarily because of its ability to specify internal cognitive functions (e.g., visualization, attention, workload) as well as most physical processing of external stimuli. Unlike other psychophysiological measures, EEG has been shown to predict and indicate a wide range of performance related variables. The brainwave recording procedure requires that electrodes be placed on the scalp to compare and measure various regions of brain activity.

Analysis of brainwave activity can provide highly sensitive measures of changes in cognitive task difficulty and working memory. When brainwave variables are analyzed in various ways, they can accurately discriminate and predict specific cognitive states. The raw EEG data are broken up into specific bands, usually ranging from 0.5 to 32 Hz, each with specialized contribution to the various performance indices.

A working-memory increase due to task load results in an increase in the frontal theta band (4–7 Hz), and a decrease in alpha band (8–12 Hz; Gevins et al., 1998). A decrease in alpha is usually indicative of fatigue and lack of attention or vigilance and has been used to reflect increased workload. Crawford, Knebel, Vendemia, and Ratcliff (1995) point out that the lower part of alpha band (7.5–9 Hz) can actually differentiate low and high sustained attention. Frontal midline (FM) theta is a useful indicator of increase in concentration and expertise (Yamada, 1998). An increase in task complexity can be determined by relative frontal and central beta (13–32 Hz) activity increase (Wilson, Swain, & Brookings, 1995). The task engagement index has been able to reflect overall task engagement best and is derived by dividing beta by alpha plus theta ($\text{beta} / (\text{alpha} + \text{theta})$). The sensory-motor reflex (SMR, 12–15 Hz) is used to determine a lateralized readiness potential (LRP). This is a type of event-related potential, useful in determining the processes that prepare the motor system for action (the preparation to respond), and which initiates but inhibits the response before it takes place (Coles, 1998).

Electromyography (EMG) is the process of recording the firing of muscle units as they relate to other muscle units. The data can determine tension and even the slightest of muscle activity without any visible muscle movement. EMG can be used in combination with EEG to weed out cognitive activity from signals related to muscle movement. Tension in the forehead and eye movements can produce EMG artifact signals in EEG recording, but with the use of recorded EMG on facial locations these artifacts can be easily recognized and removed.

EMG is a measure of tension and thus can provide insight on patterns of bodily reactions, such as startle responses, tension and movement, and breathing effort. An increase in task difficulty can be identified by an increase in EMG from the neck and shoulder muscles (Hanson, Schellekens, Veldman, & Mulder, 1993).

Electrocardiogram (EKG) measures the electrical activity that spreads across the muscle of the heart. The spread of excitement through the muscle of the ventricle produces the QRS complex, a waveform in which the intervals between the R wave indicates heart rate. Heart rate deceleration is indicative of such activities as orienting to neutral or pleasant stimuli, appropriate responding, and quicker reaction-time responses. Heart rate acceleration is a characteristic response to stimuli that induce a defensive reaction or to unpleasant stimuli. Recent research suggests that cardiovascular indices can indicate individual coping strategies to external noise in order to maintain task performance (Hanson et al., 1993). Current research also indicates that respiration rate, heart rate, and electrodermal activity (EDA) correlate with degree of immersion or presence in the virtual environment (Wiederhold, Davis, & Wiederhold, 1998).

Blood pressure is a measure of systolic (contraction) over diastolic (relaxation) heart activity. An increase in blood pressure can indicate an arousal reaction in the form of tension, aggressive activity, or thought, occurring in performance situations that evoke threat or unpleasantly arousing stimuli. *Blood volume* is a measure of slow changes in blood volume in any limb, whereas pulse volume reflects rapid change related to heart pumping and vascular dilation and constriction. Human performance variables that include orienting responses to stimuli can be determined by a general increase or decrease in blood volume in the forehead. An increase is indicative of improved perceptual ability; a decrease suggests a defensive response to unpleasant stimuli.

Electrodermal activity (EDA), also known as skin conductance level, is a measure of surface skin electrical activity. The higher the sweat rises in the eccrine sweat glands (located in palm and foot soles), the lower the resistance. EDA is of interest in human performance research because it responds to both external and internal tonic activity. Eccrine glands respond to psychological stimulation instead of body temperature change and can indicate many of the same cognitive variables as the EEG. The number of skin conductance changes in a given period of time is useful in indicating the preparation of physical motor activity. A change in skin conductance and number of spontaneous skin responses are both associated with faster

reaction time. An overall increase in EDA is indicative of better task performance, signal detection, and learning. A decrease in EDA is associated with increased task complexity and difficulty.

4.3 Data Collection Considerations

To obtain useful and reliable data, recordings must be taken in highly controlled settings considering both the individual and environmental factors that influence human physiology such as age, gender, neurological damage, noise and temperature. Moreover, recent research suggests that electromagnetic field exposure from equipment may change the psychophysiology of participants (Morris, Shirkey, & Mouloua, 2000). Andreassi (1995) discusses in depth psychophysiology in reference to human-system performance. Resources can also be found in the technical group Psychophysiology in Ergonomics (PIE) of the Human Factors and Ergonomics Society.

5. HOW TO MEASURE HUMAN PERFORMANCE

There are at least two performance measurement advantages inherent to VE systems. One is the ability to automatically capture aspects of the user's performance, such as operation of the input control devices. The other is the ability to provide an observer with comprehensive perspectives of the user's actions in the virtual environment.

An example of automated performance measurement is to have the system capture lower level performance, such as counting collisions with walls or objects in the virtual environment. Minimum processing should be conducted in real or near-real time to provide feedback to the user and the observer. More detailed processing should be delayed to avoid degrading system performance while the user is on the system. During use, the observer will have a checklist that addresses only those performance measures that must be scored in real time. For the most part the observer will concentrate on controlling the session and safety issues. Scoring of other performance measures should be postponed until session playback. Several raters may score playback independently. Additional replays could be conducted to resolve interrater differences.

One of the main strengths of performance measurement in VE is the ability to provide a human observer with flexible, comprehensive views of a VE system user's actions in the VE itself. In addition, for many systems it is possible to provide a simultaneous view of the user's actions in the real-world VE interface.

The U.S. Army's Simulation Network (SIMNET) system has demonstrated the powerful performance measurement advantages that VE displays can provide for training applications. SIMNET employed a Stealth Vehicle, invisible to training exercise participants, that allowed trainers and exercise controllers to view training exercises from any perspective within the virtual environment. In addition, a training mission can be replayed and viewed from any angle.

A more recent example is provided by the Fully Immersive Team Training (FITT) research system, which allows the observer/mission controller to view the unfolding training exercise from any perspective while trainees wearing head-mounted displays practice urban search and rescue missions within virtual environments. The view presented to the observer is intentionally modified from the view of the participants to aid the observer in scoring trainee performance. For example, the observer can view the unfolding training exercise from any angle, and zoom in or out. In addition, depictions of objects within the VE are intentionally modified to aid in measuring performance. For example, equipment in use by the trainees is represented to the observer at a much larger scale so it is easier for the observer to identify. The FITT system has a replay function that allows normal, slow, and fast playback. Fig. 35.1 shows the FITT replay

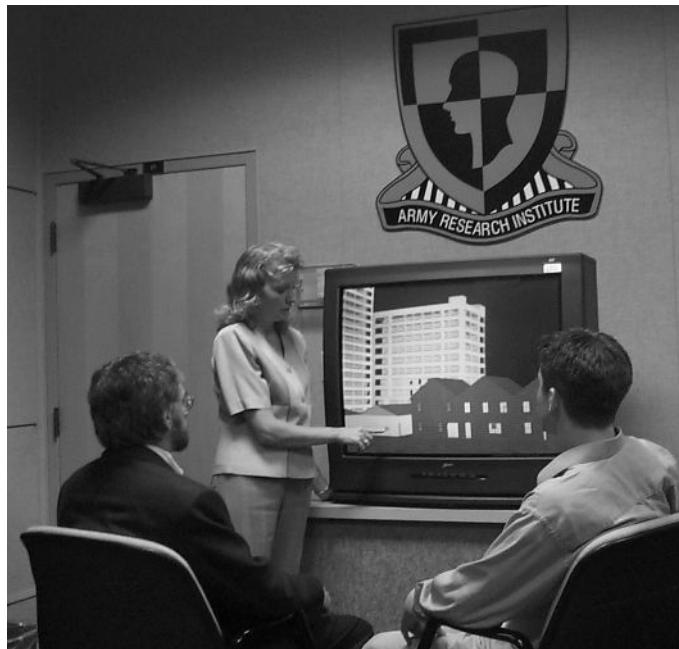

FIG. 35.1. The Fully Immersive Team Training (FITT) research system replay station.

station. Technical aspects of data sampling rate, filtering, capture, and storage are described in Parsons et al. (1998).

The scoring playback can be conducted with or without the user. In addition, the user may be interviewed and provided questionnaires to help interpret what occurred and why. Interviews are in general more flexible and easier for the user than questionnaires. Questionnaires are easier to administer and provide for more private responses than interviews.

6. WHEN TO MEASURE PERFORMANCE IN VIRTUAL ENVIRONMENTS

Some measures such as severe susceptibility to motion illness or seizures (see chaps. 29–30, this volume) should be determined before the participant is immersed in the virtual environment. These measures may be used for screening out potential users of the VE system or at least providing a cautionary alert. However, when feasible, other background measures may be taken after the participant has completed the session in the virtual environment. Scheduling paperwork for this time provides a safety period between use of the VE system and activities such as driving. Following this line of thought, even though it may be feasible to have an automated means of collecting background information that is PC-based or even VE-based, from the standpoint of mitigating cybersickness it may be preferable to have the participant complete paper and pencil questionnaires rather than prolong the amount of time spent looking at electronic displays. Because there are so many potentially important variables, when feasible a take-home package approach may be used in which the VE system user completes and returns questionnaires hours or days after using the system.

Suggested time lines for performance measurement activities before, during, and after immersion are presented in that order in Tables 35.1, 35.2, and 35.3. These tables integrate recommendations on what, how, and when to measure performance in virtual environments.

Example Time Line of Preimmersion Performance Measurement Activities

Research participant or system user recruitment

- Off-site telephone screening to confirm user has at least minimally appropriate sensory and psychomotor skills and to identify safety issues
 - Preimmersion health status questionnaire
 - Preimmersion indices of cybersickness symptoms
 - Preimmersion baseline physiological measures
 - Review of participant's previous performance on the system (when appropriate)
-

TABLE 35.2
Example Time Line of Performance Measurement Activities During Immersion

- System data capture
 - Real-time or frequently updated summary statistics of performance measures
 - Displayed to participant and controller
 - Stored for replay and subsequent data analysis
 - Physiological measures
 - Observer/controller checklists
 - Participant comments/dialog
 - Critical incident intervention (when appropriate, a safety intervention, for example)
-

TABLE 35.3
Example Time Line of Performance Measurement Activities After Immersion

- Indices of cybersickness
 - Postexposure physiological measures
 - Replay
 - Participant's comments
 - Controller's comments
 - Open interview
 - Structured interview
 - Questionnaires
 - Take-home packet
 - Follow-up interview or questionnaire
 - Off-line data analyses (example: summary statistics across immersion sessions)
 - Scoring of session replay and videotape by different scorers or raters
 - Session to reconcile difference in scoring
 - Archive performance measures in system database
-

7. PROPERTIES OF MEASUREMENTS

7.1 Psychometric Criteria for Performance Measures

The power to create VEs for research is both rewarding and challenging. Researchers have the ability to measure a myriad of performance variables in an automated fashion, but face unique psychometric obstacles. In traditional (non-VE) experimental contexts it can be a challenge to get enough human performance data, so researchers often resort to using surveys, questionnaires, or other measurement tools. In contrast, researchers using VEs often must make a conscious decision to limit the data generated by the computer system or to filter it after collection.

Because of the many possibilities for data capture in virtual environments, researchers are encouraged to carefully select performance measures that are psychometrically sound. Experts generally agree on two criteria by which to judge performance measures: reliability and validity (Whitley, 1996). However, sensitivity or discriminability of performance measures is also important (see Leavitt, 1991).

7.1.1 *Reliability*

Performance measures should tap behavior in a stable fashion. When measuring human performance in virtual environments, it is especially important to employ reliable measures because of the large and changing variety of VE hardware, software, tasks, and testing paradigms available.

Conventional explanations of reliability center around two issues: repeatability and internal consistency. Repeatability concerns whether the measure reflects performance consistently across time and testing administrations. Researchers who use VEs for training are especially interested in repeatability because performance measures that fluctuate across time or testing sessions are not comparable. Therefore, it becomes difficult to chart a trainee's progress or expertise relative to other trainees. Determining the repeatability of a performance measure is typically done by correlating measures taken during one experimental session with those taken during a subsequent session.

Internal consistency reliability indicates how well a performance measure reflects a unitary construct. For example, it is important that a measure of accuracy in a VE pick-and-place task not include an aspect of timeliness. Otherwise it would be difficult to isolate the cause of observed variability. Most researchers who study human performance calculate test-retest reliability as a substitute for internal consistency because it is more common and interpretable, and is roughly comparable to internal consistency (Whitley, 1996).

Researchers and task designers often desire to know what constitutes acceptable reliability. Although most experts have difficulty agreeing on a precise value, Whitley (1996) suggests that test-retest correlation coefficients should approximate 0.5. However, this value generally applies to paper and pencil tests. It is reasonable to assume that acceptable coefficients for other task performance data might be somewhat lower, given the relative complexity of such measures and the variability of conditions across which performance may be observed.

Researchers frequently compare task performances in VEs to those in the "real world." In some respects, data collected from immersive task performances may be more reliable than data from an actual task performance. Just as with conventional simulation, researchers using VEs have the capability to standardize aspects of the immersive experience and to hold certain task parameters (e.g., criteria for success, difficulty, and duration) constant. Loftin and Kenney's (1995) account of training astronauts to repair the Hubble Space Telescope is an example of how aspects of a VE may be standardized, augmented, or isolated to facilitate learning and retention. They constructed a VE wherein astronauts were able to rehearse major

operations necessary for one of the primary repair-mission goals. The researchers were able to standardize the task parameters so that trainees could focus on crucial mission elements and exhibit meaningful, stable performance measures.

7.1.2 *Validity*

Although repeatability and consistency are necessary qualities for performance measures, researchers must also examine the validity of measures. It is crucial that performance measures be faithful indicators of the constructs they presume to reflect. As noted by Salvendy and Carayon (1997), reliability and validity must be examined together, because a measure may consistently reflect a construct of little relevance or importance.

Evidence of performance measure precision may be reflected by content validity (whether the measure adequately measures the various facets of the target construct), construct validity (how well the measured construct relates to other well-established measures of the same underlying construct) or criterion-related validity (whether measures correlate with performance on some criterion task).

All techniques for establishing validity are inferential. Whereas it is relatively easy to calculate a reliability coefficient directly from available performance data, determining the validity of measures often requires researchers to rely on evidence obtained in an indirect fashion. Frequently such evidence includes expert judgments or correlations with other marginally validated measures. Vreuls and Obermayer (1985) noted that performance measure validation was fraught with difficulties and had not been accomplished for most simulation-based training systems. Unfortunately, the difficulties observed by Vreuls and Obermayer are generally compounded in VEs; consequently, most researchers have not attempted validation of measures (but see Zeltzer & Pioch, 1996).

The optimal way to determine precision of measures is by using construct validity. It may be feasible to estimate construct validity of some VE performance measures by comparing them to measures in other contexts such as the real world (where practical) or well-established task simulations (if such simulations exist). For example, estimating the construct validity of procedural errors in a virtual mineclearing task may be possible by comparing those errors to performance in more conventional (real-world) mine-clearing training programs. However, such validation is not practical for many immersive tasks, because there is no usable standard for comparison or because the task is too dangerous, costly, or complex to be trained in a nonimmersive fashion.

As an alternative to construct validity, researchers may wish to determine criterion validity. This may be more feasible than establishing construct validity, because measures of concurrent or future performance may be readily available. For example, data concerning mineclearing expertise would presumably be available from other test scores, rankings, or safety records. Unfortunately, using future performance as a criterion requires the researcher to wait some time before obtaining comparison data. Using current data is quicker but often forces the researcher to sacrifice comparability. For example, it would be more meaningful to compare VE mine-clearing task measures with future success in mine-clearing operations. However, researchers may opt to use currently available measures (such as performance on a test of mine-clearing equipment).

To maximize convenience, researchers often judge precision by consulting with subject matter experts. Content validity procedures make intuitive sense for situations where there are no current or future data available, or where there are no other well-established measures of the construct. The disadvantage is reliance on experts who may or may not have adequate knowledge to judge performance measure acceptability.

For traditional paper-and-pencil tests, acceptable validity coefficients typically approximate 0.3 to 0.4 (Nunnally & Bernstein, 1994, p. 100). As with reliability, however, the difficulties associated with validation of VE performance measures could drive this figure lower. Yet, given

comprehensive knowledge of the target task, researchers have the capability to maximize performance measure validity. There are few limits to a programmer's creative potential, given adequate computing resources. Some researchers have even been able to manipulate and measure abstract constructs like fear or trust. North, North, and Coble (1996) provide an interesting example of this, constructing a VE to treat agoraphobia (fear of open places, see chap. 51, this volume).

7.1.3 Sensitivity

Instructional VEs should be created so that good performers may be distinguished from poor performers. Although sensitivity of data is not always identified as a psychometric criterion by authors, it is arguably as important as reliability and validity, particularly in performance measurement situations. According to Leavitt (1991), sensitivity refers to the capability of a performance measure to adequately discriminate between experts and novices. It is important to consider sensitivity separate from reliability and validity, because performance measures may be consistent and may truly reflect the construct of interest. However, they may not reflect sufficient variability to be of use. As an example, Vreuls and Obermayer (1985) point out that low discriminability of measures severely limited the potential of some early flight simulators.

In cases where dependent measures lack sensitivity the data may reflect ceiling or floor effects, where the majority of participants score at the high or low end of the measurement range, respectively (Nunnally & Bernstein, 1994). As an example, in some of the early VE research concerning spatial navigation training, a majority of participants had problems maintaining spatial awareness and easily got lost within virtual environments. As a result, the data did not reveal much, because few people could master virtual wayfinding tasks (see chap. 24, this volume).

A common problem associated with low sensitivity is that the experimental data lack variability. Therefore, because many statistical techniques rely on variability, it may be difficult for experimenters to draw meaningful conclusions from their statistical analyses.

Unfortunately, there are no established guidelines for sensitivity measurement. Generally, it is the researcher's responsibility to examine the raw data to determine whether performance measures show acceptable levels of variability. Provided that researchers are aware of the need for sensitive measures, VEs offer the potential to optimize sensitivity. Zeltzer and Pioch (1996) provide an example of the effort necessary to ensure good sensitivity of performance measures. They describe in detail the steps they followed to construct their VE system for training submarine officers and point out the importance of consulting with subject matter experts throughout the VE development process to determine appropriate task elements to model and the degree of fidelity with which to represent them.

7.2 Issues Impacting Data Integrity in Virtual Environments

Weimer (1995) recently listed a number of potential threats to successful research, including the particular instrumentation used for task presentation and performance measurement. This is particularly evident when measuring human performance in virtual environments. Although immersive technology may hold promise for reliability, validity, and sensitivity of performance measures, researchers should acknowledge VE-related issues that threaten measurement rigor. The following sections are meant to expand upon Weimer's warning by identifying specific problems researchers may face when collecting data in virtual environments.

7.2.1 Hardware Issues

During the advent of VE technology, it was not uncommon to see processors running at a mere 66 MHz driving and updating visual displays. One consequence of slow processors

was commensurate delays in screen refresh rate. As a result, participants often had to perform tasks at speeds that were unnaturally slow as they waited for the system to "catch up." Some implications of lag for task performance have been mentioned by Kenyon and Afenya (1995). In their research, participants used a high-fidelity VE setup to learn a pick-and-place task. However, excessive lag led to task performance idiosyncrasies, such as physical movements that were overly deliberate. Unfortunately, lag may also have a negative effect on performance measure sensitivity by masking performance differences between experts and novices.

In other cases, performance measures such as reaction time may not reflect true human reaction time at all, but human reaction time filtered through an overburdened processing interface. Today, the situation has improved dramatically because graphics processors are much faster. However, even the fastest processors may be bogged down by calculations required by complex environments, position tracking, and peripheral device use. Watson, Walker, Ribarsky, and Spalding (1998) discuss how task performance may be influenced by reduced system responsiveness (SR). They summarize research findings that indicate an association between low system responsiveness and degraded task accuracy and task completion speed.

In some cases, computing resources used to generate and update virtual worlds and to collect performance measures may be accessible by multiple users on a network. Unfortunately, additional users may increase the processing load on a given processor so that VE rendering occurs at variable rates. Variability in processing loads may decrease performance measure reliability within and among participants. In some cases the authors of this chapter have had to reschedule experimental sessions or arrange stand-alone machines simply to accommodate data collection.

A more problematic issue concerns situations where the functional unit is not the individual, but a team of people immersed in the same virtual environment. While technological constraints have prevented common use of such environments, there is a clear need for VEs to train teams in applied contexts like military combat, command and control, and peace-keeping (Gorman, 1991; see chap. 44, this volume). When tapping collective performance in VEs, researchers must apply the criteria of reliability, validity, and sensitivity to performance measures taken from individuals as well as from teams. Determining individual performance efficacy can be particularly challenging when task responsibilities fluctuate among team members.

When Weimer (1995) discussed instrumentation, his main concern was equipment unreliability. Performance measures taken from first-generation VE systems often reflected sporadic equipment problems such as a visual channel that malfunctioned from time to time or position trackers that drifted in and out of calibration. When equipment is unreliable, validity may also be compromised because measures may not reflect human performance on the task so much as human adaptation to equipment idiosyncrasies. Sensitivity may also be in jeopardy because of the indiscriminant nature of some equipment problems unpredictably impacting the performances of experts and novices.

Early VE equipment configurations were often uncomfortable as well as unreliable (see chap. 41, this volume). According to Durlach and Mavor (1995), the discomfort associated with early HMDs led some researchers to consider using off-head displays. Additionally, Stanney, Mourant, and Kennedy (1998) have suggested that use of some peripherals may lead to repetitive motion injuries such as carpal tunnel syndrome or tenosynovitis. Such discomfort may negatively impact performance measure reliability, because greater performance decrements are likely with prolonged peripheral use. Validity, also, may suffer because performance data may partly reflect frustration with peripheral devices. Sensitivity may be compromised because participants of all expertise levels may react differently to uncomfortable peripherals.

A related challenge faced by participants is learning to use peripheral devices to navigate and manipulate objects. As shown in early VE research by Lampton et al. (1995), such learning is not

a trivial matter. Unfortunately, the reliability and stability of measures often suffer because the normal learning curve is extended to account for control device unfamiliarity. Also, participants may show reluctance to exploit the advantages of immersion (such as head rotation). Recently, researchers have begun to investigate the feasibility of using voice to interact with elements of the virtual world (Normand, Pernel, & Bacconnet, 1997). If successful, voice interaction may provide a way to overcome the performance limitations of uncomfortable, unreliable peripheral devices.

The correspondence between peripheral device movements and reactions in the virtual world is also of concern (see chaps. 11, 13, this volume). Optimally, devices used for manipulation and navigation within a virtual world should be intuitive for the user population. However, some peripheral devices may be problematic for use by participants because of issues of compatibility and ease of use. A pervasive problem is misalignment between one's physical hand and the virtual representation of it (see Groen & Verkhoven, 1998). Significant effort has been devoted to eliminating discrepancies such as these. While decrements could be expected for performance measure sensitivity and reliability, it is likely that validity may suffer worst because actions required to activate a peripheral device may not be the same as those required to accomplish a similar task in the real world.

Given the plethora of equipment manufacturers and the transient popularity of VE equipment, research participants may navigate and manipulate using Spaceballs, flight controllers, standard joysticks, gloves, or other equipment. As a result, performance measures may not be comparable from one experiment to another. Sensitivity likely suffers because experts learn to perform well using one equipment configuration but not another. Additionally, there is the potential for performance measures drawn from low-fidelity systems to have poor validity when compared with measures taken from higher fidelity VE configurations, or from real-world performance conditions. As an example, Kozak, Hancock, Arthur, and Chrysler (1993) highlighted such differences as possible reasons for lack of training transfer from a virtual to real task-performance environment. Yet Stanney, Mourant, and Kennedy (1998) attribute this lack of transfer to the choice of training task (i.e., VE training may not have significantly added to the learners' performance due to ceiling effects of an overtrained task—i.e., picking up and placing a can).

7.2.2 Software Issues

Virtual environments that are used for research vary widely in terms of their complexity. Some researchers use simple models consisting of 20,000 polygons or less with elementary object dynamics, and others use models that are extremely complex (over 1,000,000 polygons) and place heavy computing demands on processing resources. Not only does model complexity differ among environments, it may differ within the same environment. Because of this variability, highly precise measures of performance may appear unreliable. For example, reaction time estimates may fluctuate widely between simple and complex environments, or at different physical locations within the same environment. Furthermore, the difference between novice and expert performance may vary with environment complexity, decreasing measurement sensitivity.

Another issue concerns fidelity, or how closely a constructed environment approximates an operational environment. According to Hays and Singer (1989), a distinction may be made between physical fidelity (the physical similarity of a constructed environment to an actual environment) and functional fidelity (the capacity for realistic interaction within a constructed environment). It is plausible to assume that a lack of either type of fidelity will compromise measurement validity. Performance measures may not reflect the constructs they were designed to reflect, because participants will not interact with the environment in a natural, spontaneous

fashion. This idea is suggested by some theories of presence that suggest the realism of an environment may be judged by whether users interact realistically with it (see Sheridan, 1992; see chap. 40, this volume). There is research to suggest that learning and performance may be enhanced in well-designed VEs that are high in fidelity, because participants experience higher levels of enthusiasm and motivation than in conventional (real-world) environments (North, 1996).

For some specialized training applications, it is necessary to combine aspects of VE technology with aspects of an actual task to enhance training. However, augmented reality applications may threaten the validity and sensitivity of performance measures because the constructs indicated by the performance measures are unclear. For example, if one trainee performs worse than another, it may be difficult to isolate the reason. Performance differences may be due to aspects of the virtual environment, aspects of the real world, or aspects of the task to be trained. Similarly, validity of the measures may be in question because of the unclear link between performance measures and the constructs of interest. There is also some concern about excessive cognitive demands that augmented reality systems may place upon users (see Stedmon, Hill, Kalawsky, & Cook, 1999).

7.2.3 Task Issues

In some cases, the structure of the tasks that participants are required to perform while immersed may alter the reliability, validity, or sensitivity of the performance measures. Some immersive training situations may in effect be part-task simulation exercises because the training task is simplified in the virtual world. Such simplification may occur for a variety of reasons, including costs associated with full task programming or the desire to conserve computer-processing power. However, if researchers create VEs without considering desired behavioral outcomes (by conducting a task analysis such as that advocated by Stanney, 1995) the result may be measures with low validity. In addition, sensitivity may suffer because of the potential for ceiling effects.

Another potential threat to sensitivity concerns the fact that some research participants may be confused or overwhelmed by the immersive experience. Bliss, Tidwell, and Guest (1997) noted occasional confusion by older participants who were not familiar with computers or virtual environments. In cases such as these, the performance measures chosen may lose sensitivity due to floor effects, where most of the participants' cognitive resources are focused on adjusting to the novelty of the virtual environment, and few remain for completing the experimental task.

Because of modeling and rendering limitations, some simulations of operational tasks may lack realism. For example, in many operational environments time is a critical constraint. Other factors difficult to replicate include environmental influences such as heat, cold, vibration, noise, and the presence of other team members. If aspects of the operational task are not represented faithfully, then validity of the performance measures may suffer because they reflect skill at accomplishing a diluted task. Similarly, performance measure sensitivity may be limited if true expertise depends upon the ability to perform in a variety of environmental conditions.

In a similar vein, most real-world operational tasks include consequences for poor performance. In some cases, these consequences are quite dramatic, such as injury or death. As with most laboratory research in the behavioral sciences, it is difficult to adequately represent in VE consequences for poor performance. In many task simulations, consequences for poor performance generally resemble those of a video game. As a result, the dedication and effort of the participants may be questioned. Psychometrically, the result may be compromised performance measure validity.

7.2.4 User Characteristics

Researchers have found certain participants may perform better in VEs than others because of their demographic makeup or past technological experience. In addition, Howe and Sharkey (1998) recently created a method for identifying successful users of VEs based on competence and temperament. This underscores the need to select research participants with care, as noted by Whitley (1996). Particularly when using VEs to simulate task conditions or training scenarios, users must echo the target population where possible. Yet behavioral researchers often rely on a sample of convenience, usually college students. If college students are used for testing in a virtual environment, there may be the potential for a ceiling effect because of students' greater familiarity with computers. On the other hand, if a specialized sample is used there may be a danger of a floor effect because of limited experience with technology.

As demonstrated by Witmer and Singer (1994), people vary with regard to how deeply they may become psychologically immersed in a virtual environment. Some people find it quite easy to accept the VE as a distinct, separate world that they can influence. Others may find it difficult to suspend their disbelief when experiencing the same environment. Because susceptibility for presence often dictates how participants will act when immersed, researchers should assume that such differences will adversely impact performance measure reliability.

Researchers have at times noted performance differences in VEs with regard to gender. In some cases, the differences that arise are due to other related factors (i.e., males typically use computers for recreation more often and are generally less susceptible to motion sickness). Researchers should be cautious to maintain participant gender ratios that are ecologically valid. However, they should also be aware that threats to data validity and sensitivity might exist when testing gender-diverse samples.

Speed and accuracy of virtual task performances have been shown to vary as a function of both computer and video game familiarity. Therefore, it is wise to employ caution when investigating data trends. Although participant samples may echo the operational environment demographically, their experience with technology may introduce unexpected variability in performance measures, lowering measure validity and sensitivity. One related issue that is frequently observed is the influence of participant age on performance. For example, McCreary and Belz (1999) found that older adults exhibited significantly worse retention of spatial knowledge and slower task performance in VEs than younger adults.

Finally, of particular interest to researchers has been the influence of cybersickness on human performance in virtual environments (see Kolasinski, 1995; chap. 30, this volume). Accurate measurement of performance in VEs may be jeopardized by participants' varying levels of susceptibility to cybersickness and the variety of ways such sickness can manifest itself. For example, performance measures may be rendered less reliable because of the growth of cybersickness symptoms during a testing session. Validity may also suffer because participants may become too incapacitated to respond quickly or accurately. Finally, measures may lose sensitivity because experts, in contrast to novices, may be disproportionately vulnerable to cybersickness.

8. SUMMARY

The measurement of human performance should be a consideration throughout the design and life cycle of a VE system. An integrated approach to performance measurement should take into account the what, how, and when of performance measurement and consideration of psychometric properties of data. For most VE systems, performance measurement will involve

a combination of automated data capture and observation by human raters. Other relevant chapters are: chapter 13, "Principles for the Design of Performance-oriented Interaction Techniques;" chapter 30, "Signs and Symptoms of Human Syndromes Associated With Synthetic Experiences" (i.e., cybersickness); chapter 34, "Usability Engineering of Virtual Environments;" and chapter 44, "Team Training in Virtual Environments." The cybersickness chapter is relevant in that certainly sickness can affect performance and performance can influence cybersickness. The team-training chapter presents not only an excellent discussion of team performance measurement but also describes how a proactive approach to VE design can aid performance measurement.

1. INTRODUCTION

When computer technology permeated society, few envisioned that it would disable rather than enable the workforce. In fact, the U.S. Department of Labor has concluded that musculoskeletal disorders, such as carpal tunnel syndrome, "have been the largest single job-related injury and illness problem in the United States for the last decade," disabling workers in epidemic proportions (OSHA, 2000). This has led the Occupational Safety and Health Administration to issue an Ergonomics Program standard (29 CFR 1910.900) "to address the significant risk of employee exposure to ergonomic risk factors in jobs in general industry workplaces." A proactive approach might have minimized such risks, and those venturing into virtual environment (VE) technology applications can learn from this experience.

The problems associated with VE technology are real. In fact, they could make carpal tunnel syndrome pale in comparison, because beyond the traditional problems associated with computer technology, they comprise a host of new problems (see chaps. 29–32, this volume). Virtual environment exposure can cause people to vomit (about 1%), experience nausea (about 69.9%), disorientation (about 67.5%), and oculomotor problems (about 77.7%). It can also cause sleepiness (about 41.9%) and visual flashbacks (about 11%).* Approximately 80% to 95% of those exposed to a VE report some level of symptomatology postexposure, which may be as minor as a headache or as severe as vomiting or intense vertigo (Stanney, Salvendy et al., 1998). More troubling, the problems do not stop immediately upon cessation of exposure. In fact, VE exposure is associated with aftereffects (see chaps. 31, 37–39, this volume), which can render the exposed individual ill equipped to operate in their normal environment for a period

* Statistics derived from a database of 785 participants exposed to VE for 15 to 60 minutes (Stanney, 2001).

of time after exposure. Such aftereffects bring about products liability concerns for those who use the technology without appropriate safeguards (see chap. 27, this volume). In addition, beyond the workforce, these problems may be particularly troublesome for other venues, such as entertainment-based applications (see chap. 55, this volume), which are generally less supervised than workplace applications, such as those used in training (see chaps. 43 and 44, this volume), education (see chaps. 45 and 46, this volume), and medicine (see chaps. 47–51, this volume).

The response to VE exposure varies directly with the dose (i.e., VE stimulus intensity), capacity of the individual exposed (e.g., susceptibility, experience), and exposure duration (see chap. 30, this volume). This indicates that through effective usage protocols that address the strength of the VE stimulus, screening of individuals, and usage instructions the problems associated with VE technology can be minimized.

2. STRENGTH OF THE VIRTUAL ENVIRONMENT STIMULUS

The “dose” of a VE stimulus is determined by technological factors that in some way disturb the internal state of the individual exposed. In particular, sickness and other adverse effects are generally thought to be due to sensory conflicts between the design of the VE stimulus and what users expect due to their previous experiences in the real world (see chaps. 30 and 31, this volume). Different VE systems have different levels of conflict, and thus system developers and administrators need to assess the strength of their VE stimulus (i.e., how likely it is to cause adverse effects during and after exposure). Once the stimulus strength is known and the capacity of those exposed has been determined, appropriate usage protocols can be established.

In establishing the strength of a VE stimulus it is beneficial to know which technological factors lead to a more intense stimulus. Measures can then be taken to reduce technological issues associated with the adverse effects of VE exposure. In general, system factors thought to influence stimulus strength include: system consistency (Uliano, Kennedy, & Lambert, 1986); lag (So & Griffin, 1995); update rate (So & Griffin, 1995; see chap. 3, this volume); mismatched interpupillary distance (IPDs) (Mon-Williams, Rushton, & Wann, 1995; Mon-Williams, Wann, & Rushton, 1993, 1995; see chap. 37, this volume); large field of view (FOV), Kennedy & Fowlkes, 1992; see chap. 3, this volume); spatial frequency content (Dichgans & Brandt, 1978, cf. Figure 6, p. 770); visual simulation of action motion (i.e.,vection [Kennedy, Berbaum, Dunlap, & Hettinger, 1996; see chap. 23, this volume]); and unimodal and intersensorial distortions (both temporal and spatial). While the technological factors within any given system can produce varying adverse effects, system developers should ensure that the guidelines in Table 36.1 are heeded to minimize stimulus strength.

Focusing on the parameters in Table 36.1, system developers should identify the primary factors that are inducing adverse effects in their system. For example, in the domain of the visual system the mismatch between accommodation and vergence demands has been highlighted (Howarth & Costello, 1996; Mon-Williams et al. 1993; Wann, Rushton, & Mon-Williams, 1995). Although IPD settings may not be critical (Howarth, 1999), it can be demonstrated that a mismatch between the orientation of the optical axes of a display and the axes assumed for software generation may produce large errors (Wann, Rushton, & Mon-Williams, 1995). DiZio and Lackner (1997) identified large end-to-end visual update delays and a large FOV as significant etiologic factors in a VE that used a head-mounted display (HMD). Although FOV and display resolution may affect the usability of a display system and lead to motion sickness, they have not been shown (with current displays) to be critical factors in producing visual stress. It is pertinent to note that both common and unique stimulus factors can arise from

TABLE 36.1
Addressing System Factors That Influence the Strength of a VE Stimulus

- Ensure any system lags/latencies are stable; variable lags/latencies can be debilitating.
 - Minimize display/phase lags (i.e., end to end tracking latency between head motion and resulting update of the display).
 - Optimize frame rates.
 - Provide adjustable IPD.
 - When large FOVs are used, determine if it drives high levels ofvection (i.e., perceived self motion) (see chap. 23, this volume).
 - If high levels ofvection are found and they lead to high levels of sickness, then reduce the spatial frequency content of visual scenes.
 - Provide multimodal feedback that minimizes sensory conflicts (i.e., provide visual, auditory, and haptic/kinesthetic feedback appropriate for situation being simulated).
-

TABLE 36.2
Steps to Quantifying VE Stimulus Intensity

1. Get an initial estimate. Talk with target users (not developers) of the system and determine the level of adverse effects they experience.
 2. Observe. Watch users during and after exposure and note comments and behaviors.
 3. Try the system yourself. Particularly if you are susceptible to motion sickness, obtain a firsthand assessment of the adverse effects.
 4. Measure the dropout rate. If most people can stay in for an hour without symptoms, then the system is likely benign; if most people drop out within 10 minutes, then the system is probably in need of redesign.
 5. Measure. Use simple rating scales to assess sickness (see chap. 30, this volume) and visual, proprioceptive, and postural measures to assess aftereffects (see chaps. 37–39, this volume).
 6. Compare. Use Table 36.3 to determine how the system under evaluation compares to other VE systems.
 7. Report. Summarize the severity of the problem, specify required interventions (e.g., warnings, instructions), and set expectations for use (e.g., target exposure duration, inter-session intervals).
 8. Expect drop-outs. With a high-intensity VE stimulus, dropout rates can be high.
-

either HMD or spatially immersive displays (SIDs or Cave Automatic Virtual Environments [CAVEs] [see Cruz-Neira, Sandin, & DeFanti, 1993]). A unique factor that is present in an HMD is lag between head movement and update of the visual display. Much like an HMD, a stereoscopic SID may also present a discord between accommodation and vergence stimuli (Wann & Mon-Williams, 1997). In addition to this, an SID may, from some viewing positions, require a small degree of aniso-accommodation (unequal focus across the two eyes). It can be demonstrated that under intensive viewing conditions, even a desktop stereoscopic display can produce aftereffects for the binocular visual system, whereas a nonstereoscopic display will not (Mon-Williams & Wann, 1998). As can be seen from the various studies reported here (see Stanney et al., 1998), the manner in which individual software and hardware components can be integrated varies greatly; thus, to establish the stimulus strength of any given system, the steps in Table 36.2 should be taken.

The comparative intensity of a VE system can be determined via reference to Table 36.3, which provides quartiles of sickness symptoms based on 29 VE studies (Cobb, Nichols, Ramsey, & Wilson, 1999; Kennedy, 2001; Kennedy, Jones, Stanney, Ritter, & Drexler, 1996; Stanney, 2001; Stanney, & Hash, 1998) that evaluated sickness via the Simulator Sickness Questionnaire (SSQ); Kennedy, Lane, Berbaum, & Lilienthal, 1993). If a given VE system is

75 th	27.9
95 th	33.3
99 th	53.1

TABLE 36.4
Factors Affecting Individual Capacity to Resist Adverse Effects of VE Exposure

1. Adaptation. Set intersession exposure intervals 2 to 5 days apart to enhance individual adaptability.
2. Age. Expect little motion sickness for those under age 2; expect greatest susceptibility to motion sickness between the ages of 2 and 12; expect motion sickness to decline after 12, with those over 25 being about half as susceptible as they were at 18 years of age.
3. Gender. Expect females to be more susceptible than males (perhaps as great as three times more susceptible).
4. Anthropometrics. Consider setting VE stimulus intensity in proportion to body weight/stature.
5. Individual susceptibility. Expect individuals to differ greatly in motion sickness susceptibility and use the MHQ or another instrument to gauge the susceptibility of the target user population.
6. Drug and alcohol consumption. Limit VE exposure to those individuals who are free from drug or alcohol consumption.
7. Rest. Encourage individuals to be well rested before commencing VE exposure.
8. Ailments. Discourage those with cold, flu or other ailments (e.g., headache, diplopia, blurred vision, sore eyes, or eyestrain) from participating in VE exposure; encourage those susceptible to photic seizures and migraines, as well as individuals with preexisting binocular anomalies to avoid exposure.
9. Clinical user groups. Obtain informed sensitivity to the vulnerabilities of these user groups (e.g., unique psychological, cognitive, and functional characteristics). Encourage those displaying comorbid features of various psychotic, bipolar, paranoid, substance abuse, claustrophobic, or other disorders where reality testing and identity problems are evident to avoid exposure.

of high intensity (say the 50th or higher percentile, with a total SSQ score of 20 or higher), significant dropouts can be expected. In VE studies, dropout rates of 20% or more are common, with about 50% of the attrition occurring within the first 20 minutes of exposure (Stanney, Lanham, Kennedy, & Breaux, 1999).

3. INDIVIDUAL CAPACITY TO RESIST ADVERSE EFFECTS OF VE EXPOSURE

Given the current state of knowledge, it is difficult to differentiate the interpretation of adverse effects of VE exposure according to influencing individual factors, such as age, gender, anthropometrics, drug and/or alcohol consumption, and health status. However, sufficient knowledge is available to set general guidelines regarding the capacity of those exposed (see Table 36.4).

Capacity can be defined as the capability of an individual to resist adverse effects resulting from VE exposure. The capacity of an individual to undergo VE exposure varies greatly both

within an individual and between individuals. Within an individual, capacity can be reduced (e.g., via high VE stimulus intensity, extended exposure duration, consumption of drugs and/or alcohol) or enhanced (e.g., via repeated exposures and related adaptation, see chap. 31, this volume). Previous exposure to a provocative environment influences susceptibility to motion sickness. Kennedy et al. (1993) found that for repeated exposures in simulators to be effective in desensitizing individuals to sickness, the intersession interval should be short (1 week or less). This finding is consistent with other reports of motion sickness, where (1) some adaptation was retained during 7-day intervals between Slow Rotation Room exposures but not during a 30-day interval (Kennedy, Tolhurst, & Graybiel, 1965); and (2) intersession intervals in navy flight trainers of 1 day or less showed no evidence of increased tolerance, nor did those greater than 6 days apart, whereas those 2 to 5 days apart appeared to be optimum (Kennedy et al., 1993).

Between individuals, there are several individual factors related to oculomotor and disorientation effects of VE exposure, including age, gender, height, and weight.¹ (Note: Interestingly, in the data set examined nausea was not correlated to any individual factors, but solely to technical factors and exposure duration). Before the age of two, children appear to be immune to motion sickness, after which time susceptibility increases until about the age of 12, at which point it declines again. In a large study ($N > 4500$) Lawther and Griffin (1986) make this point quite clearly. Those over 25 are about half as susceptible as they were at 18 years of age (Mirabile, 1990). Whether or not this trend will hold in VE systems is not currently known, but Paige (1994) has shown increased susceptibility tovection in older adults.

Some studies have found that females generally experience greater motion sickness than males (Kennedy, Lanham, Drexler & Lilienthal, 1995). In one VE study a similar gender contrast has been reported (Kennedy, Stanney, Dunlap, & Jones, 1996). In this study the mean symptomatology for females after VE exposure was 3.4 times greater than for males. This gender difference is thought to be hormonally related (Schwab, 1954; see chap. 32, this volume). It is possible that at certain phases of the menstrual cycle a woman is more susceptible to motion sickness than at others. In studies of postoperative nausea and vomiting (PONV) the severity of sickness has been found to be dependent on the stage in the menstrual cycle and if a woman is on the contraceptive pill (Beattie, Lindblad, Buckley, & Forrest, 1991; Honkavaara, Lehtinen, Hovorka, & Korttila, 1991; Ramsay, McDonald, & Faragher, 1994).

As with other poisons (see *poison theory* discussion in chap. 32, this volume), the same dosage appears to be more detrimental to those of smaller stature. Thus, the relation to height, weight, and even gender may indicate that VE stimulus intensity should be given in proportion to body weight. It must be noted, however, that there are great individual differences in susceptibility to toxins (Konz, 1997); thus, it is beneficial to use body stature in conjunction with motion sickness susceptibility to set exposure guidelines.

Susceptibility to motion sickness is thought to be influenced by several factors (Kennedy, Dunlap, & Fowlkes, 1990). Physiological predisposition has been associated with hormonal and cardiovascular factors, as well as hypersensitivity of the vestibular system. Psychological predisposition is generally attributed to personality type (e.g., propensity to report adverse effects, neuroticism, and anxiety) and cognitive style (e.g., field articulation and perceptual rigidity). Regardless of the factors that predispose one to motion sickness, an individual is generally very aware of their personal level of susceptibility; thus self-report can be used to gauge this factor.

The Motion History Questionnaire (MHQ), which was developed 30 years ago to study airsickness and disorientation due to Coriolis stimulation, is often used to assess susceptibility to motion sickness (Kennedy & Graybiel, 1965). The MHQ assesses susceptibility based on past occurrences of sickness in inertial environments. Using this multi-item paper-and-pencil questionnaire, individuals list past experiences in and preferences for provocative motion

environments. Scores on the MHQ are generally predictive of an individual's susceptibility to motion sickness in physically moving environments.

Except in some clinical cases (see chaps. 49–51, this volume), VE exposure should be limited to those individuals who are free from drug or alcohol consumption. (Note: In clinical user groups, informed sensitivity to the vulnerabilities of these groups (e.g., unique psychological, cognitive, and functional characteristics) should be obtained. See (chap. 50, this volume). Both drug and/or alcohol consumption and VE exposure have been shown to degrade hand-eye coordination (see chap. 38, this volume), postural stability (see chap. 39, this volume), and visual functioning (see chap. 37, this volume). While limited research has been conducted on the combined stress of drug and/or alcohol use and VE exposure, such biodynamics (Hettinger, Kennedy, & McCauley, 1990) have been studied in the context of other environments that cause illusory self-motion (Gilson, Schroeder, Collins, & Guedry, 1972; Schroeder & Collins, 1974). If one applies the findings of these studies to VE exposure, the expectation is that adverse effects of VE exposure will be exacerbated by drug and alcohol use.

Virtual environment exposure is also known to lead to motion induced drowsiness, known as the sopite syndrome (see chap. 30, this volume). Thus, individuals should generally be well rested before commencing VE exposure. If the immune system is already compromised by ill health, this may intensify the adverse effects of VE exposure. Thus, those with cold, flu, or other ailments should be discouraged from participating.

There are some individuals who should probably not participate in VE exposure. This includes but is not limited to those susceptible to photic seizures and migraines (see chap. 29, this volume), those displaying comorbid features of various psychotic, bipolar, paranoid, substance abuse, claustrophobic, or other disorders where reality testing and identity problems are evident (see chap. 50, this volume) and those with preexisting binocular anomalies (see chap. 37, this volume). Binocular vision develops early and is relatively stable by the early school years, but the age at which children should be allowed unconstrained access to HMD-based systems is still open to debate. Similarly, adults vary in the robustness of their visual systems. It can be predicted that someone with unstable binocular vision may experience stronger postexposure effects if there are stimuli that place some stress on either the accommodation (focal) system, vergence system or the cross-links between them (Wann et al., 1995).

4. VE USAGE PROTOCOL

A systematic VE usage protocol can be developed that minimizes risks to users. A comprehensive VE usage protocol will consider the following factors:

1. Following the guidelines in Table 35.1, design VE stimulus to minimize adverse effects (see section 2).
2. Following the guidelines in Table 35.2, quantify VE stimulus intensity of target system and compare to quartiles in Table 35.3.
3. Following the guidelines in Table 35.4, identify individual capacity of target user population to resist adverse effects of VE exposure.
4. Provide warnings (see chap. 27, this volume) for those with severe susceptibility to motion sickness, seizures, migraines, cold, flu, or other ailments (see section 3).
5. Educate users as to the potential risks of VE exposure (see chaps. 29–33, this volume). Inform users of the insidious effects they may experience during exposure, including: nausea, malaise, disorientation, headache, dizziness, vertigo, eyestrain, drowsiness, fatigue, pallor, sweating, increased salivation, and vomiting. Depending on VE content, potential adverse psychological effects may also need to be considered (see chap. 33, this volume).

6. Educate users as to the potential adverse aftereffects of VE exposure (see chaps. 37–39, this volume). Inform users that they may experience disturbed visual functioning, visual flashbacks, as well as unstable locomotor and postural control for prolonged periods following exposure. Relating these experiences to excessive alcohol consumption may prove instructional.
7. Inform users that if they start to feel ill they should terminate their VE interaction, because extended exposure is known to exacerbate adverse effects (Kennedy, Stanney, & Dunlap, 2000).
8. Donning an HMD is a jarring experience (Pierce, Pausch, Sturgill, & Christiansen, 1999). Depending on the complexity of the virtual world, it can take 30 to 60 seconds to adjust to the new space (Brooks, 1988). Prepare users for this transition by informing them that there will be an adjustment period.
9. Adjust environmental conditions. Provide adequate air flow and comfortable thermal conditions (Konz, 1997). Sweating often precedes an emetic response; thus proper air flow can enhance user comfort. In addition, extraneous noise should be eliminated, as it can exacerbate ill effects.
10. Fatigue can exacerbate the adverse effects of VE exposure. To minimize fatigue, ensure all equipment is comfortable and properly adjusted for fit (see chap. 41, this volume). HMDs should fit snuggly and be evenly weighted about a user's head, stay in place when unsupported, and avoid uneven loading to neck and shoulder muscles. Many HMDs have adjustable head straps, IPDs, and viewing distance between the system's eyepieces and user's eyes. Ensure users optimize these adjustments to obtain proper fit. Tethers should not obstruct movements of users. DataGloves and other effectors should not induce excessive static loads via prolonged unnatural positioning of the arms or other extremities.
11. For strong VE stimuli, limit initial exposures to a short duration (e.g., 10 minutes or less) and allow an intersession recovery period of 2 to 5 days.
12. For strong VE stimuli, warn users to avoid movements requiring high rates of linear or rotational acceleration and extraordinary maneuvers (e.g., flying backward) during initial interaction (McCauley & Sharkey, 1992).
13. Throughout VE exposure, an attendant should be available at all times to monitor users' behavior and ensure their well-being. The attendant may also have to assist users if they become stuck or lost within the virtual world, as often happens (see chap. 24, this volume).
14. Indicators of impending trouble include excessive sweating, verbal frustration, lack of movement within the environment for a significant amount of time, and less overall movement (e.g., restricting head movement). Look for red flags. Users demonstrating any of these behaviors should be observed closely, as they may experience an emetic response. Extra care should be taken with these individuals postexposure. Note: It is beneficial to have a bag or garbage can located near users in the event of an abrupt emetic response.
15. Set criteria for terminating exposure. Exposure should be terminated immediately if users verbally complain of symptoms and acknowledge they are no longer able to continue. Also, to avoid an emetic response, if telltale signs are observed (i.e., sweating, increased salivation), exposure should be terminated. Some individuals may be unsteady upon postexposure. These individuals may need assistance when initially standing up after exposure.
16. After exposure, the well-being of users should be assessed. Measurements of their hand-eye coordination and postural stability should be taken. Similar to field sobriety tests, these can include measures of: balance (e.g., standing on one foot, walking an imaginary line, leaning backward with eyes closed); coordination (e.g., alternate hand

- clapping and finger to nose touch while the eyes are closed); and eye nystagmus (e.g., follow a light pen with the eyes without moving the head). Do not allow individuals who fail these tests to conduct high-risk activities until they have recovered (e.g., have someone drive them home).
17. Set criteria for releasing users. Specify the amount of time after exposure that users must remain on premises before driving or participating in other such high-risk activities. In our lab a 2-to-1 ratio is used; postexposure users must remain in the laboratory twice the amount of exposure time to allow recovery.
 18. Call users the next day or have them call to report any prolonged adverse effects.

5. CONCLUSIONS

The risks associated with VE exposure are real and include ill effects during exposure, as well as the potential for prolonged aftereffects. To minimize these risks, VE system developers should quantify and minimize VE stimulus intensity, identify the capacity of the target user population to resist the adverse effects of VE exposure, and then follow a systematic usage protocol. This protocol should focus on warning, educating, and preparing users, setting appropriate environmental and equipment conditions, limiting initial exposure duration and user movements, monitoring users and looking for red flags, and setting criteria for terminating exposure, debriefing, and release. Adopting such a protocol can minimize the risk factors associated with VE exposure, thereby enhancing the safety of users, limiting the liability (see chap. 27, this volume) of system developers and administrators.

1. INTRODUCTION

This chapter is organized in the following manner. First, a detailed consideration of the ocular-motor system is provided. This section must be reasonably detailed in order to justify the measures recommended. Second, a series of clinical tests are detailed that are useful in indicating whether the ocular-motor system has been placed under stress. These tests are used generally to explore ocular-motor status before and after using a particular virtual environment (VE) system for a given period of time. Finally, a different approach to investigating the impact of VE systems on the ocular-motor system is discussed. This final section describes experimental results that highlight some interesting features of the ocular-motor system. These results are used to illustrate the fact that VE systems can help us understand the nervous system and to argue that the most profitable aftereffect measurements result from paradigms that probe the manner in which the nervous system adapts to virtual environments.

2. BINOCULAR ORGANIZATION

2.1 Refraction

It is possible to think of the eye as an optical system where the cornea and crystalline lens have a certain refractive power with a corresponding focal length (the distance from the optical system to a principal focal point) as illustrated in Fig. 37.1. The length of the eye can be considered as being independent of the power of the optical system. If the length of the eye is such that the retina is at the focal length of the optical system, the eye is described as being *emmetropic*. If

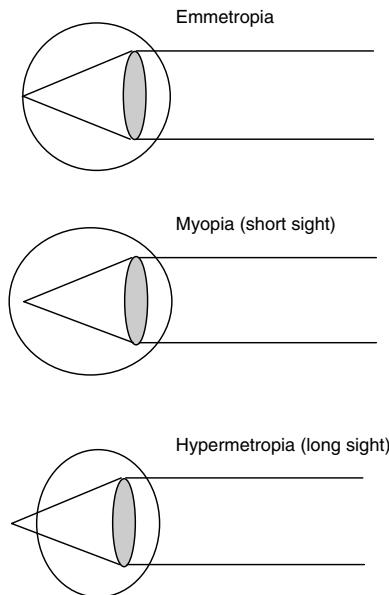

FIG. 37.1. It is possible to think of the eye as an optical system where the cornea and crystalline lens have a certain refractive power with a corresponding focal length (the distance from the optical system to a principal focal point) as illustrated. If the length of the eye is such that the retina is at the focal length of the optical system, the eye is described as being emmetropic (*upper plot*). If the retina is beyond the focal length, the eye is described as being myopic (*middle plot*), and if the retina is closer than the focal length, the eye is described as hypermetropic (*lower plot*).

the retina is closer than the focal length, the eye is described as *hypermetropic*, and if the retina is beyond the focal length, the eye is described as being *myopic*. It is possible for the optical system of the eye to cause two separate focal planes, of which both can fall behind, both can fall in front, or one can fall on either side of the retina. Such eyes are described as *astigmatic* (it is easiest to think of the astigmatic optical system being shaped like an egg instead of a sphere). Eyes that are myopic, hypermetropic or astigmatic are described as having *refractive error*. The refractive error refers to the extent to which the eye is too long or too short for the power of the optical system and is described in terms of dioptres: the reciprocal of the refractive error in meters. It is normal to express the refractive error in terms of the lens that needs to be placed in front of the eye to correct for the refractive error—myopia requires a concave (negative) lens, whereas hypermetropia requires a convex (positive) lens. Lens power is specified in dioptres, which are equivalent to the reciprocal of focal distance specified in meters.

An eye's refractive state is not constant over the life span. It has been well established that newborn babies are born with hypermetropia (approx. 2–3 dioptres) and astigmatism. Over the first 6 months of life, however, the hypermetropia and astigmatism disappear and the majority of children end up being emmetropic. This progression from hypermetropia to emmetropia is known as *emmetropisation* and is widely held to be a process under active neural control (see Saunders, 1995). Although the majority of children are emmetropic, it is reasonably common for myopia to develop between the 12 and 25 years of age (so-called late onset myopia). The etiology of late onset myopia is unknown but there is a reasonable amount of evidence that links the condition to prolonged close fixation and visual stress. Thus, it seems sensible to suggest that individuals between the ages of 12 and 25 years should beware of prolonged exposure to poor quality VE displays that require close fixation.

2.2 Eye Movements

Horizontal movements of the two eyes may be considered as either conjugate, when the eyes move in the same direction, or disconjugate when the eyes move in opposite directions. These two types of eye movement are also commonly referred to as version and vergence movements, but because the phonetic similarity leads to confusion, the term *conjugate* is used herein rather than version. Conjugate eye movements are responsible for maintenance of static fixation (gaze holding), rapidly changing eye fixation position (saccadic movement), or continuously maintaining fixation on a moving object (pursuit). The majority of humans are binocular, and thus conjugate eye movements require coordinated movement of both eyes. Hering (1977) originally suggested that the nervous system controls the two eyes as if they were a single organ, and this idea has subsequently received a large amount of empirical support (see Mon-Williams & Tresilian, 1998). Hering's law suggests that the same command (e.g., move 10 degrees to the left) is sent to both eyes. In order for this control arrangement to succeed, it is necessary for the peripheral ocular-motor system to adapt in response to changes between the two eyes. Thus, it appears as if the nervous system has a large degree of peripheral adaptability in order that the central command structure can remain reasonably invariant. The adaptability allows the system to respond to changes induced by neuromuscular fatigue or disease, as well as respond to changes in the viewing environment. This suggests that a crucial issue in the design of VE is the extent to which a VE system places adaptive pressures on the ocular-motor system and the manner in which the nervous system responds to those pressures. It seems reasonable to suggest that the primary adaptive pressures placed on the ocular-motor system relate to binocular vision. It is the case that a poorly designed VE headset could induce adaptation in reflexive type eye movements (e.g., the vestibular ocular reflex, see chap. 39, this volume) by introducing temporal lags between sensed changes in head movements and the resulting visual display. Nonetheless, it is difficult to see a well-designed system placing pressure on monocular viewing. Thus, the fundamental problem faced by the ocular-motor system relates to the binocular coordination between the eyes. The binocular system is, therefore, herein considered in some depth. It is important at this stage to differentiate two different types of VE systems—*biocular displays* and *stereoscopic binocular displays*. Biocular displays present identical images to the two eyes, whereas stereoscopic binocular displays present different images to the eyes (the differences, or disparities, can provide a powerful phenomenological impression of three-dimensional (3-D) depth). As demonstrated in the discussion below, the potential for visual aftereffects is far higher in stereoscopic binocular displays than in biocular displays. Indeed, a well-designed biocular display is likely to place few adaptive demands on the ocular-motor system.

2.3 Vergence and Accommodation

In this section, the components of the ocular-motor system, which are responsible for providing clear and single vision (accommodation and vergence eye movements, respectively), are briefly described. It is assumed initially that the eye is emmetropic. It is possible to represent the key features of accommodation and vergence in an heuristic model of the vergence and accommodation control system (see Fig. 37.2, modified from Schor & Kotulak, 1986). If an observer wishes to change fixation from a distant object to one near (or vice versa), the retinal image of the target object is initially defocused (blur describes this error of focus) and there is

a fixation error between the image of the target and the fovea (disparity refers to this error of fixation). In order to bring clarity to the retinal image the eye must focus in a process known as accommodation, and to overcome disparity the eyes must change vergence angle to maintain fixation within corresponding retinal areas (if noncorresponding points of the retina are stimulated then double vision will result).

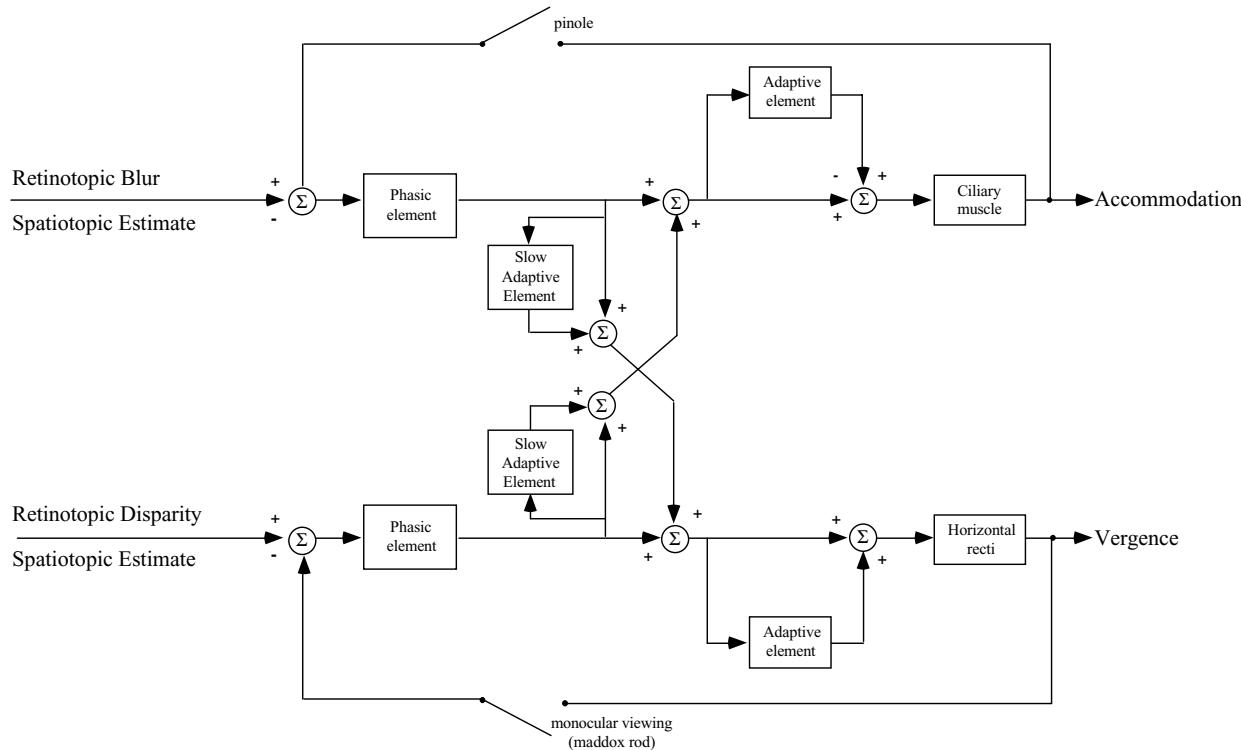

FIG. 37.2. A heuristic model of the vergence and accommodation control system (modified from Schor & Kotulak, 1986). In normal situations the systems rely on negative feedback, with a phasic element in the feed-forward pathway rapidly eliminating blur and disparity. A tonic controller is also present in both systems, and this adapts to reduce any steady-state demands placed on the phasic response component. The tonic controller ensures that the accommodation and vergence system are kept in the middle of their functional range. In order to further maximize system efficiency, the accommodation and vergence responses are neurally cross-linked so that accommodation produces vergence eye movements, whereas vergence causes accommodation. The negative feedback loop to accommodation may be opened by removing blur information (e.g., by viewing through a pinhole), and the vergence feedback loop may be opened by removing disparity (e.g., by covering one eye). The open-loop vergence bias is known as heterophoria (see text for details).

Although blur and disparity are extremely effective *retinotopic* feedback signals, they are only effective over small distances so that larger changes are driven by *spatiotopic* stimuli (Schor et al., 1992). The spatiotopically driven changes get the accommodation and vergence systems into the right “ ballpark,” and then retinotopically driven responses achieve precisely located fixation. Despite the importance of the spatiotopic response, it remains unclear what information provides the necessary stimuli—it is an issue of distance perception, which is still a topic of considerable debate (Mon-Williams & Tresilian, 1999).

In retinotopic conditions, the systems rely on negative feedback, with a phasic element in the feed-forward pathway rapidly eliminating blur and disparity. The feedback loop to accommodation may be negated (“opened”) by removing blur information (e.g., by viewing through a pinhole), and the vergence feedback loop may be opened by removing disparity (e.g., by covering one eye). These procedures allow measurement of the bias within the system. The bias reflects the resting position of the system and can be modified through visual demand.

2.3.1 Phasic Elements

Figure 37.2 illustrates that accommodation is driven (retinotopically) through blur, whereas vergence responds to disparity (see Schor, 1983, 1986, for a comprehensive overview). An initial change in vergence angle or accommodative state is initiated by a phasic element within the vergence and accommodation system, respectively. The phasic controller acts to rapidly eliminate blur and disparity in order that a clear and single image is achieved. The disparity that drives vergence is the absolute disparity of the target object (i.e., the disparity with respect to the horopter). The horizontal disparities that provide for stereopsis are derived from relative disparities. It follows that the disparity signal for vergence is not the same as that used for stereopsis.

2.3.2 Tonic Elements

A tonic controller in the vergence and accommodation system can adapt to reduce any steady-state demands placed on the phasic response component (e.g., Carter, 1965; Schor, 1979). The tonic controller ensures that the accommodation and vergence system are kept in the middle of their functional range.

2.3.3 Cross-links

In order to maximize system efficiency, the accommodation and vergence responses are neurally cross-linked (see Schor, 1986) so that accommodation produces vergence eye movements (accommodative vergence), whereas vergence causes accommodation (vergence accommodation). Accommodative vergence is normally expressed in terms of its ratio with accommodation (the AV/A ratio), and vergence accommodation is expressed in terms of its ratio with vergence (the VA/V ratio). The cross-coupling interactions between accommodation and vergence are stimulated by the phasic but not by the tonic control elements (Schor, 1986). Thus, the cross-links have been shown to originate after the phasic element but before the site of the tonic controller.

2.4 Vergence (or “Prism”) Adaptation

In the initial consideration of the vergence system it was emphasized that a tonic element exists in the feed-forward pathway, and that this component acts to minimize any demands placed on the phasic controller. It follows that if the eyes maintain a convergent position for a prolonged period of time, the resting position of the eyes will shift inwards and reciprocally after prolonged divergence the resting position of the eyes will shift outward.

The tonic element means that a change in the demands placed on the vergence system will not necessarily produce visual problems: It is possible that any demands will be accommodated by the adaptable element within the vergence system. On the other hand, it has been established that symptomatic individuals have reduced tonic adaptability (Fisher, Ciuffreda, Levine, & Wolf-Kelly, 1987). A reduced ability to adapt to steady-state viewing together with large vergence demands may cause some individuals to suffer from visual fatigue. Vergence adaptation is often described as *prism adaptation*, as the easiest way of artificially inducing the adaptive behavior is to place unyoked prisms in front of the eyes. A poorly designed VE system can induce prism through a misalignment of the viewing optics in situations where the lenses are not collimated to infinity (Mon-Williams, Wann, & Rushton, 1993). In a binocular VE system, the screens can be set at any viewing distance from optical infinity to very close to the observer. The closer the viewing distance, the greater the vergence demand. It is necessary to realize that what constitutes too large a vergence demand varies from individual to individual (North & Henson, 1981) and between age groups (Winn, Gilmartin, Sculfor, & Bamford, 1994). Importantly, it has been shown that individuals with binocular vision anomalies lack the ability to adapt to induced changes in vergence bias (Henson & Dharamshi, 1982), and this has been hypothesized as being one of the causes of binocular vision problems (Schor, 1979). A well-designed binocular VE system can avoid the vergence system needing to adapt to the virtual environment.

It is worth drawing attention to another factor that can place demands on the adaptable element of the vergence system. As vertical gaze angle (the vertical orientation of the eyes with respect to the head) is changed, the effort required of the extraocular muscles becomes modified (Heuer & Owens, 1989; Heuer, Bruwer, Romer, Kroger, & Knapp, 1991). This may be readily demonstrated by fixating the tip of a pen held close (e.g., 10 cm) to the face and raising and lowering the pen. It will be noted that it is considerably more comfortable to fixate the pen when it is approximately in line with the mouth and considerably less comfortable to fixate when at eye level. The reason for these changes in comfort relate to the fact that the muscles used to lower the eyes also aid convergence, whereas the muscles used to raise the eyes aid divergence (Mon-Williams, Burgess-Limerick, Plooy, & Wann, 1999). Thus the vertical position of VE screens can alter the vergence demands placed on the ocular-motor system. It should not be assumed that the user will adjust a VE headset if the gaze angle is inappropriate. The major determinant of a head-mounted display's (HMD's) position on the head is the design of the headset together with the muscular-skeletal position of greatest comfort (see chap. 41, this volume). Once the HMD is in place it is highly unlikely that a user will equate eyestrain with the vertical location of the headset. It should also be noted that the majority of HMDs allow for initial adjustment of head position, after which time the headset is fixed in place (normally by means of a headband that is tightened).

We have previously used a software calibration routine that allows for the measurement of heterophoria within a VE headset (essentially, this routine displays a tangent screen on one screen and a vertical line on the other). Use of this routine allows a user to adjust a VE headset until the heterophoria measures reach a minimum value. Furthermore, we have described a routine that enables any demands placed on the vergence system by a VE system to be minimized (Wann, Rushton, & Mon-Williams, 1995). Such software may be extremely useful when adjusting an HMD's position on the head and ensuring that the VE system is not placing large demands on the adaptable component of vergence.

2.5 Accommodative Adaptation

In the same manner as the vergence system, the accommodation system has a tonic element in the feed-forward pathway in order to minimize any demands placed on the phasic controller. The easiest way of inducing accommodative adaptation is by placing refractive lenses in front

of the two eyes. It follows that VE systems that use refractive lenses to present images to the human observer may induce accommodative adaptation. In general, such adaptive demands are met readily by the ocular-motor system unless the viewing distance is very close. One additional issue of accommodative adaptation that arises with VE systems is the extent to which the eyes are capable of *aniso-accommodation* (Marran & Schor, 1998). Aniso-accommodation describes the response of the ocular-motor system to unequal accommodative demands between the two eyes. Situations can arise naturally when the eyes have unequal refractive error and thus have different focusing demands. In general, large interocular refractive discrepancies lead to strabismus and amblyopia (see later), but it has been reported that the ocular system can respond to small discrepancies by adjusting the tonic accommodative resting position of the eyes independently (Marran & Schor, 1997; Marran & Schor, 1998). It is possible for a poorly designed VE system to introduce unequal focusing demands if the optical focus is not perfect for the two eyes. It is likely that such a system would place adaptive pressures on both the accommodation and vergence system. Nonetheless, such problems will only occur in poorly designed VE systems.

2.6 Cross-link Adaptation

Helmholtz (1924) argued that developmental change (such as increasing interocular distance and sclerosis of the crystalline lens with age) requires that the cross-links should be open to adaptation. Although some studies have provided indirect evidence for plasticity, there is no conclusive evidence that environmental pressures will directly change the normal cross-link relationship. The VA/V ratio has received relatively little attention owing to difficulties in its measurement, but it is known that the AV/A cross-link may be temporarily modified through cycloplegia, miosis, visual fatigue, and orthoptics (Christoferson & Ogle, 1956; Flom, 1960; Manas, 1955; Parks, 1958). On the other hand, it is not certain whether these transient modifications actually reflect plasticity within the cross-links or arise from an alteration in other components of the motor systems. It has been demonstrated that fatigue in the adaptable tonic component can produce predictable changes in cross-link behavior for individuals with abnormal binocular vision. Schor and Tsuetaki (1987) showed that reducing adaptability of tonic accommodation increases the AV/A and decreases the VA/V, whereas reducing adaptability of tonic vergence has the opposite effect.

What has not been determined unambiguously is whether it is possible to directly modify the cross-links in individuals with normal binocular vision. One technique for placing pressure on the cross-links is to use telestereoscopes to optically increase interocular separation, or cyclopean spectacles to negate interocular separation (see Fig. 37.3). In telestereoscopes the observer must increase vergence relative to the focal depth of a target, hence pressure is placed on the AV/A to increase and the VA/V to decrease. In contrast, cyclopean spectacles require a decrease in the AV/A and an increase in VA/V. An appropriate increase in the AV/A has been observed following the use of telestereoscopes for 30 minutes, but in conflict, a corresponding decrease in the AV/A ratio was not found after the use of cyclopean spectacles (Judge & Miles, 1985; Miles & Judge, 1982; Miles, Judge, & Optican, 1987). Cyclopean spectacles require accommodation to vary normally, whereas vergence is fixed (see Fig. 37.3), which is difficult, and hence single vision is often lost. Miles et al. (1987, p. 2585) reported that "subjects had difficulty in obtaining single, sharp images when viewing nearby objects through the cyclopean spectacles and were never able to overcome this problem entirely." To achieve adaptation, comparison is required between the ocular motor response and the perceptual goal (a clear, single target image). If the goal of single vision is consistently disrupted due to other neuromuscular factors, the cyclopean paradigm fails to provide the requisite conditions for adaptation to occur. In summary, telestereoscopes have been used to successfully increase the AV/A ratio, but attempts to reduce the AV/A ratio with cyclopean spectacles have been unsuccessful. Schor and Tsuetaki (1987)

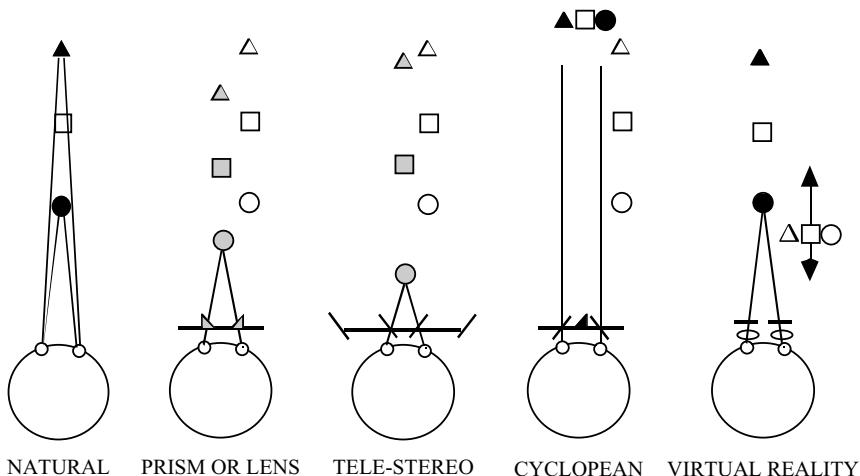

FIG. 37.3. Stimuli to accommodation and vergence in natural conditions; when a constant vergence or accommodation bias is introduced; and when viewing in optical devices. In natural conditions the stimuli to accommodation (empty symbols) and vergence (shaded symbols) are in accordance. If a lens or prism power is induced, a constant offset (bias) is introduced. It is possible for a poorly designed VE system to induce such biases (see text for details). Telestereoscopes necessitate an increase in vergence per unit change in natural unaltered accommodation. Cyclopean spectacles require normal accommodation, whereas vergence remains fixed at optical infinity. In a stereoscopic VE display, accommodation and vergence stimuli are disassociated, and the degree of disassociation depends on viewing distance (thus requiring a change in the gain of the AV/A and VA/V ratios) even when the VE system is optically perfect.

have argued convincingly that because the AV/A always rose together with a concomitant fall in the VA/V in studies using telestereoscopes, the response to the telestereoscopes might have been due to fatigue of adaptable tonic accommodation rather than direct cross-link modification.

The issue of cross-link adaptation is extremely important with regard to VE systems. Biocular VE systems will not place any adaptive demands on the cross-links. In contrast, a stereoscopic binocular system requires individuals to maintain a constant level of accommodation while changing vergence angle when changing fixation between near and far objects. The stereoscopic binocular systems thus place large adaptive demands on the ocular-motor system and raise the crucial issue of whether the cross-links themselves are open to direct adaptation.

2.7 Strabismus

Binocular fixation of a stationary object requires that both visual axes are aligned with an object of interest in order to eliminate double vision. Examination of the muscular and neurological systems involved in the coordination of the two eyes can be carried out using a *cover test*. The cover test consists of the covering and uncovering of each eye in turn while the fellow eye maintains fixation on a target. Any movement of the eye when its fellow is being covered indicates the presence of heterotropia (commonly referred to as strabismus or squint). Strabismus can either be convergent (esotropia) or divergent (exotropia) and can affect either eye (e.g., right esotropia). The primary sensory effect of strabismus is amblyopia in the nonfixating eye. One of the consequences of amblyopia is an increased threshold for stereopsis. Strabismus can result from adaptive pressures being placed on a compromised binocular system.

2.8 Heterophoria

The majority of human observers do not have strabismus (i.e., no bias is present in closed-loop situations) but do show an open-loop vergence bias. It is possible to measure the constant resting point (or bias) that exists within the vergence system by opening the normal feedback loop to vergence (e.g., by removing any disparity information). Open-loop vergence bias is known as heterophoria and may be defined as a slight deviation from perfect binocular positioning that is apparent only when the eyes are dissociated. Esophoria refers to convergent visual axes when the eyes are dissociated and exophoria to divergent axes (see Fig. 37.4). Note that the gain of the cross-links is less than one. This means that individuals are generally exophoric when fixating close targets.

It should also be noted that it is possible to observe vertical or rotational biases in the vergence system. The ocular-motor system shows a markedly lower ability to adapt to vertical or rotational deviations from perfect binocular positioning, and thus such deviations will normally produce double vision. Nevertheless, it is possible for poorly aligned VE systems to require small amounts of vertical or rotational adaptation, and thus it is necessary to test for such deviations when measuring visual aftereffects following VE exposure. In the interest of brevity, the following discussion restricts the consideration of heterophoria to the more commonly observed horizontal deviations.

2.9 Binocular Vision Anomalies

It is not uncommon for binocular vision to break down or fail to develop properly. Binocular vision anomalies can be classified according to the scheme in Fig. 37.5. Incomitant deviations are far rarer than comitant deviations. Incomitant deviations describe deviations that vary with the direction of gaze and arise due to direct trauma of the neuromuscular system. It is comitant deviations that are important with regard to VE systems. Heterophoria is often a precursor to strabismus (strabismus representing the situation when the system can no longer maintain binocular vision and normal binocular vision breaks down). Heterophoria can be classified in the following manner:

2.9.1 *Esophoria*

1. Divergence weakness esophoria. Esophoria at distance > esophoria near.
2. Convergence excess esophoria. Esophoria at distance < esophoria near.
3. Basic esophoria. Esophoria at distance = esophoria near.

2.9.2 *Exophoria*

1. Convergence weakness exophoria. Exophoria at distance < exophoria near.
2. Divergence excess exophoria. Exophoria at distance > exophoria near. This often breaks down into strabismus for distance viewing.
3. Basic exophoria. Exophoria distance = exophoria near.
4. Convergence insufficiency.

A consideration of the organization of the accommodation and vergence system provides insight into the etiology of heterophoria and strabismus. It has been well established that abnormalities of the cross-link ratios in childhood are associated with strabismus. One of the most common forms of childhood strabismus is the Donders' squint or accommodative strabismus. This strabismus arises in children who have a high hypermetropic prescription. The need to exert high levels of accommodation to produce clear vision creates a high level

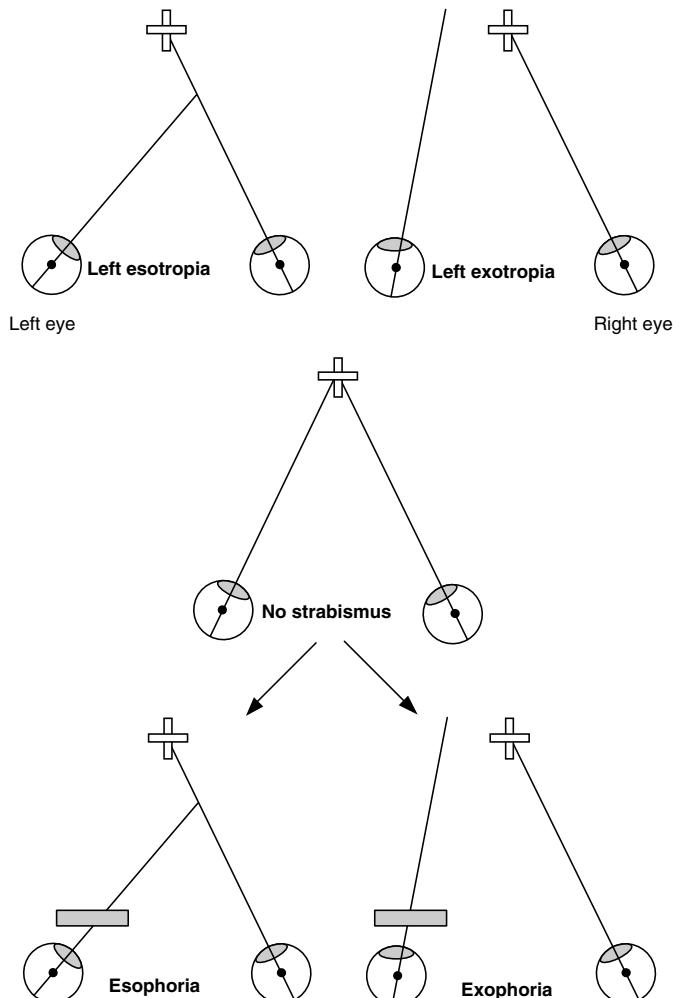

FIG. 37.4. In normal binocular viewing, the visual axes of both eyes are in alignment with a fixated target (*middle plot*). If the axes are not in alignment, the system is described as strabismic or heterotropic. The left upper plot illustrates esotropia (convergent visual axes), and right upper plot illustrates exotropia (divergent visual axes). It is possible to measure the constant resting point (or bias) that exists within the vergence system in people without strabismus by opening the normal feedback loop to vergence (e.g., by covering one eye). Open-loop vergence bias is known as heterophoria. Esophoria refers to convergent visual axes (*left lower plot*) when the eyes are dissociated and exophoria to divergent axes (*right lower plot*).

of vergence because of the accommodation-vergence cross-link. These demands ultimately result in esotropia. Note that poorly designed VE systems can induce the same high levels of accommodation as hypermetropia.

An alternative mechanism of strabismus can occur when the cross-links have too high or too low a gain. For example, a high AC/A ratio results in convergence excess and a low AC/A ratio results in convergence insufficiency. Recall that high adaptation of accommodation and low adaptation of vergence results in a low AC/A ratio and vice versa. One possible treatment of high and low AC/A ratios is thus to fatigue the highly adaptable element. In cases of convergence insufficiency, this is achieved by having patients track the tip of a pencil backward

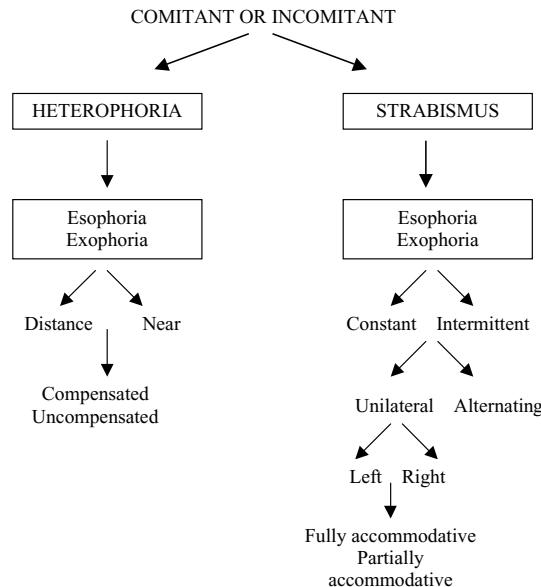

FIG. 37.5. Classification scheme for binocular visual anomalies.

and forward. Schor and Tsuetaki (1987) have shown that such treatment can restore normal cross-link function. Quick et al. (1994) have found that monkeys with esotropia show either a reduced or an abnormally high AV/A ratio. Moreover, Parks (1958) has reported a high incidence of abnormal accommodative vergence in adult humans with strabismus. The fact that the cross-links are placed under particular adaptive pressure by binocular stereoscopic VE systems has already been discussed. It is worth highlighting the fact that VE systems may also hold the key to treating binocular anomalies—the very adaptive pressures that might cause problems to a normal oculomotor system might be beneficial to a malfunctioning system.

The importance of considering the etiology of strabismus and heterophoria when evaluating VE systems relates to the pressures potentially placed by VE on the cross-links and adaptable elements of vergence and accommodation. It seems reasonable to suggest that these issues are of paramount importance when considering the use of VE systems with young children in whom binocular vision is not yet fully developed.

2.9.3 Position-specific Heterophoria Adaptation

Heterophoria describes the difference in position between the two eyes when one eye is occluded. In situations where a prism is placed in front of one eye (see section 2.4), the stimulus for adaptation is reasonably constant at all direction of gaze. In situations where a magnifying lens (for example) is placed in front of one eye, the amount of adaptation required changes as the eye moves eccentrically from the optical center of the lens (Maxwell & Schor, 1994). The ocular-motor system is known to be able to adapt in a position specific manner, but the time constants of such adaptive behavior are far greater than those observed in uniform adaptation. Indeed, the initial response of the ocular-motor system to position-specific vergence pressure is to adapt uniformly in order to decrease or eliminate the demand on at least one part of the visual field (Maxwell & Schor, 1994). The initial global adaptation process is followed by a slower acting position-specific alignment. It is possible for position-specific heterophoria to be induced by a poorly designed VE system (once more through optical errors). It should also be noted that the representation of true 3-D space with two-dimensional (2-D) image planes has

the potential to introduce spatial biases between the two eyes, with the biases becoming larger as gaze becomes increasingly eccentric (Wann et al., 1995). It is possible that these biases will place position-specific adaptation pressures on the ocular-motor system. It is not clear whether these small distortions have practical implications with prolonged exposure to VE systems that use flat screen projections of 3-D images.

2.9.4 Summary of Some Key points

Although it is possible for a binocular VE display to promote changes in the user's visual system, adaptive pressures are only likely to be found in a system with very poor optical quality or poorly integrated tracking. In contrast, the basic design of all current stereoscopic binocular systems means that they will place adaptive pressures on the user because the binocular stimuli are not commensurate with natural viewing (Fig. 37.3). In some cases, the adaptive pressure may be minor, but sustained usage of a binocular display that presents large depth intervals is likely to produce transient aftereffects. The consequence of such effects depends on the individual's visual status and cannot be predicted without a full clinical appraisal. Where sustained usage is planned with binocular displays that present large depth intervals, prepost visual screening (see section 3) should be undertaken with candidate observers prior to unsupervised use, and any observers with pre-existing binocular anomalies should be excluded or carefully monitored. Symptoms (headache, difficulty focusing) should be used as indicators that display usage should cease, but symptoms cannot be used as the sole criteria for evaluating potential problems, hence questionnaire studies are imprecise tools for assessing visual aftereffects.

3. CLINICAL MEASURES OF VISUAL AFTEREFFECTS FOLLOWING VE EXPOSURE

There are two methods of measuring visual aftereffects following VE exposure. One method is to take a series of measures before and after VE use and explore whether there are any statistically reliable differences between these measures. Additionally, it is possible to compare any changes with a control condition in which the same measures are taken before and after the same period of time viewing, for example, a standard computer monitor. The alternative method is to take a series of clinical measures before and after VE use and determine whether any of these measures has shown a clinically significant change. We would argue that this technique provides a far more powerful tool and avoids the problems associated with testing the null hypothesis (a single person developing strabismus might not produce a statistically reliable change in the population means but would unarguably represent a significant aftereffect). We will outline a series of useful clinical measures that should be evaluated with regard to VE systems.

3.1 History and Symptoms

A general medical and ocular history should be recorded together with any symptomatic complaints. Participants should be asked to report if they are suffering from any adverse symptoms including a list of headache, diplopia, blurred vision, sore eyes, or eyestrain. Participants should be asked to report verbally any such symptoms during or following use of the VE system.

3.2 Vision/Visual Acuity

The term *eyesight* is herein used to describe the clarity of the retinal image. The reason for using this terminology is because the terms *vision* and *visual acuity* have specialist meanings

within the ophthalmic literature: *Vision* refers to uncorrected eyesight, whereas *visual acuity* describes the level of eyesight obtained with optimum refractive correction. Participants should be assessed in their normal situation so that vision is recorded for participants who do not normally wear spectacles or contact lenses, and visual acuity for those who have (and wear) a refractive correction. It is most important to assess binocular eyesight, as disturbances of the ocular-motor system can cause a reduction in the normal advantage of binocular viewing. Eyesight is typically assessed with some form of letter chart and expressed as a fraction where the numerator refers to the distance of the chart and the denominator refers to the distance at which the smallest visible letter subtends five minutes of arc. The standard clinical chart is placed at 6 meters (or 20 feet), and a person with "good" eyesight is expected to read letters that subtend 5 minutes of arc at that distance. If someone can read the small letters near the bottom of a chart then they will typically have eyesight equal to 6/6 or better (20/20 in imperial measures), but if only the large letter on top of the chart could be read then the eyesight would be equal to 6/60 (6/12 occurs about halfway down). Traditional (Snellen) eyesight charts have major disadvantages for scientific studies. These disadvantages relate to: (1) the lines changing in unequal step sizes and (2) the lines having an unequal number of letters. These two facts make it impossible to report valid statistics for Snellen eyesight measures. For this reason we propose the use of logarithmic charts when evaluating eyesight. For example, we have used previously the Glasgow Acuity Cards designed for clinical screening (McGraw & Winn, 1993). The Glasgow Acuity Cards use a progression of letter sizes in a geometrical series with a ratio of 0.1 log units per card. Each card contains four letters of equal legibility and equivalent letter-row spacing is maintained throughout. Vision is recorded either as the log of the minimum angle of resolution or as a decimal value from 0.0 (6/60 Snellen) to 1.0 (6/6 Snellen). Use of the Glasgow Acuity Cards allows for accurate measurement and better analysis of the vision/visual acuity than the traditional Snellen chart.

It should be noted that ophthalmic charts typically measure high-contrast eyesight (i.e., a well-defined black shape or letter against a bright white background). The problem with such charts is that they do not indicate how well the visual system can process retinal information at different spatial frequencies (e.g., how well someone can see when contrast is low). A number of methods do exist, however, that allow eyesight to be assessed over a range of spatial frequencies. It is possible (in principle) for a VE system to cause a decrease in the mid-range spatial frequency sensitivity. The reason for this is that the visual system responds to an amelioration of high spatial frequencies by depressing the mid-range spatial frequencies in order to unmask the higher frequency channels (Mon-Williams, Tresilian, Strang, Kochar, & Wann, 1998). A VE system that has poor image quality effectively filters the high-spatial-frequency information from a display and thus might cause the visual system to adapt. There are a number of commercially available contrast sensitivity charts for use in a clinical setting. One such chart is the Pelli-Robson chart (Pelli, Robson, & Wilkins, 1988). This chart is wall mounted and consists of 16 letter triplets. The triplets are of constant contrast, but the contrast reduces between triplets from the top to the bottom of the chart. The Pelli-Robson chart and other available alternatives allow for easy measurement of contrast sensitivity. In all methods of eyesight measurement it is important that the recommended level of illumination is used.

3.3 Refractive Error

It is worthwhile measuring the refractive state of the eye before and after the use of a VE system to ensure that the refraction has not changed because of accommodative adjustment. The most common clinical method of assessing refractive status involves a *retinoscope*. The standard retinoscopy technique involves shining a light into the eye while viewing the resultant

retinal reflection (the “red eye” observed in flash photography) along the visual axis through a semisilvered mirror. The practitioner then rotates the retinoscope and observes the resulting movement of the beam. If there is no resultant movement there is no refractive error; if the reflex moves in the same direction as the retinoscope (with it), then the eye is hypermetropic, and if the reflex moves in the opposite direction, the eye is myopic.

3.4 Ocular–motor Balance

Examination of the muscular and neurological systems involved in the coordination and integration of the two eyes can be carried out using a battery of clinical tests. The cover test is described in section 2.7, which consists of the covering and uncovering of each eye in turn while the other eye maintains fixation on the smallest target visible to both eyes. Any movement of the eye when its fellow is being covered indicates the presence of strabismus, whereas any movement of the eye when it is being uncovered shows the presence of heterophoria. Further assessment of heterophoria can be carried out using a Maddox rod at 6 meters and a Maddox wing for use at 33 centimeter in good illumination (500 lux). A “flashed” approach is the optimum method of obtaining the heterophoria reading for distance and for near. It is important to assess the horizontal, vertical, and rotational components of binocular alignment.

One useful index of binocular function is provided by *fixation disparity*: small errors of binocular fixation that do not disrupt binocular vision, as the errors do not exceed Panum’s fusional areas (the corresponding retinal errors in the two eyes). It is straightforward to measure fixation disparity, but we suggest that associated heterophoria provides a much better indicator of binocular stress. *Associated heterophoria* is the term used to describe the amount of prism required to reduce fixation disparity to zero and is readily measured using a Mallett unit. (Mallett, 1974) Mallett units use a binocular lock consisting of the letters OXO and monocular markers in line with the X to demonstrate the presence of uncompensated heterophoria, because viewed through Polaroid filters, the monocular markers will remain in line only in the absence of uncompensated heterophoria. The existence of uncompensated heterophoria provides a useful indication of binocular stress. Standard Mallett distance and near units can be used with loose trial case prisms within a trial frame in order to produce absolute alignment of the nonius lines using the minimal value of prism in 0.5 prism diopter steps for the distance and 1 prism diopter steps for near. Participants should be instructed to look for even very small movements of the nonius lines. A full review of Binocular Vision tests is presented in Pickwell (1984). An example of a Mallet unit adapted for use within a VE display is presented in Wann et al. (1995).

3.5 Near Point of Convergence

Clinical measurement of pursuit convergence should be taken with a vertical line target brought toward the eyes on the median plane until diplopia (double vision) is reported and/or one eye can be seen to diverge. It is also possible to assess “jump” vergence by asking participants to rapidly change fixation from a near target to a far one and vice versa.

3.6 Amplitude of Accommodation

The dynamic recording of accommodation is technically demanding (in contrast to the relatively straightforward techniques available for recording eye movements). It is possible, however, to use the retinoscope (see section 3.3) to determine the level of accommodation that occurs in response to a proximal target. The eye’s ability to change focus from the far point

to the near point of vision should be measured in dioptres using subjective report of near text becoming illegible. Amplitudes of accommodation should be checked for any abnormality. Accommodative facility can be assessed by placing ophthalmic lenses in front of the eyes and evaluating the time it takes for the eyes to relax or increase accommodation.

3.7 Stereopsis

There are a large number of clinical tests of stereopsis (including the TNO test, the Frisby test, the Stereo random dot E test, the Titmus random dot test, and the Lang test). Stereopsis provides a good indication of binocular status, because stereoscopic sensitivity drops rapidly when binocular vision is compromised. It is important to ensure that the tests are conducted at a standardized distance, as disparities are inversely proportional to the square of the distance. It is also important to ensure that the test is carried out under good illumination (e.g., 500 lux).

4. BEYOND CLINICAL MEASURES

The measures described in section 3 are proposed as the basic requirements in an applied setting for appraising any new or substantially modified display system or to screen any group of individuals who may be required to use a binocular display for sustained or repetitive periods. In addition to these measures, it is possible to undertake a more analytical approach in an experimental setting to evaluate the impact of different adaptive pressures. In this section, an example of undertaking such a study is outlined using an infrared optometer and eye tracking to appraise the response of the AV/A cross-links (section 2.3.3) to sustained and demanding usage of a conventional binocular VE system.

4.1 A Study of AV/A and VA/V Adaptation

The AV/A and VA/V ratio (section 2.3.3) were objectively measured before and after usage of a VE system. Two volunteer participants (AS and MB) took part in the experiments. Both were 25 years of age, emmetropic, did not take any medication, had no ophthalmic abnormalities, and were naive to the purpose of the experiment. The participants gave written consent and the experiments met the approval of the university ethics committee. Clinical measures of accommodation amplitude, stereoacuity thresholds, AV/A and VA/V ratios were all normal. LCD shutter goggles were used to present field-sequential computer generated images at 120 Hz on a high-resolution computer monitor. The participants viewed a high-contrast cross for 60 minutes in the dark oscillating from optical infinity to either 33 centimeter or 16 centimeter with accommodative demand set at the closest distance. The angular size of the target cross was kept constant as it moved in depth creating the percept of a single cross of unchanging size located at a constant egocentric distance. In the early stages of adaptation, participants had to exert voluntary vergence to eliminate double vision. At first participants had problems consistently fusing the target, but after the first 10 minutes they reported that it was easy to keep a clear single target though both complained of sore eyes and frontal headaches. Hence this presented a highly demanding task that is unlikely to occur in many occupational setting, but similar stimuli may occur if close visual monitoring is required of targets moving in depth over a sustained period (e.g., some military applications or some games). The experimental issue was what changes resulted from the sustained usage.

Dynamic accommodation was measured using a modified Canon Autoref R-1 infrared (IR) objective optometer. The autorefractor determines the position of focus in three meridians, from which the spherocylindrical refractive error can be computed to an accuracy of $\pm 0.12\text{D}$

per second. Vergence was recorded with a purpose built differential IR limbal tracker, accurate to 10 arcmin under the employed experimental conditions. The IR sources were chopped at greater than 1000 Hz, with the detectors set to only recognize this frequency (thus avoiding direct current drift, reducing 1/f noise, and eliminating cross-talk between the photodiodes and the IR optometer). Cross-axis sensitivity was found to be $\pm 10\%$. The analogue output of the eye trackers was fed into a digital storage oscilloscope, which was controlled by an IBM-clone computer via an IEEE-488 interface. This system allowed inspection of the analogue signals to be made in real time so that artifacts (e.g., blinks) could be identified. Comprehensive calibration routines were carried out before preadaptation measurements and after postadaptation recordings. The ambient room illumination was constant at approximately 250 lux. Natural pupil size was monitored on an external 9-inch video monitor (Sony PVM 97) using the magnified ($8.2 \times$) image provided by the IR optometer to ensure that pupillary changes were not a confound (pupil size always exceeded 0.5 cm).

Accommodative vergence was measured by covering the left eye with an occluder. Participants fixated a high-contrast Maltese cross through a 5-dioptre Badal lens, whereas accommodative demand was altered via ophthalmic trial lenses so that the only change in the stimulus was due to accommodation. Targets were presented along the optical axis of the right eye to ensure that eye movements did not interfere with the accommodative recording. Vergence accommodation was measured using a Difference of Gaussian (DoG) stimuli. The DoG presented a blurred vertical bar of 0.4 cm, which acted as a stimulus to vergence but not to accommodation. Vergence demand was altered via ophthalmic prisms so that the only change in the stimulus was due to disparity vergence.

Accommodation and vergence responses were expressed in dioptres (D) and meter angles (MA) respectively: Both are the reciprocal of distance in meters (MA is the angle through which each eye has rotated from the primary position in order to fixate an object located 1 meter away), so 1 D or 1 MA corresponds to 100 centimeter, 2 D, or MA corresponds to 50 centimeter, etc. The normal AV/A ratio is approximately 0.60 ± 0.2 MA/D, and the VA/V ratio is around 0.5 ± 0.2 D/MA. The cross-link response was assessed using five separate measurements of accommodation and vergence for seven different stimuli conditions presented in a randomized order (to control for hysteresis). The stimuli were in unitary D or MA steps from optical infinity to six. Measurement of the AV/A and VA/V was alternated pre- and postadaptation and between participants.

4.2 Results

Figure 37.6 shows that cross-link interaction changed following adaptation. Regression lines are plotted and correlation coefficients are provided, although the nonlinear nature of the post-adaptation data weakens any regression analysis (the post-adaptation data for AS showed a significant, $p < 0.05$, quadratic component). Dunn's procedure (Keppel, 1982, p. 146) was carried out on the data points of interest.

The target distance did not produce exact accommodation or vergence, emphasizing the importance of measuring ocular response when computing cross-link ratios. The pre- and postadaptation vergence responses were identical for MB but showed a mean decrease of 0.28 MA for AS (maximum of 0.6), whereas the accommodation responses decreased by a mean of 0.36 D for MB and 0.54 for AS (maximum of 0.6 and 0.98, respectively). The maximum shift was always found in the stimuli where the ocular demands were greatest. These decreases suggest that some plant fatigue is occurring, but the shifts cannot explain the cross-link changes.

In participant MB it is clear that the AV/A and VA/V ratios have been reduced, thereby allowing accommodation and vergence to independently respond to blur and disparity cues. The

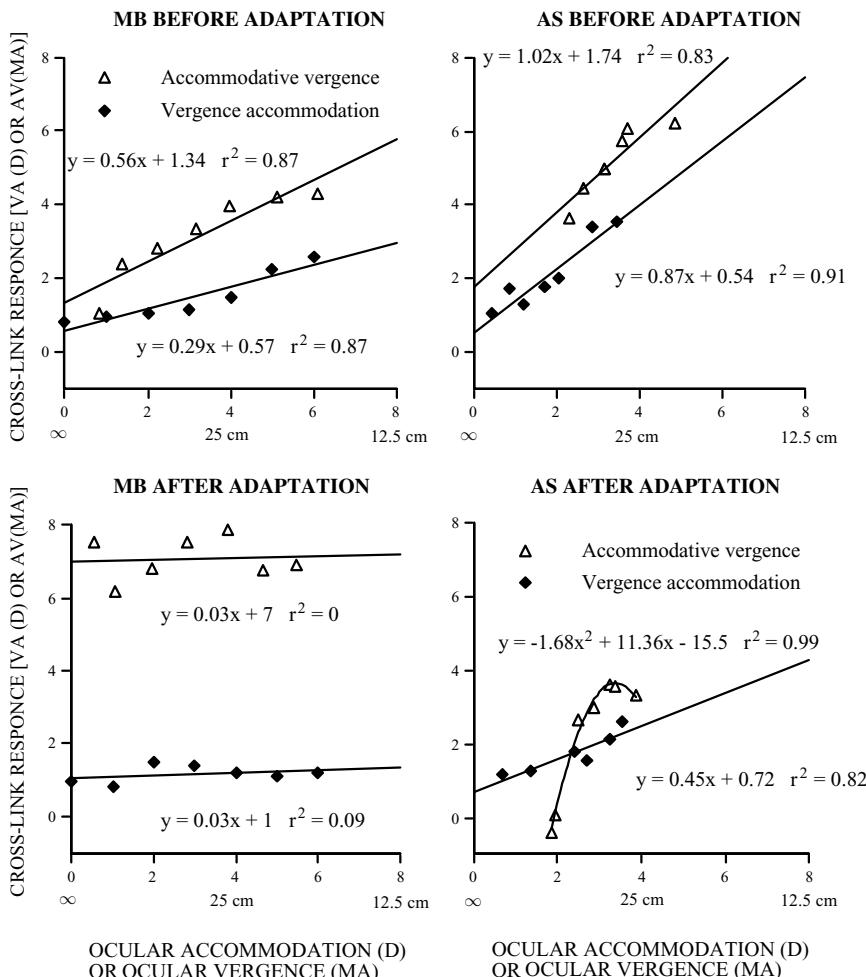

FIG. 37.6. The cross-links between accommodation and vergence before (above) and after (below) adaptation for MB (left) and AS (right). Each point is the mean of five randomly organized measurements. The standard deviation of the measurements was smaller than the plot symbol. The primary response (ocular accommodation [A in Dioptres] or vergence [V in Meter Angles]) is plotted on the abscissa with the secondary [cross-link] response (accommodative vergence [AV in MA] or vergence accommodation [VA in D], respectively) shown on the ordinate. The normal ratios may clearly be seen to change following adaptation.

variability in the AV/A response is typical of an uncoupled system, whereas the accommodation produced by the VA/V stabilizes around the bias found in the absence of accommodative stimuli.

The data from participant AS are less compelling than those of MB. On the other hand, it is clear that the cross-link responses have changed. The change in the VA/V is very similar to the clear lowering of the ratio observed in participant MB. The change in gain of the AV/A ratio is less straightforward, as the postadaptation AV/A ratio showed a significant quadratic component. It therefore appears that part of the slope has increased its gain, whereas the other part has flattened.

The data from participant MB are very compelling, suggesting that the AV/A and VA/V ratios have both decreased following exposure to the VE display. The data from participant AS are less impressive, but detailed examination shows a similar picture to the data from

participant MB. The data suggest that both participants have reduced the normal action of accommodative vergence and vergence accommodation. This is the ideal response to a VE system where there is no correlation between the continually changing vergence disparity and accommodative stimulus.

5. CONCLUSIONS

To reiterate the summary in section 3, binocular visual displays can result in unusual visual pressures being placed on accommodation and vergence. These may be partially reduced by a change in tonic accommodation and tonic vergence, but where objects are presented with a wide range of depths, tonic shifts cannot provide a solution (Fig. 37.3). Global shifts in bias can only decrease the ocular-motor demands of uniform disparities or blur. We propose that non-uniform demands (like those produced in VE systems) require a response from the cross-links systems. The results presented in section 4 suggest that the cross-links between accommodation and vergence are directly open to adaptive pressures. These results highlight the importance of addressing fundamental issues of binocular coordination when considering the pressures placed on the ocular-motor system by VE systems. The simultaneous decrease observed in the AV/A and VA/V ratios cannot be explained (in a parsimonious manner) by an alteration in the adaptability of the respective tonic components or by plant fatigue. This may be viewed as a positive adaptation to the VE setting, but the negative consequences, highlighted by the symptoms of headache and sore eyes, should not be overlooked. Adaptation of this type is not stress free, and we would take the conservative position that it is not desirable if it can be avoided through the design of VE tasks (not just display design, but the rendered stimuli) or limiting exposure periods. Our previous suggestion that binocular VE systems may place pressure on the accommodation and vergence system was initially controversial (Mon-Williams et al., 1993; Wann et al., 1995). There is now ample evidence from a number of studies to confirm our original hypothesis. It is important therefore that such effects are monitored and managed in any setting where sustained usage of a binocular system is likely to occur.

1. INTRODUCTION

Until relatively direct interfaces with brain signals become widely available, users will have to play a physically active part in controlling the virtual environment (VE). This involves moving the head, eyes, limbs, or whole body. Control and perception of movement depends heavily on proprioception, which is traditionally defined as the sensation of limb and whole body position and movement derived from somatic mechanoreceptors. This chapter presents evidence that proprioception actually is computed from somatic (muscle, joint, tendon, skin, vestibular, visceral) sensory signals, motor command signals, vision, and audition. Experimental manipulation of these signals can alter the perceived spatial position and movement of a body part, attributions about the source and magnitude of forces applied to the body, representation of body dimensions and topography, and the localization of objects and support surfaces. The effortless and unified way these qualities are perceived in normal environments depends on multiple, interdependent adaptation mechanisms that continuously update internal models of the sensory and motor signals associated with the position, motion and form of the body, the support surface, the force background, and properties of movable objects in relation to intended movements.

An understanding of these mechanisms is important to VE users because VEs will sometimes inadvertently and sometimes purposely expose active users to never before encountered combinations of sensory and motor signals and environmental constraints. In many cases, this will lead to perceptual and motor errors in the VE until internal adaptation has been updated. When a user who has adapted to a VE carries the new adaptive state back into the normal environment, he or she will experience aftereffects, usually in the form of mirror image errors to those initially made in the VE (see chap. 31, this volume). These can include deviated execution of limb and whole body movements, proprioceptive errors, misestimates of externally imposed forces, and visual and auditory mislocalizations.

This chapter will use concepts derived from laboratory studies as a basis for interpreting measurements of proprioceptive side effects and aftereffects in virtual environments. It discusses what VE conditions will alter the state of sensory and motor adaptation, what components of the movement and orientation control system will adapt, what side effects and aftereffects will result from adaptive modification of these subsystems, and what contexts will evoke aftereffects. This survey emphasizes facets of proprioception relevant to VEs involving manual performance and whole body motion tasks. A balanced presentation is attempted of both the value and the limitations of laboratory-based conceptual distinctions for making the best predictions in practice.

2. PROPRIOCEPTION, MOTOR CONTROL, AND SPATIAL ORIENTATION

2.1 Multisensory and Motor Factors

In his analysis of sensation and motor control, Sherrington (1906) coined the term *proprioceptors* for the mechanoreceptors located inside body tissues that are primarily responsive to changes within the animal itself. Examples of these receptors are spindle organs in the muscles, Golgi tendons organs, unmyelinated Ruffini endings of the joints, and various sensor types in the viscera and vasculature, which were thought to be inaccessible to external energy but well attuned to body orientation, configuration, and movement. In contrast, systems whose sensors are located on the body surface and receive external stimuli were categorized as exteroceptive. The skin mechanoreceptors are located on the boundary of the environment and the body and have overlapping proprioceptive and exteroceptive roles. They are involved in discriminating form, texture, pain, temperature, and other complex properties of the external world as well as body configuration, motion, and orientation (especially for the fingers, lips, and tongue). Vision, audition, and olfaction are exteroceptive systems, but they can also be used to monitor motion and orientation of the limbs and the whole body. Sherrington noted that the vestibular labyrinth of the inner ear (semicircular canals and otolith organs) is developmentally derived from the exteroceptive system, but it acts in concert with the proprioceptive system because it is stimulated by pressure changes and shear forces in the sensory end organs usually brought about by head and body motion and changes in orientation. His analysis acknowledges that proprioception is multisensory and overlaps with other experiential domains.

Proprioception is also directly related to motor control. Internal signals corresponding to movement commands (or the command not to move) have been posited as contributing to proprioception and spatial awareness. They have been called “the desire” (Aristotle, 1978), “the perceived effort of will” (Helmholtz, 1925), “efference copy” (Von Holst & Mittelsteadt, 1950), or “corollary discharge” (Sperry, 1950). The idea that such efference copy signals are sufficient for conscious perception of movement or position lacks strong empirical support (see McCloskey & Torda, 1975, for a review). For example, when humans are subjected to local ischemic nerve block or systemic neuromuscular block and attempt to move one of their paralyzed limbs they do not perceive any illusory movement, but instead have a sense of great heaviness (Lazlo, 1963; Melzack & Bromage, 1973). However, internal motor signals seem to interact with afferent signals in visual perception and oculomotor control. For example, fruitless attempts to move a paralyzed eye are accompanied by a great sense of effort and apparent motion and displacement of visual targets (Matin et al., 1972). In Von Holst and Mittelsteadt’s (1950) terms, motor control and perception mechanisms must discriminate between “reafferent” sensory signals brought about by self-initiated movement

and “exafferent” signals evoked by external events. One way for this to happen would be for an efference copy signal to cancel only the reafferent portion of the total afferent signal. This requires an internal calibration in which the afferent and efferent signals are represented in comparable units and in the appropriate proportions.

2.2 Sensorimotor Calibration

The correlations between afferent and efferent signals, however, are very complex. For example, there is no unique pattern of motor command and sensory feedback signals associated with even a simple single-joint arm movement. Raising the forearm 45 degrees vertically or flexing it 45 degrees in a horizontal plane involve very different efferent commands to and sensory feedback from the biceps brachii and brachialis muscles because the gravity torques are so different. The muscle command and feedback signals also differ when weights are wielded or machines are manipulated, even for the same movement amplitude and orientation of the arm. A constant efferent command will not produce the same force in fatigued and rested muscle. Self-locomotion or vehicular transport can generate accelerative loads requiring unique muscle forces for accomplishing an arm movement, relative to when the body is stationary. To complicate matters further, body acceleration activates vestibular afferent discharge, which through vestibulospinal pathways innervates skeletal muscles and modulates muscle spindle sensitivity (cf. Wilson & Melville-Jones, 1976). In order for the central nervous system to use an efference copy signal to cancel just the reafferent portion of the total afferent signal, it must first parcel the sensory signals into components due to intended movement and anticipated external loads and the efferent signals into voluntary and involuntary components.

In other words, calibration of perception and motor performance involves internalization of the relationship between combinations of sensory and motor signals in relation to body movement and orientation, external loads, environmental constraints, and internal conditions. Recalibration is required when conditions change. For example, alterations in body dimensions, strength and sensory capacity throughout the life span, loss or distortion of motor or sensory function due to illness or injury, migration to a novel environmental medium (land to water) all require adaptive accommodations. There is ample evidence that given sufficient time humans can adapt to a wide range of stable sensory-motor rearrangements produced in the laboratory or in applied technological environments such as aerospace flight, traditional simulators, teleoperation, and VEs (Held & Durlach, 1991; Kennedy, Fowlkes & Lilienthal, 1993; Lackner, 1976, 1981; Rock, 1966; Wallach, 1976; Welch, 1978; chap. 31, this volume). Adaptation is often accompanied by aftereffects that degrade performance on return to the normal environment. Such aftereffects raise questions that must be addressed by VE system designers (see Table 38.1).

2.3 Muscle Spindles

Muscle spindle organs provide signals correlated with the full natural range of muscle length (limb position) and velocity (Harvey & Matthews, 1961). Spindles are connected in parallel with the muscle body so that they can be unloaded when the muscle contracts on receiving input from alpha motor neurons and loaded when the muscle lengthens. Stretch receptors embedded in each spindle's visco-elastic central region project two types of sensory fibers signaling both the spindle's length and rate of change of length (primary fibers) or only its length (secondary fibers). The polar regions of each spindle are composed of contractile fibers innervated by gamma motor neurons that provide independent central regulation of their afferent sensitivity (see Fig. 38.1). Heightened gamma innervation shortens the polar regions and thereby stretches

TABLE 38.1
Questions Concerning the Nature of Aftereffects of VE Exposure

- What conditions will trigger adaptation?
- How does the internal calibration change?
- Can multiple states of calibration be maintained?
- In what contexts will different calibration states dominate?

These theoretical questions translate into practical ones for the VE context:

- Which VEs will elicit adaptation of proprioception, motor control, and perceived orientation?
- What kinds of aftereffects will be expressed, and under what conditions?

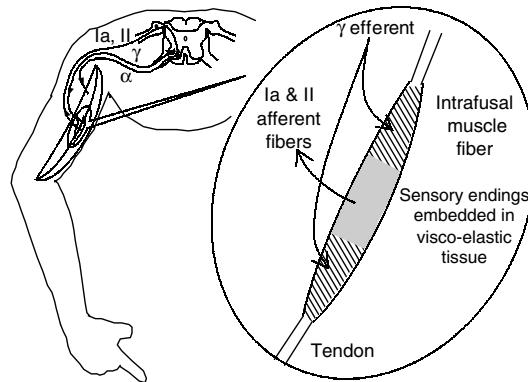

FIG. 38.1. Muscle spindles reside in parallel with extrafusal muscle fibers, which are excited by α -motor neurons and provide the contractile force for movements. In this simplified diagram, the primary (Ia) and secondary (II) afferent fibers are shown with sensory endings on the central visco-elastic portion (gray area) of a single spindle, but in reality, type Ia and II fibers innervate different types of spindles. Primary fibers discharge in proportion to muscle length and rate of change in length, and secondary fibers discharge in relation to length. Afferent discharge can be modulated by γ efferent activity innervating intrafusal contractile fibers (striped areas) located at the poles of each spindle, which loads or unloads the central region containing the sensory endings but does not contribute to overall muscle force.

the central region and produces a greater afferent discharge rate, for the same overall muscle length. In contrast, quiescent gamma efferent activity relaxes the spindle poles, unloads the central region, and decreases the afferent activity while muscle length remains constant.

Until relatively recently, muscle spindle organs were thought to be important in reflexive motor control but not to influence the conscious awareness of limb position. Position sense was thought to arise from receptors in the joint capsules, but this view was weakened by evidence from humans with artificial hips. Although capsular receptors are absent in artificial joints, patients postsurgery were found nevertheless to have normal position sense accuracy of their hip (reviewed by Burgess & Wei, 1982). Muscle spindle activity is still present and is implicated in their hip position sensitivity.

In relaxed mammals, the muscle spindle firing rate is very low, about 0 to 4 impulses/sec. Hagbarth and Eklund (1966) found that low amplitude mechanical vibration applied to the skin over a muscle causes reflexive contraction of that muscle by entraining spindle afferent discharge to the vibration frequency and activating the stretch reflex. This phenomenon is

known as the tonic vibration reflex (TVR). The vibration technique was extended by Goodwin, McCloskey, and Matthews (1972) to demonstrate that spindle afferent signals influence conscious sense of limb position and motion. In these experiments, the biceps brachii was vibrated and the participant's unseen forearm was restrained so that reflexive contraction would not shorten the muscle and unload the spindles. All participants reported feeling an increase in the elbow joint angle. The illusion could be quantified by having participants match the perceived angle of the elbow of their vibrated arm with the other arm and measuring the discrepancy in forearm positions (see Fig. 38.2A). Similarly, triceps vibration elicited an illusory flexion of the forearm. Thus, an abnormally high discharge rate in the vibrated muscle is interpreted as lengthening of the vibrated muscle and this "lengthening" is referred to the joint(s) controlled by the muscle. If the same arm vibration experiment is done in 0 G, weightless conditions, the magnitude of the illusion is smaller than in normal 1 G conditions, and in an increased gravitoinertial force background the illusion is larger (Lackner, DiZio, & Fisk, 1992). (Note: Gravitoinertial force is the resultant of gravitational and inertial acceleration on a mass. 1 G equals the force due to acceleration due to gravity at sea level.) The novel force background affects the otolith organs, which influence muscle tone by activating gamma motor neurons in the spinal cord, heightening the spindle afferent signal in high-force backgrounds, and decreasing it in 0 G. This mechanism is part of the vestibulospinal regulation of the antigravity musculature of the body. Clearly, muscle spindle afferent and efferent signals influence proprioception and motor control.

2.4 The Role of Body Schema and Spatial Orientation

Vibration of the proper muscles can produce apparent displacement and motion of the head, arm, leg, and trunk (Lackner, 1988) in a dark room. The character of these vibratory myesthetic illusions demonstrates that perceptual interpretation of the afferent signal takes into account the anatomy and dimensions of the body. For example, a vibration-induced increase in biceps brachii spindle afferent discharge: (1) affects the perceived angle of the elbow joint, which is spanned by the biceps brachii; (2) alters it in a direction (extension) that agrees with the bicep's role as a flexor; and (3) evokes apparent spatial hand motion in an arc consistent with the elbow joint's hingelike motion and the length of the forearm. Some participants experience anatomically impossible hyperextension of the forearm during biceps vibration whereas others after reaching the normal limits of extension perceive a paradoxical illusion of continuous motion without further displacement (Craske, 1977). Even nonmotile appendages can undergo apparent distortion. For example, Lackner (1988) showed that if the participant holds the tip of the nose while the biceps brachii is vibrated, he or she will perceive the nose to grow in length as the forearm extends away from the face, as illustrated in Fig. 38.2B. The relatively stable, but modifiable, cortical representation of the body schema (topography and dimensions of the body) interacts with the moment-to-moment representation of body configuration based on peripheral muscle spindle and tactile signals. This conclusion is consistent with phantom limb experiences (Henderson & Smyth, 1948).

Achilles tendon vibration gives rise to a whole body movement backward relative to the support surface because of the TVR activation of the calf muscles (Eklund, 1972). When the Achilles tendons of participants restrained in a standing position are vibrated they perceive forward body pitch, sometimes in full 360-degree circles, and even though they are physically stationary, they also show nystagmoid eye movements similar to what would be evoked by vestibulo-ocular reflexes during real body tumbling. Tactile cues from environmental surfaces can modify postural vibratory myesthetic illusions. Achilles tendon vibration normally leads to apparent pivoting about the ankles, but if the participant bites a rigid dental mold then it may become the pivot point (Lackner & Levine, 1979). If a head-fixed target light is present during such illusions, it will be perceived as moving spatially relative to the current axis of rotation,

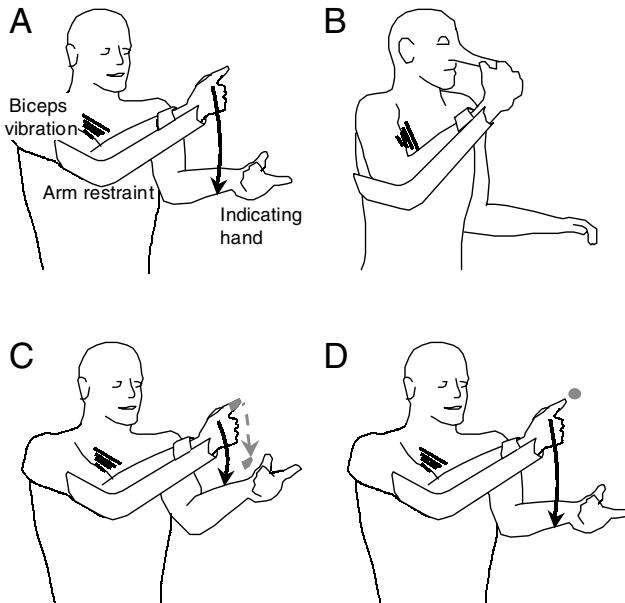

FIG. 38.2. Illusions experienced during vibration of the restrained right biceps in darkness, with different visual cues and tactile contact conditions. A: In complete darkness, biceps vibration elicits illusory extension of the restrained forearm (*solid arrow*), which can be measured if the participant points to the felt position of the hand of the vibrated arm with the other unrestrained, nonvibrated arm. B: In complete darkness, the Pinocchio illusion, elongation of the nose is experienced when it is grasped by the hand of the arm undergoing illusory elbow extension due to biceps vibration. C: When just the index finger of the vibrated right arm is made visible with phosphorescent paint (*gray*) in an otherwise dark room, the participant sees the stationary finger move down (*gray, broken arrow*) and feels the forearm displace less than in complete darkness (*compare black arrow with panel A*). D: A dim target light (*gray dot*) located 1 millimeter away from the fingertip of the restrained vibrated arm looks stationary while the concurrent apparent downward displacement of the arm is as great as in complete darkness during biceps vibration.

either the feet or the mouth. Thus, limb position, body orientation, and object localization are overlapping, interdependent representations, each derived from different combinations of muscle spindle information about a particular appendage and tactile and vestibular signals about spatial orientation. Exposure to VEs will generally not alter muscle spindle signals directly, but often will affect the user's spatial orientation, which will influence the central interpretation of proprioceptive signals, resulting in perceptual and motor errors until adaptation occurs.

2.5 Bidirectional Interactions of Visual and Muscle Spindle Influences

Most VEs will have prominent visual displays, so research on the registration of seen versus felt body position and orientation is very relevant. Lackner and Taublieb (1984) assessed this in experiments where they made either the whole hand or a single finger visible in a dark room by application of phosphorescent paint. When the biceps brachii was vibrated, participants felt the unseen forearm move and saw their finger or hand move as well but through a smaller distance (see Fig. 38.2C). The magnitude of felt motion of the forearm was less with the finger visible than in complete darkness, and it was least with the hand visible. In other words, “visual capture” (Hay, Pick, & Ikeda, 1965) was incomplete because the physically stationary visual finger did not prevent participants from seeing and feeling motion of their finger. Proprioceptive capture was substantial, the finger was seen to move nearly as much as the forearm was felt to displace.

If participants attempted to fixate their unseen hand as it underwent illusory downward motion their eyes moved down. However, when they fixated on a visible finger that they perceived as moving down during vibration their gaze remained spatially constant. The character and magnitude of vibration illusions changed in normal illumination conditions where participants could see their hand or finger in relation to the contours of the room, with the remainder of their arm being hidden below a screen. In this case, when the biceps brachii was vibrated, participants felt their unseen forearm move down but did not see the unoccluded finger or hand move. Felt motion of the arm was about 30% of what it had been in the dark room. These results indicate that multiple, interdependent, body-centered and spatially centered representations of hand and arm position exist, which are influenced by the visual and muscle spindle inputs. Seen and felt hand position are dissociable from each other and from motor responses. The strength of the bidirectional visual-proprioceptive influence relates to the amount of the limb that is represented. In VEs, the spatial correspondence of visual and real body positions, the level of detailed visual representation of the body and of the remainder of the virtual visual context will determine the magnitude and nature of proprioceptive and motor errors.

2.6 The Role of Tactile Cues in Unifying Muscle Spindle and Other Sensory Influences

When the fingertip is portrayed only by a single point of light or a punctate sound source, there are still bidirectional influences and the role of tactile contact cues is paramount. For example, if in darkness a small target light is taped to the index finger of a participant's spatially fixed arm, the stationary light will appear to displace when the biceps brachii is vibrated, but the felt motion of the arm will be less than if no target were present (Levine & Lackner, 1979). If the two forearms are restrained in a horizontal plane and vibration is applied to the right and left biceps brachii, then the apparent distance between the fingertips will increase. If target lights are attached to the opposing index fingers, participants will see them get further apart as they feel their fingers move apart (DiZio, Lackner, & Lathan, 1993). During vibration, if physical contact of a target light and finger is broken by moving the light a millimeter or more away from the finger, then the illusory visual target movement and displacement will be abolished and the illusory felt movement of the unseen limb augmented (see Fig. 38.2D). In this case, the lights seem to represent external objects instead of the tips of the fingers. During vibration eliciting apparent forearm extension or flexion, a participant will hear a sound source attached to their hand move and change spatial position in keeping with the change in apparent hand position. Breaking tactile contact with the auditory target abolishes its illusory movement during vibration. Taken together with the experiments in which various amounts of the hand were visible, it is clear that the strength of interaction among multimodal representations of self and target position depends on tactile contact cues, visual configural cues, and visual context cues.

These results have important implications for whether VEs should represent body parts with simple visual icons, high-fidelity visual representations, or haptic interfaces. In the natural world, perception and motor control are unified and accurate because there are adequate contextual cues defining how to group multisensory representations and adequate internal calibrations of how these signals should be combined. By contrast, VEs create alternate physical worlds that may require novel combinatorial rules. For example, if adequate visual form cues and tactile contact cues are present for the visual image to be perceptually grouped with the muscle spindle representation of hand position, then the visual and felt locations will influence each other. If either the visual or proprioceptive signal is inaccurate, then both perceptual representations will be biased. However, if only a visual icon is present and there isn't a contact cue with the body, then the visual object will likely be perceived as an external target rather than a representation of the hand, and the spatial perception of each may be independent.

3. PROPRIOCEPTIVE ADAPTATION OF THE ARM TO VISUAL DISPLACEMENT

3.1 Sensory Rearrangement

Visual distortion is a likely scenario in VEs involving manual tasks, and exposures will likely be prolonged and require users to be active. The retinal image may be degraded or augmented by many VE factors such as the computer model of environmental objects, the technique for tracking the user's visual perspective, the graphical rendering system, and the optics of the display system. Retinal image rearrangement may be caused by inadvertent technological limitations or deliberate augmentation of reality. A typical unplanned distortion is where the visually displayed virtual position of an object does not correspond to its haptic or auditory virtual position because one or more of the display devices is inaccurate. Improper initial alignment and random slippage of a head-mounted display's (HMD's) focal axis relative to the user's optic axis are sources of such unintentional visual inaccuracy (see chap. 3, this volume). A system latency in rendering a user's moving hand in an HMD that occludes the real hand results in a dynamic spatial dissociation of the seen and real hand positions (Ellis, Young, Adelstein, Ehrlich, 1999; Held & Durlach, 1991). A deliberate distortion is introduced, for example, when the visual image is magnified, as in the case of virtual microsurgery systems (Hunter et al., 1994). The laboratory studies reviewed below will illustrate that the type of rearrangement, activities performed, and opportunity for reafferent and efferent sensory stimulation govern the nature, internal form and specificity of adaptation that occurs with exposure to visual rearrangements. Measuring and understanding the side effects and aftereffects of sensory-motor adaptation requires observing baseline performance before the rearrangement is introduced, the initial and subsequent performance during exposure, and the initial postexposure performance when normal conditions are restored (cf. Held, 1965).

Lateral displacement of the visual world by wedge prisms is an experimental analog of a possible visual rearrangement in a virtual environment. The vast literature on this topic (cf. Howard, 1966; Rock, 1966; Welch, 1978, for reviews) originates from Helmholtz's (1925) demonstration that small azimuthal displacements by prisms of the visual field can be adapted to in a matter of minutes. If a participant looks through base-left wedge prisms without sight of the hand, any object chosen as the target for a reaching movement will appear to the right of its true position, and a movement will be directed accordingly to the right. The prisms will make the hand as it comes into view look like it is moving more to the right than intended, away from the target, and typically participants will steer the hand nearer to the target in midcourse, but the movement endpoint will tend to be right of the target. Participants will see this gap and may also describe with surprise not seeing their arm where they feel it. It takes only 10 to 20 reaches to the same target under these conditions for participants to hit it and to move straight again, but when the prisms are removed they will reach too far to the left initially. Fig. 38.3A illustrates typical reaching paths before, during, and after exposure to wedge prisms. Improvement of performance while the world is viewed through prisms and the aftereffect when they are removed are measures of adaptation. Similar improvement and aftereffects are seen when lateral displacements are purposely introduced in a virtual environment (Groen & Werkhoven, 1998).

3.2 The Internal Form of Adaptation

Harris (1963) argued that when one can see only his or her arm and external targets in a featureless background, adaptation is achieved by an internally modified position sense of the arm. The participant eventually feels the arm where he or she sees it. For example, after

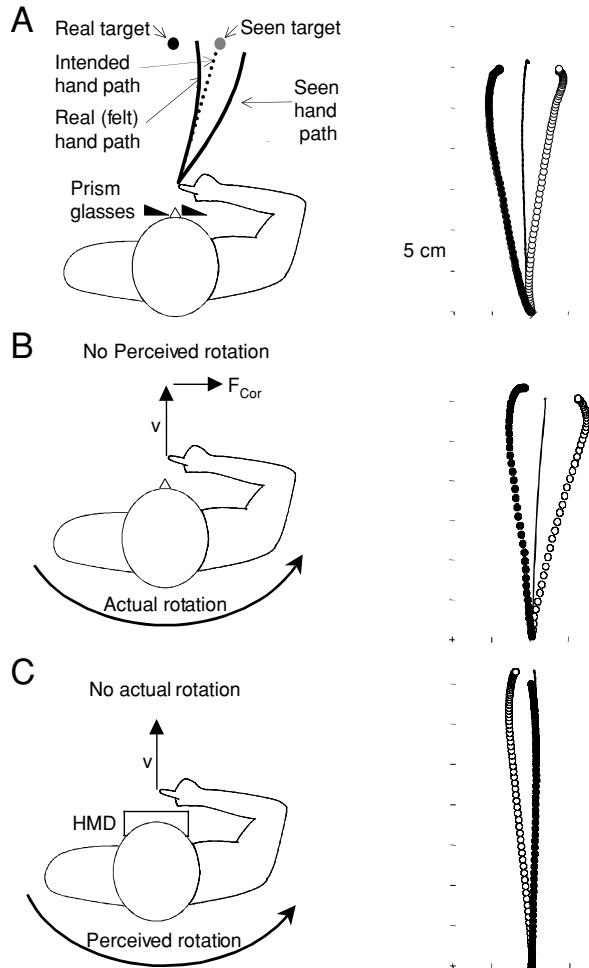

FIG. 38.3. The panels on the left are schematics of different sensory-motor rearrangements that evoke reaching errors, and with continued exposure different forms of adaptation. The panels on the right are plots (top view) of finger trajectory before the rearrangement (solid line), during the initial reach attempted in the presence of the rearrangement (open symbols), and during the initial reach attempted on return to normal conditions (filled symbols). A: Wearing prisms that shift a visual target to the right causes the initial reach to deviate to the right and to curve slightly due to corrections made when the hand comes into view. With many attempts, participants learn to make straight accurate reaches (not shown) by modifying their internal representation of felt arm position (see text). Persistence of the adaptation when the prisms are removed causes leftward end-point and curvature errors, mirror symmetric to the initial reaches made during prism exposure. B: When participants are unaware they are rotating, they do not compensate for the Coriolis forces (F_{Cor}) their movements (v) generate and initially make reaching errors in the direction of the Coriolis forces (open symbols). With practice they modify their motor commands as necessary to restore their baseline trajectory. When rotation ceases and they again feel stationary, they make leftward end-point and curvature errors (filled symbols). The per and postexposure reaching errors are the same in A and B, although the internal form of adaptation differs. C: Stationary participants feel like they are rotating when viewing a moving visual scene presented in a head mounted visual display (HMD). Their reaching movements deviate in the direction opposite to the Coriolis force, which would be present if they were actually rotating (open symbols). With practice they regain straight accurate movement paths by learning not to compensate for anticipated Coriolis forces. This motor adaptation is specific to the self-rotation context simulated by the HMD and does not carry over to a normal stationary context; consequently, there are no aftereffects when the HMD scene is again stationary (filled symbols).

adaptation to base-right prisms the participant will reach to the target's true position but see and feel the arm to the right of that position. The felt arm position then does not correspond to the real position, but visual and proprioceptive perception are unified and reaching movements are directed accurately to the target.

Harris recognized but rejected other possible forms of adaptation under these conditions. For example, he rejected the possibility that the adaptation is simply a conscious process of reaching to the left of where the target appears because when the prisms were removed his participants showed negative aftereffects instead of reverting to their baseline performance. Second, the adaptation is not an internal change in visual perception. Such a change would mean that a midline target optically shifted right would in the course of adaptation come to be perceived as straight ahead, and when the prisms are removed it would be registered to the left of its true position and any movement aimed at it should deviate to the left. Contrary to this, Harris found that when prisms were removed an adapted participant pointed accurately with the unadapted hand, there was no intermanual transfer. Participants positioned their adapted hand to the left of the unadapted one when asked to align the two hands in azimuth in darkness. Also contradicting a visual shift was the finding that after the prisms were removed participants made comparable errors pointing to a visual target or to an unseen sound source. An alternate explanation to Harris's is motor adaptation. Participants could, for example, change the direction in which they reach to targets without a concurrent change in the felt sense of limb position. Motor adaptation will be discussed in section 4.

The internal form of adaptation is influenced by activities performed and feedback obtained while wearing prisms and how much of one's body and the world is visible. An interesting case is walking around but keeping the arm out of sight while wearing rightward displacing prisms (Held & Bossom, 1961). At first, participants bump into things but are soon able to get around. When the prisms are removed the participants initially point incorrectly, leftward, with both arms to visual targets. They also adopt a resting head posture that is deviated in the direction of the optical displacement. These facts have been interpreted as meaning that adaptation in this context is achieved by an internal recalibration of perceived head position on the torso (Harris, 1965). In the paradigm where participants just sat and reached with one arm, only that arm had to be remapped to compensate. This illustrates that the nervous system tends to adapt in the way most specific to the conditions encountered during exposure to rearrangement. More extensive reviews on this topic are available (Dolezal, 1982; Lackner, 1981).

In the two cases presented above, the sensory rearrangement is the same but the resulting form of internal adaptive shift differs. There can be an arm–torso recalibration when the participant just sits and points to a single target in a featureless field and a head–torso recalibration when the participant walks about in the normal world. This means that detecting and understanding VE side effects and aftereffects must take into account the physical distortions introduce by the VE, the nature of the visual field, and the tasks required of the user. There is enough evidence to indicate that the form of adaptation to a sensorimotor rearrangement depends on fine details of task characteristics, but not enough to make accurate predictions for every case imaginable in practical virtual environments. Several examples not explicitly covered by the reviewed studies are VEs where the visual position of the user's hand and the whole visual scene are displaced, VEs where the virtual visual objects have real or virtual counterparts, and VEs where the hand is represented as a symbolic visual icon instead of realistically.

3.3 Conditions Necessary for Adaptation to Occur

Understanding what factors are necessary for adaptation to take place is important for predicting proprioceptive side effects and aftereffects from VE exposure. Held and colleagues (Held, 1965;

Held & Bossom, 1961) showed that active reaching or locomotory movements during visual rearrangement could elicit adaptation, but a laterally displaced view of one's passively moved arm or sight of the world during passive transport did not generate adaptation. This led to the idea that efference copy signals are required for adaptation. Held developed a model in which efference copy signals were stored along with their correlated reafferent sensory signals so that any active movement would call up the normally associated visual reafferent signal for comparison with the actual one. In the reaching and locomotion paradigms, discrepancies between the reactivated and current reafferent visual patterns were thought necessary for adaptation to occur. A practical implication is that greater activity within a VE should speed up adaptation.

An alternative point of view is that active movements are only superior because they enhance proprioception (Paillard & Brouchon, 1968). Consistent with the idea that active movement is not necessary, Wallach, Kravitz, and Lindauer (1963) demonstrated that partial adaptation of reaching movements to visually displaced targets occurs if an immobile observer simply views the rest of his body through displacing prisms for ten minutes. Lackner (1974) went further, showing that a discrepancy between actual visual feedback and the usual feedback associated with a voluntary movement is not sufficient for adaptation to occur, but a visual-proprioceptive discrepancy is necessary and sufficient for eliciting adaptation to laterally displacing prisms. When participants reached without sight of their arm to visually displaced dowels and contacted hidden, vertically aligned, similarly shaped extensions of these targets there was no visual feedback about the arm to compare with the visual feedback normally associated with the executed movement. Adaptation still occurred in this condition because there was a discrepancy between the visual and felt target position. Adaptation did not occur if the visual-proprioceptive discrepancy was eliminated by having participants point to the same array of prism-displaced dowels whose hidden lower halves were laterally offset to match the optical displacement. The results emphasize the importance for adaptation of sensory discordance as well as active control. They also demonstrate that adaptation is enhanced by establishing through fingertip contact an association between the unseen arm and visual targets. In VE systems, finger contact can contribute to the fidelity of the synthetic experience if vision and haptic interfaces are in register, or create side effects and aftereffects if they are discrepant.

3.4 Retention and Specificity of Adaptation

To assess retention of adaptation of reaching errors caused by laterally displacing prisms, Lackner and Lobovitz (1977) had participants participate in two adaptation sessions 24 hours apart. Each session had pre- and postexposure periods of reaching to virtual visual targets without sight of the arm and a prism exposure period in which participants reached to the same loci with their arm in view. A surprising finding was that in the preexposure period of the second session, reaches were deviated in the direction of the aftereffects from the previous day, although none of the participants reported any difficulty with visuomotor control between sessions outside the laboratory. This demonstrated a long-term aftereffect and raised the possibility that it was a context-specific aftereffect. To further evaluate retention and context specificity, Yachzel and Lackner (1977) gave participants six adaptation sessions over a 4-week period. The sessions were similar in that participants pointed to visual targets with their arm under a screen before and after exposure to visual displacement in which they reached with sight of their arm. Tests were conducted in two different sets of apparatus requiring different arm movements. Retention of adaptation from session to session was seen in the form of preexposure baseline shifts across the first five sessions, which were spaced two or three days apart. The size of the long-term aftereffect did not depend on what apparatus the participant was tested in. Aftereffects appeared when the participants were tested without being able to see their

arm and never were noticed during daily activities. Diminished aftereffects were still evident in the sixth session, which was delayed for two weeks relative to the fifth. These results indicate that proprioceptive adaptation to displaced vision can be retained for long periods and are not necessarily context-specific. The adaptation retained does not reveal itself in daily activities unless visual cues about the arm are reduced. Long term-after effects from simulator and VE exposure are likely caused by long-term retention of adaptation, but more research is required to understand what contexts will evoke aftereffects and what sensory cues will hold them at bay.

4. ADAPTATION TO ALTERED FORCE BACKGROUNDS

The notion of motor adaptation introduced in section 3.2 is crucial for understanding side effects and aftereffects in real and virtual environments involving novel force backgrounds. Motion-coupled VEs rearrange the external force environment. For example, in VEs involving real body motion or visual portrayal of body motion, the background gravitoinertial forces on the body are different from the forces that would be present if the body were physically moving in the experienced fashion. This is a situation where motor adaptation occurs and individuals need to reprogram their limb movements to achieve accurate control for the current force background. This can produce aftereffects when the individual leaves the virtual environment. The situation is very different when a novel real or virtual tool or machine is introduced. In this case, individuals make errors until they learn the properties of the manipulated device. Such tasks do not lead to aftereffects outside the specific context of that device.

4.1 Motor Adaptation to Coriolis Force Perturbations in a Rotating Room

Traditional vehicle motion simulators often have motion bases to try to mimic features of the gravitoinertial force backgrounds of moving vehicles. For example, a rotating room generates centripetal acceleration that simulates artificial gravity, but it also generates a Coriolis force on any object moving nonparallel to the spin axis of the room. The Coriolis force is only present when an object is moving in relation to the rotating room and acts perpendicular to the direction of object motion, according to the cross-product rule: $F_{cor} = -2m(\omega \times v)$, where m and v are the mass and linear velocity, respectively, of the object and ω the angular velocity of the room.

When an occupant of a room rotating counterclockwise reaches forward, a rightward Coriolis force is generated on the arm deviating it rightward. Both the movement's path and end point are displaced relative to the prerotation pattern of straight movements directly to the target. Subsequent reaches during rotation return quasi-exponentially, within 10 to 20 trials, to prerotation straightness and accuracy. A new set of motor commands is being issued in order to move the hand straight to the target. When rotation stops and Coriolis forces are absent, reaching movements show curvature and endpoint deviations in the direction opposite those of the initial perturbed movements (Lackner & DiZio, 1994).

This pattern of pre-, per-, and postrotation movements resembles the pre-, per-, and postexposure phases of a prism displacement experiment (compare Figs. 38.3A and 38.3B), but there are important differences. Adaptation to rotation involves motor remapping instead of the proprioceptive shifts that underlie some forms of adaptation to prism spectacles. Adaptation to rightward prism displacement can make movements that go straight ahead to a midline target feel like they are going rightward, and it may cause participants to make errors aligning the adapted hand with the unadapted one if it is hidden. By contrast, the true trajectory of the arm is experienced throughout the pre-, per-, and postexposure phases of adaptation to rotation.

Participants who adapt to reaching with one arm during rotation also can accurately align their left and right fingertips.

4.2 Motor Adaptation and Force Perception

Another special feature of motor adaptation to rotation is the alteration of force perception that accompanies it. Participants report their first movement during rotation as being deviated by a magnetic-like pull in the direction of the Coriolis force, whereas no unusual force is perceived during movements whose visual paths are perturbed by prisms. When participants adapt fully to rotation, they no longer can feel the Coriolis forces that are still present during their movements, even if their attention is called to them. They report that whatever had initially perturbed their arm is now gone and they can produce the desired movement with the same effort as before the perturbation. When rotation stops and there are no Coriolis forces during movements, participants report feeling a force on their arm that is the mirror image of the Coriolis force they had adapted to. The relationship of actual to perceived force is modified during adaptation because of an internal calibration mechanism that interrelates force feedback signals, position, and velocity signals and motor commands. Informal observations clearly show that adaptation to rotation alters the feel and control of objects and surfaces that are handled following return to a normal stationary environment. Virtual environments that alter the force environment or that involve visual simulation of body acceleration without the normal concomitant gravitoinertial forces will cause illusions in the feel of tools and affect the manual control of a vehicle or other machines.

4.3 Context-specific Motor Adaptation and Aftereffects in Different Force Environments

Participants who sit quietly in an enclosed rotating room turning at a constant velocity feel after about 60 seconds like they are in a completely normal, stationary environment. This is because the angular velocity sensitive semicircular canals have had time to return to their resting discharge level after acceleration to constant velocity, and the room is fully enclosed so there are no visual flow cues about rotation. Thus, participants who adapt their reaching movements in this situation learn to associate making Coriolis force compensations and receiving Coriolis force feedback with an internally registered nonrotating context. These recalibrations are carried over to the postrotation period, which also is internally registered as being a normal stationary environment, and cause aftereffects. If after adaptation to rotation, the rotating room instead of being stopped is accelerated to twice the initial speed, then after a minute the participant will again feel stationary and when reaching for the first time will make renewed endpoint and curvature errors of the same magnitude and in the same direction as the first movements at the previous speed (Lackner & DiZio, 1995). The Coriolis forces are greater at the new speed, but the motor mapping from the lower speed is carried over because the internally registered nonrotating state is the same.

Understanding whether adaptation to one rotation speed will carry over to a different speed requires the converse of the conditions provided by the rotating room where participants are rotating but feel stationary. Participants who are actually stationary can experience virtual rotation by viewing a moving visual scene in a head-mounted display. The first reaches of participants experiencing constant velocity counterclockwise rotation and displacement will be deviated leftward in path and end point (see Fig. 38.3C; Cohn, DiZio, & Lackner, 2000). The magnitude of the reaching errors is proportional to the perceived speed of self-rotation. If the participants had actually been rotating counterclockwise there would have been a rightward Coriolis force when they reached. Their leftward errors show that they had anticipated and

generated muscle forces to resist the expected but absent Coriolis forces. These participants also report feeling a phantom leftward force on their arm, which has the characteristic bell-shaped profile of a Coriolis force. When repeated reaches are made during virtual rotation, the reaches become straighter and progressively more accurate, and the “force” perceived to be deviating the arm vanishes. When the visual scene is again stationary and participants feel stationary, their first postexposure reaches feel normal and go straight to a target. That is, there is no aftereffect.

These results show that the motor plan for a forthcoming reaching movement compensates for the Coriolis forces normally generated at the currently registered speed of self-rotation. In other words, we normally maintain multiple motor adaptation states that are context-specific for registered body motion. Experimental alteration of the relationship between Coriolis forces and registered body speed alters the motor compensation only for the body rotation speed at which movements are practiced and is not carried over to other speeds. Thus motor adaptation is specific to the registered context of body motion where aberrant forces were experienced. Not enough is known to allow prediction of how faithfully a moving base training simulator must reproduce an operational environment in order for training to transfer. Virtual training environments that simulate body motion with just a dynamic visual scene are unlikely to cause motor aftereffects in everyday life, but they may well produce adaptation in which participants cease to compensate or anti-compensate in terms of postural and movement control for inertial forces that will actually be present in the operational moving environment. That is, they could maladapt participants to the operational context.

4.4 Motor Adaptation to Environments Versus Local Contexts

The rotating room and virtual rotation provide environmental contexts in which individuals carry out all their actions. Real and virtual tools and machines create force-reflected feedback or force fields that are local contexts a user may interact with in a limited fashion. For example, humans can use a planar robotic linkage to control a cursor on a video screen in the presence of external forces generated by torque motors on the handle. Shadmehr, Mussa-Ivaldi, and Bizzi (1993) created a force field that resembles the Coriolis force field in a rotating room, such that the manipulandum pushed the hand perpendicular to its current velocity. Their participants’ movements were initially perturbed, but after many hundreds of trials straight paths ending at the target characteristic of movements with a null force field were regained. This contrasts sharply with the complete adaptation participants achieve in 10 to 20 movements to Coriolis force perturbations of their reaching movements in a rotating room. Thus, learning an internal model of an electromechanical device takes much longer than recalibrating one’s own unfettered movements. The nature of force perception also differs sharply during self-calibration versus internalization of a machine’s force properties. As described above, perturbing Coriolis forces become perceptually transparent when motor adaptation of free reaching movements to rotation is complete. However, participants interacting with a manipulandum can still detect and describe the forces it applies even after they have learned to resist them and to move their arm in the desired path to the target. The implication of this is that learning a local force field by interacting with a real or virtual machine will not cause aftereffects in any context outside the confines of the machine. By contrast, learning to move one’s arm will affect perception and performance in any local context embedded in an environment that provides the same stimuli about self-motion as the environment in which adaptation was acquired.

4.5 The Role of Touch Cues in Motor and Proprioceptive Adaptation

Cutaneous contact cues during a movement and at the terminus of the movement contribute to perception and adaptation of limb position and force. Continuous cutaneous contact cues throughout movements are prominent differences between Coriolis force perturbations in the

rotating room and force field perturbations produced by a manipulandum. When a manipulandum perturbs a movement the muscle spindles, Golgi tendon organs, and vision can signal that the movement deviated from the intended path, and the cutaneous mechanoreceptors of the hand signal the continuous presence of a local external force. There is a systematic correlation of the cutaneous force profile and the compensatory muscular forces that need to be learned. The nervous system, following the principle of making the most parsimonious change possible, can simply learn the dynamics of the perturbing object. In adaptation to Coriolis force perturbations, there is no local cutaneous stimulation because the Coriolis force is a noncontacting inertial force applied to every moving particle of the limb. In the absence of an external agent contacting the limb, the most specific form of adaptation is an alteration in motor control of the exposed limb. This is because the central nervous system recognizes a situation requiring motor recalibration when it detects an error in movement path without an external obstruction while the movement is in progress.

The transient cutaneous stimuli occurring when the finger lands on a surface at the end of a reaching movement also influence proprioception and motor adaptation in real and virtual environments. Coriolis force induced end-point and curvature deviations of visually open-loop reaching movements in a rotating room are eliminated by adaptation within 10 to 15 movements if the reaches end on a smooth surface. However, only 50% of the initial end point error is eliminated before performance reaches a steady asymptote if the reaches end with the finger in the air. In other words, if terminal contact is denied participants will not fully adapt. This pattern shows that information obtained from finger touchdown provides information about limb position errors, which is critical for adaptation to rotation. The source of this information is the direction of shear forces generated in the first 30 ms after a reaching movement contacts a smooth surface. These shear forces are systematically mapped to the location of the finger and code where the finger is relative to the body (DiZio, Landman, & Lackner, 1999). These shear forces are about 1 N in magnitude. When participants reach in the air to objects on a virtual instrument panel their end-point variability is greater than when reaching to a similar real panel (DiZio & Lackner, forthcoming). The variability is greatest if the virtual panel is presented only in the visual mode and the reaches end in midair. It is greatly reduced by the addition of a real contourless surface in the same spatial plane as the visual virtual panel (see Fig. 38.4). Thus, minimal haptic cues, just a flat surface in the proper plane, can improve proprioception, reduce movement errors and enhance the usability of VE visual interfaces.

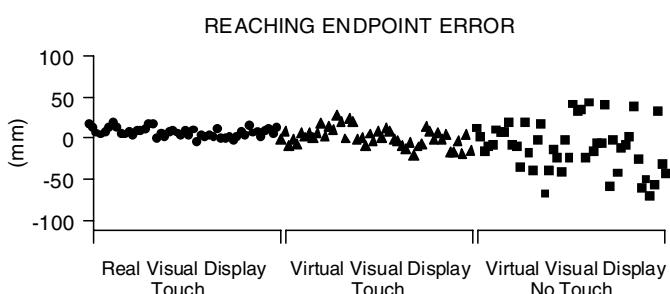

FIG. 38.4. Plot of end-point errors of repeated reaches made without sight of the arm to a single target on a real or virtual horizontal work surface. Variability is least in the first set of movements, where the target is a light-emitting diode (LED) embedded in a smooth sheet of Plexiglas with no distinguishing marks indicating the target location. Variability is greater in the second set of movements, which are aimed at a virtual target on a virtual surface programmed to coincide with the spatial location of a real Plexiglas work surface which the participant contacts at the end of each movement. The same virtual target and surface are presented without the real surface in the last set of reaches, and the variability increases markedly in the absence of physical contact. Reintroducing the real surface (not shown) restores low variability immediately.

5. PERCEPTION OF LIMB AND BODY MOTION DURING POSTURE AND LOCOMOTION

Control of posture and movement are highly integrative, multimodal processes, requiring sensitivity to complex environmental constraints. Touch cues play a major role in control and perception of whole body movement, the apparent stability of the environment, and attributions of causality.

5.1 Touch Stabilization of Posture

Fingertip contact with environmental surfaces has a stabilizing influence on standing posture. If participants standing on one foot or heel-to-toe in darkness hold their index finger on a stable surface with a force of about 0.4 N (about 41 grams), their body sway amplitude is cut in half relative to not touching (Holden, Ventura, & Lackner, 1994; Jeka & Lackner, 1994). This level of force is too low to provide mechanical stabilization, but it corresponds to the maximum sensitivity range of fingertip sensory receptors (Westling & Johansson, 1987). The horizontal and vertical forces at the fingertip fluctuate with a correlation of 0.6 to both body sway and ankle EMG activity, but lead EMG by about 150 ms and body sway by 250 to 300 ms. Light touch even attenuates body sway when the eyes are open. The stabilizing influence of touch is lost if sensory-motor control of the arm is disrupted by vibration of brachial muscles, but with the arm functioning normally touch can stabilize the body even when excessive sway is induced by ankle muscle vibration (Lackner, Rabin, & DiZio, 2000). Patients with no vestibular function who cannot stand in darkness for more than a few seconds can maintain stance for as long as desired and are as stable as control participants with eyes closed if allowed light touch of the finger (Lackner et al., 1999). These findings indicate that the finger-arm system functions as an active proprioceptive probe providing sensory information about body position and velocity. This stabilization system works with nested sensory-motor loops. A finger to brachial sensory-motor loop stabilizes the finger relative to the surface and minimizes the force changes at the fingertip. These residual fingertip force fluctuations activate the leg muscle to stabilize posture better than is possible with ankle proprioception, vision, or vestibular signals alone.

Light contact cues with a simple surface are an effective way to stabilize body sway in VEs where participants are free standing. An HMD and head-tracking system that introduces temporal distortions of visual feedback when head movements are made induces severe postural instability, and light touch suppresses this side effect (DiZio & Lackner, 1997). Postural after-effects also occur upon return to a normal environment resulting in further postural disruption. Light touch stabilizes posture and suppresses aftereffects in such situations.

5.2 Touch and Locomotion

A seated individual holding his or her hands or feet in contact with a rotating floor or railing will experience self-rotation in the opposite direction (Brandt, Buchele, & Arnold, 1977; Lackner & DiZio, 1984). Actively pedaling the free wheeling floor while seated or turning the railing with a hand-over-hand motion makes the experience very powerful. Pedaling movements made without surface contact do not elicit any experience of self-motion. These demonstrations illustrate that in normal bipedal locomotion contact with the floor is very important.

The pattern of ground reaction forces during locomotion is not related to body motion through space in a univariant way. For example, walking down a hill, one is progressing forward but pushing backward. An experimental situation used by Lackner and DiZio (1988) to assess the interactions among surface contact, leg movements, and whole body motion is illustrated

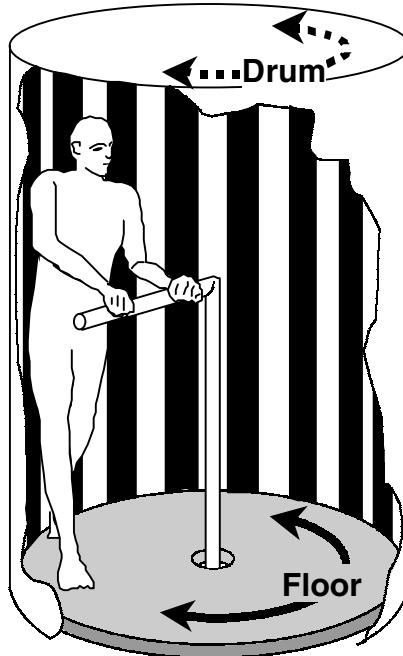

FIG. 38.5. Schematic of the apparatus used to uncouple visual motion, inertial motion, and over-ground motion during treadmill locomotion.

in Fig. 38.5. It is basically a VE in which the visual display and the substrate of support can be independently manipulated. A participant holding onto the world-fixed handlebar and walking in place on the backward rotating floor experiences forward motion through space. The experience is compelling and immediate if the chamber walls also are rotated backward, but it occurs in darkness (Bles & Kapteyn, 1977) and even if the stationary walls are in plain view. In the latter case, the motor and somatosensory signals from walking in place capture the visual scene, which will appear to be dragged along (Lackner & DiZio, 1988).

If the visual scene is moved backward twice as fast as the floor, a participant who is walking in place will feel the handlebar pulling him forward and sense an increase in body velocity through space. Some participants report an illusory elongation of each leg at the toe-off phase of the step cycle, and others sense that the floor has become rubbery and bounces them forward. If the visual scene motion is reversed, participants stepping forward in place will report either that they are moving backward through space and making backward stepping movements or the steps, which usually propel them forward are now propelling them backward. These effects powerfully demonstrate that afferent signals about limb movements, the body schema representation, internal calibration of body motion, and apparent environmental stability are all interrelated.

5.3 Proprioceptive Recalibration of Locomotion

These relationships can be recalibrated by walking in place on a circular treadmill for an extended period. After doing so for an hour in a visually normal environment, participants walk in a curved arc when trying to maintain a straight line on solid ground in darkness (Gordon, Fletcher, Melville-Jones, & Block, 1995). When passively pushed in a wheelchair, eyes closed, they can differentiate straight and curved paths as well as they can before the treadmill exposure,

indicating vestibular function is not changed. These investigators concluded that the aftereffects are due to adaptive recalibration of a “podokinetic system,” which through ground contact, leg proprioception, and motor copy signals provides a representation of trunk rotation relative to the stance foot. When forced not to turn by guide rails after prolonged stepping around in place, participants feel they are turning in the other direction, and they exhibit nystagmoid eye movements consistent with their perceived direction and rate of turning, not their actual body motion (Weber, Fletcher, Melville-Jones, & Block, 1997). Allowed visual feedback, the participants can walk in their desired path with no ocular nystagmus. This is an example where potentially dangerous aftereffects due to internal recalibration of proprioception in the exposure environment can be masked by the appropriate sensory information.

6. CONCLUSIONS

Many VEs will intentionally or inadvertently introduce users to sensorimotor rearrangements that will result in side effects, followed by adaptation, and aftereffects or maladaptive transfer on return to a normal environment. Proprioceptive adaptation is one form of adaptation associated with potential VE side effects and aftereffects. Two important facets of proprioception that can undergo adaptive modification are the sense of position and orientation and the sense of force or effort. Predicting and measuring the manifestations and underlying form of adaptation require understanding that it is not a unitary phenomenon. Proprioception involves the interplay of afferent and efferent signals about limb and body position and motion, internal representations of the body schema, and spatial orientation and representations of environmental constraints. All of these variables are labile and can undergo long-term adaptive changes in relation to the others. Reaching errors in a VE that look similar on the surface can have different causes that lead to diverse forms of adaptation and aftereffects. For example, virtual visual displacements, mismatches of the virtual gravitoinertial force environment, and novel contact force fields cause adaptation of proprioception, of motor control, and of internal models of objects, respectively. Understanding the cause and form of adaptation in a specific VE context will help predict ways of enhancing adaptation, for example, when more user activity versus sharpening the sensory discordance will help. Principles governing the specificity of adaptation are key for understanding what aftereffects will occur when a user leaves the VE and either goes about daily life or engages in the real-world operational task that was simulated. Such principles are scarce, but one important factor is feedback from contact cues during movement. Continuous and terminal cutaneous signals contribute to neural computations that partition the net force environment into functionally relevant components. For example, in adaptation of reaching movements, cutaneous signals are critical for determining whether the motor system will recalibrate or the representation of a tool’s properties will be updated. Motor adaptation in a VE will carry over to any task performed with the exposed limb, but learning an internal model of a device will not deleteriously affect performance on dissimilar devices. Touch cues and visual cues can also mask potentially dangerous long-term aftereffects that appear in impoverished conditions or specific contexts.

1. INTRODUCTION

Virtual environments (VEs) are altered environments that provide novel patterns of intersensory stimulation. The novelty may be correct (i.e., if the VE corresponds accurately to a real environment that is new to the user), or incorrect (i.e., if the VE presents perceptual stimulation that is not faithful to the simulated environment; Moroney & Moroney, 1998; Riccio, 1995; Stoffregen, Bardy, Smart, & Pagulayan, in press; cf. Stappers, Overbeeke, & Gaver, in press). In either case, adaptation is the natural response to VE systems (Stanney, Kennedy, Drexler, & Harm, 1999; see chap. 31, this volume). The majority of research interest is focused on VE-related patterns of stimulation that are not faithful to the simulated environment. Due to technological limitations, such as slow system update rates, sluggish and imprecise position-tracking sensors, and imperfect models of environmental dynamics, the user is exposed to unusual patterns of intersensory stimulation (e.g., a disparity between seen and felt limb position). The change may not be apparent to the user until critical performance errors arise while actively interacting with the virtual environment. There is substantial evidence for the existence of adaptation and aftereffects in VEs; such effects indicate altered demands on various perceptual-motor systems, such as the visual system (Stanney et al., 1999; see chap. 37, this volume), proprioceptive (see chap. 38, this volume), and the visual-vestibular systems (Draper, 1998b). With VEs, adaptation and aftereffects can also include a wide variety of

subjective experiences, such as fatigue, malaise, nausea, headache, eyestrain, and drowsiness (see chap. 30, this volume). The vestibular system may be implicated in many of these experiences.

This chapter presents an introduction to the diverse area of vestibular adaptation research, focusing on its application to virtual environments. This task is not straightforward for two reasons. First, the concept of vestibular adaptation is not clearly and uniquely defined. Second, the concept seems to imply adaptation of the vestibular organ itself. It is unclear whether any meaningful form of adaptation happens in the vestibular organs; however, this issue may not be important for the design or use of virtual environments. Design implications arise from the perceptual and/or behavioral adaptations that are influenced by vestibular input. Therefore *vestibular adaptation*, as defined for this chapter, implies adaptations to vestibule-driven perceptual-motor systems that impact user behavior and task performance.

Adaptation has been defined as “a semipermanent change of perception or perceptual-motor coordination that serves to reduce or eliminate a registered discrepancy between or within sensory modalities or the errors in behavior induced by this discrepancy” (Welch, 1986, p. 24–33; see chap. 31, this volume). Reason and Brand (1975) described perceptual adaptation as a process in which conflicting signals from two or more perceptual systems become “normalized” over time, such that these intersensory signals are no longer perceived as being in conflict.

Exposure to a new or altered environment often causes a loss of accuracy in perception, performance, or both. With continued exposure, perception and performance can exhibit gradual improvement (i.e., adaptation), often leading to a return to baseline levels. On return to the original environment there may be a renewed error, or *aftereffect*, which itself gradually diminishes with readaptation. The sequence of events is illustrated in Fig. 39. 1. *Negative*

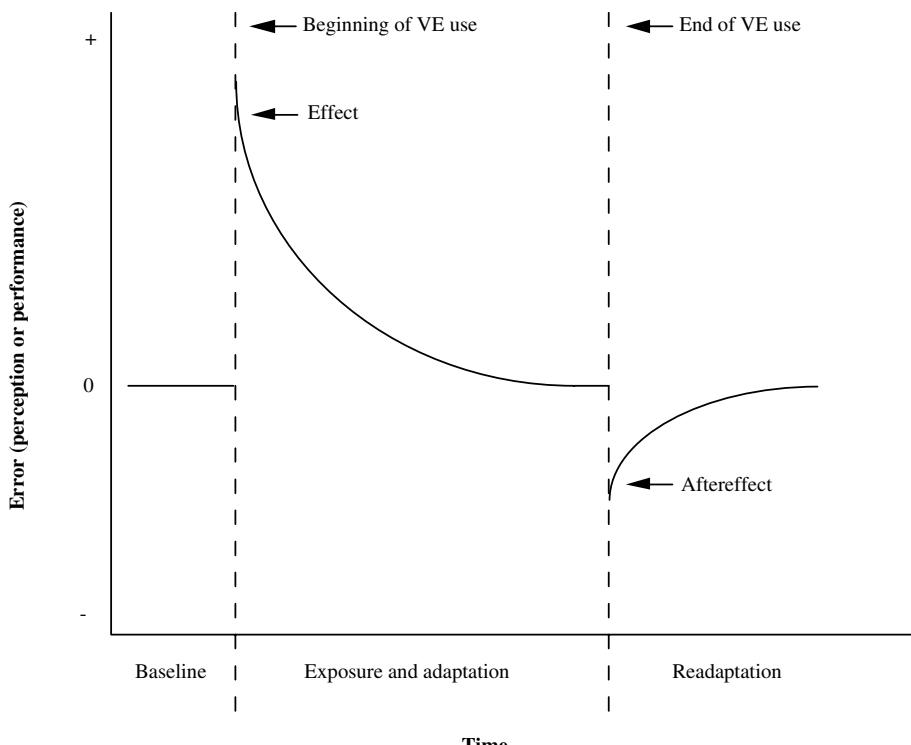

FIG. 39.1. The time course and general characteristics of adaptation and aftereffects.

aftereffect refers to errors observed after return to the normal environment that are in the opposite direction to errors made on initial exposure to the virtual environment (Fig. 39. 1). Research has demonstrated that more complete adaptation is generally associated with more substantial or lasting negative aftereffects (e.g., Dolezal, 1982; Welch, 1986). However, repeated exposures to the altered environment generally result in faster adaptation with reduced aftereffects (Bingham & Romack, 1999). In essence, the time constant for adaptation (and readaptation) decreases with multiple exposures.

In this chapter, the nature and measurement of vestibular adaptation as related to VEs is discussed. In section 2, an overview of the vestibular system is provided and some of the perceptual-motor phenomena that utilize vestibular input are reviewed. This review is intended for VE professionals who are unfamiliar with this area. Section 3 offers detailed descriptions of three forms of vestibular adaptation: the vestibulo-ocular reflex; the control of body posture; and past-pointing. Because the type and extent of vestibular adaptation will likely vary as a function of the specific VE involved, in section 4 a system for identifying and classifying a VE in terms of its primary visual–vestibular interactions is proposed. Section 5 considers implications of vestibular adaptation for VE applications, whereas section 6 offers a summary and conclusions. Although vestibular adaptation is believed by many to play a significant role in the occurrence of motion sickness in VE systems, this topic is more fully addressed in chapter 30 (this volume). General issues surrounding VE adaptation are discussed in chapter 31 (this volume).

2. THE VESTIBULAR SYSTEM

2.1 Overview

The vestibular apparatus is a small sensory organ in the bony labyrinth of each inner ear. Its primary function is to detect rotational and translational movements of the head and generate a corresponding response signal (see chap. 7, this volume). These signals contribute to the effective coordination of eye movements, posture and balance, and the perception of motion and orientation. Partial or complete loss of vestibular functioning makes it difficult to perform even the most basic of tasks (Howard, 1986b; Sharpe & Barber, 1993).

The vestibular apparatus consists of two principle sets of structures, the semicircular canals and the otolith organs (Fig. 39. 2), which work together to provide information on head motion and orientation. The eighth cranial nerve is the main efferent pathway for vestibular signals.

As shown in Fig. 39. 2, in each vestibular apparatus there are three semicircular canals (SCC), termed the anterior, posterior, and horizontal. These SCCs are roughly orthogonal to one another, and their collective function is to sense angular accelerations of the head (the canals may also be sensitive to higher order parameters of motion, such as jerk). These canals are each bidirectionally sensitive and, when combined across the two vestibules, form three approximately perpendicular “push–pull” pairs so as to detect angular head acceleration in any direction.

Each SCC functions as a complete and independent circuit in detecting angular acceleration (Howard, 1986b). Endolymph fluid within each SCC is prevented from free flow by the cupula, a thin elastic diaphragmlike flap. When the head rotates, the force generated by the endolymph viscosity and inertia acts against the cupula of each SCC existing within the plane of motion, causing it to deflect. This deflection bends tiny hair cells located at the base of the cupula, which generates an efferent signal. Though sensitive to rotational acceleration, the SCC efferent signal is proportional to head rotational velocity for most normal head movement frequencies (Howard, 1986b). Thus, each SCC has some characteristics of a signal integrator.

The hair cells at the base of the cupula can respond to angular accelerations as small as 0.1 deg/sec^2 . However, with continued constant angular rotation (i.e., zero acceleration), the

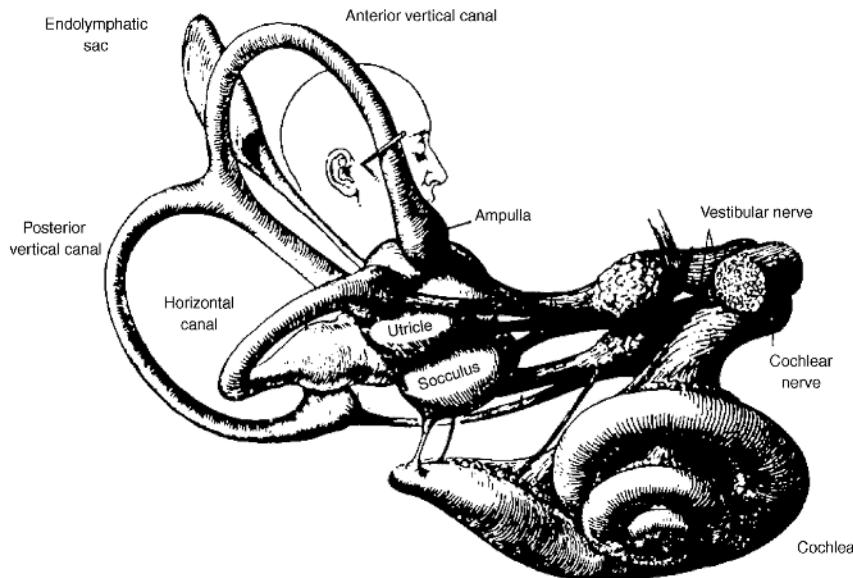

FIG. 39.2. The vestibular apparatus (From Hardy, 1934).

response diminishes. In functional terms, then, the SCCs are sensitive only to dynamic changes in head movement. The time constant for cupula deflection in humans is approximately 5 to 7 seconds (Howard, 1986b; Robinson, 1981).

In addition to the three SCCs, each vestibular apparatus also contains two otolith organs, the utricle and saccule (see Fig. 39.2), whose activity is influenced by linear acceleration of the head. Given that the gravito-inertial force vector (i.e., the vector sum of gravity and inertial forces) constitutes an accelerative force that acts on the head, the activity of the otolith organs is influenced by static head position (i.e., head tilt) as well as dynamic linear forces (Stoffregen & Riccio, 1988). The receptor portion of these organs, termed the macula, contains many hair cells. The macula is covered with a gelatinous substance that contains tiny crystals of calcium carbonate, called *otoliths*. When there is a change in the orientation of the head relative to the gravito-inertial force vector, inertia causes the otoliths to deform the gelatinous mass; this creates a shear force that bends the receptor hair cells in the macula, generating the efferent signal. The utricle's macula is located in the horizontal plane, which means that it is strongly influenced by horizontal linear accelerations. The saccule's macula is positioned vertically and is strongly influenced by vertically directed linear accelerations (Robinson, 1981).

2.2 Major Influences

Stimulation of the vestibular system affects a wide variety of behaviors. A few of these behaviors are summarized below.

2.2.1 Gaze Stabilization

In order to maintain successful vision, the eyes must be stabilized relative to the object of regard. The principal threat to ocular stability is head motion, as when one turns their head while attempting to maintain fixation on a given object of interest. Errors in stabilization lead to degraded visual performance, principally because the retina moves relative to the optical projection of the object of regard (this movement is widely known as *retinal image slip*).

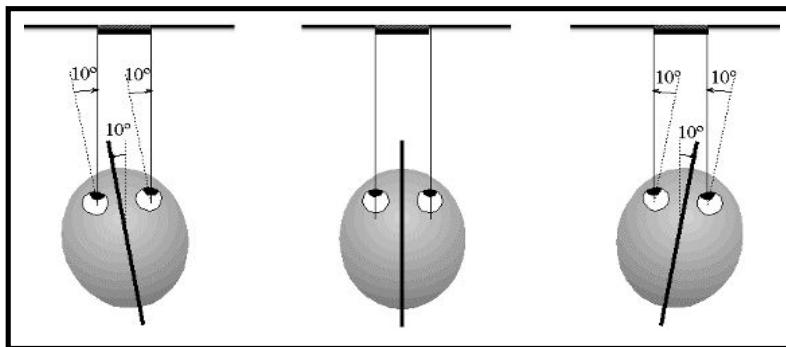

FIG. 39.3. The VOR. Left and right head rotations of 10 degrees result in a compensatory counter-rotations of the eye. Dashed lines represent original positions (for the eyes, it represents gaze direction assuming no compensation occurs for head movement); solid lines represent final positions (for the eyes, it represents gaze direction assuming a VOR gain of 1.0).

Stabilization of gaze across head movements (i.e., stabilization of the eyes relative to the illuminated environment) requires information about how the head has moved relative to the gravito-inertial force environment. This information is available to the vestibular system. Gaze stabilization across head movements is commonly studied in the context of the *vestibulo-ocular reflex* (VOR).

When the head begins to move in any direction, the vestibular apparatus senses this movement and sends velocity information directly to the oculomotor system. The oculomotor system responds by driving the eyes (conjunctively) at an approximately equal rate but opposite direction to compensate for head movement and help keep the visual image stabilized on the retina. This, in essence, is the VOR. Figure 39.3 presents a simplistic depiction of the VOR for head rotations to the left and to the right of a center position. The VOR is a very-low-latency oculomotor response to head movements, with compensatory eye movements beginning as early as 4 ms after the onset of head rotation (Sharpe & Johnston, 1993).

Gain and phase estimates fully describe the VOR. VOR gain is defined as the ratio of slow-phase eye velocity (i.e., the response) to head velocity (i.e., the inertial stimulus). It is a relative measure of the amplitude of eye movement velocity for a given head movement. Phase (in angular degrees) describes the relative timing of eye to head motion. Phase lead indicates that the eye response precedes head movements, whereas phase lags indicate that eye response lags behind head movements.

The vestibular component alone is generally not sufficient for accurate gaze stabilization. This is because oculomotor vergence information is used to adjust the magnitude of counterrotation as a function of the distance of fixated targets (Owen & Lee, 1986). In addition, another visual component (i.e., optokinetic nystagmus) aids gaze stabilization at frequencies below about 2 Hz (Howard, 1986a; Robinson, 1981).

The vestibule is responsive to head rotation along any axis of movement. However, most studies that measure the VOR have limited rotations to a single, standard axis of motion, resulting in measurements of either the horizontal VOR (associated with yaw rotations), vertical VOR (associated with pitch rotations/tilt), and to a lesser extent the torsional VOR (associated with roll movements/tilt). Although both the SCCs and the otolith organs contribute to the rotational VOR, it is commonly believed that in many situations the otolith input is minor and transitory, whereas the SCC input dominates the response (Howard, 1986b; Robinson, 1981). Both vertical and torsional VORs can involve significant contributions from the otoliths.

2.2.2 Postural/Balance System

The vestibule is known to influence the control of posture and balance. At the same time posture and balance are strongly influenced by stimulation of other perceptual systems, such as vision (i.e., optic flow), audition, and touch. Posture and balance are likely to be influenced by the overall pattern of stimulation across these systems.

Most VE systems do not include a motion base. Stimulation usually is limited to vision, audition, and/or touch. VE-based stimulation of these senses can have powerful affects on postural control and on the perception of body orientation and motion, but these systems do not directly stimulate the vestibular system. For such non-motion-base VE systems, any role of the vestibular system must come in the context of interactions between the vestibule and other perceptual systems that are directly stimulated by the virtual environment.

2.2.3 Vestibular Influence on Hand–Eye Coordination: Past-pointing

In the natural world one often points at objects that are out of reach. In such situations accurate pointing is not verified by direct touch (the target is not touched), but must be verified on the basis of other types of stimulation, such as vision. The accuracy of visually guided pointing can be influenced by changes in the visual, haptic (e.g., Riley & Turvey, 2001), and vestibular systems, and by changes in relations between these three systems. Examples include pointing tasks in which the hand is visible as it moves toward a visible target (e.g., pointing finger to nose), or pointing at visible distal targets. Changes in vestibular adaptation often produce pointing errors, which are known collectively as *past-pointing*. Past-pointing was originally observed and studied as a result of the placement of refracting prisms in front of the eyes. A review of past-pointing phenomena and research can be found in Dolezal (1982). More recently, past-pointing and related effects on manual pointing have been observed among users of VE systems (see chap. 38, this volume).

2.2.4 Other Influences

The vestibular system has been identified as directly or indirectly influencing autonomic function (Furman, Jacob, & Redfern, 1998; Harm, 1990). This includes various vasomotor, cardiac, gastrointestinal, and respiratory reflexes. The potential also exists for vestibular links to panic disorders, agoraphobia, orthostatic intolerance, and sleep apnea (Furman, et al., 1998). Lastly, the vestibular system is believed to play a role in the onset of motion sickness and simulator sickness (see chap. 30, this volume).

3. EXAMPLES OF VESTIBULAR ADAPTATION

In this section, the focus is on three manifestations of vestibular adaptation: the vestibulo-ocular reflex (VOR), the control of posture, and past-pointing. Although these are not the only behaviors that are influenced by vestibular adaptation, they are relatively well studied and can be expected to be of particular relevance to VE applications.

3.1 Vestibulo-ocular Reflex (VOR)

3.1.1 Overview/Description

As noted earlier, the VOR is a compensatory eye movement response that helps to stabilize a visual image on the retina during head motion, promoting clear vision. Adaptation of the VOR has been demonstrated in response to changes in the dynamics associated with real

and virtual self-motion. Adaptation stimuli can be naturally occurring (e.g., due to the effects of disease or trauma to the vestibular and/or oculomotor systems) or generated by artificial means (e.g., wearing prescription, telescopic, or prism spectacles that change the optic flow in response to head movements). This chapter concentrates on vestibular adaptations that result from exposure to virtual environments.

As an example of VOR adaptation in VEs, consider the left side of Fig. 39.3. If the head were to rotate to the left at 10 deg/sec, the eyes would have to counterrotate 10 deg/sec to the right in order to maintain a stable retinal image of a visual target. Assuming that the VOR accounts for the all required compensation, this indicates a VOR with a gain of 1.0. If, however, the VE visual scene responded to that same leftward head movement by moving to the right at only 8 deg/sec (due to miscalibrations, image scale inaccuracies, etc.), the oculomotor response would need to be reduced through adaptation to 0.8 gain in order to maintain stable vision. Additionally, if the VE visual image were delayed in responding to a head movement (due to a system time delay), adaptation of VOR phase would likely occur to minimize retinal slip. Thus, if the motion dynamics in a VE differ from the motion dynamics in the real world, VOR adaptation will need to occur in order to minimize retinal image slip and promote stable gaze. A brief overview of this adaptation process is presented below, whereas more comprehensive descriptions can be found elsewhere (Howard, 1986a; Robinson, 1981).

The amount of VOR gain adaptation achieved depends mainly on: (1) the magnitude of retinal slip generated by the altered visual–vestibular motion stimulation (i.e., the adaptation demand); and (2) on the exposure time to the adaptation stimulus (Collewijn, Martins, & Steinman, 1983). If adaptation demand is relatively small (e.g., 30% or less), VOR gain can fully adapt within 3 to 5 minutes (Collewijn, et al., 1983). Since the majority of adaptation stimuli the VOR system will encounter in real life and within VEs will be modest in magnitude, VOR adaptation is assumed to be a fairly common phenomenon. For example, simply putting on prescription spectacles results in a 3% to 5% change per diopter of VOR gain adaptation demand (Collewijn, et al., 1983). Additionally, small visual fields, which are common in most current-generation VE head-mounted displays (HMDs), have been demonstrated to facilitate VOR adaptation nearly as well as full-field visual scenes (Shelhamer, Tiliket, Roberts, Kramer, & Zee, 1994). However, if the peripheral visual field is unobstructed such that normally occurring visual–vestibular motion relationships exist in that area (e.g., as often found in augmented reality applications), then VOR adaptation to a centrally projected adapting stimulus will be reduced (Demer, Porter, Goldberg, Jenkins, & Schmidt, 1989). Adaptation of VOR phase has also been demonstrated (Kramer, Roberts, Shelhamer, & Zee, 1998; Powell, Peterson, & Baker, 1996), but this area has received less attention from researchers.

3.1.2 Measurement Techniques

As indicated above, gaze stabilization depends on both vestibular and visual information. One way to explore gaze stabilization processes is to explore how the VOR adapts to changing motion dynamics. Due to space restrictions, the following discussion is restricted to VOR arising from on-axis rotation in the horizontal plane.

Evaluation of VOR adaptation implies measurement of VOR gain and/or phase before and after exposure to an adapting stimulus. VOR measurement generally requires that the participant's head be rotated while head and eye position data tracks are recorded (an exception to this rule, caloric testing, is often used in clinical settings). These data are then processed, filtered, and converted to velocity information so that the relative eye motion response can be standardized and quantified. The main features of VOR measurement are described below.

Certain stimuli cause the eyes to exhibit a rhythmic oscillatory pattern called *nystagmus*. There are different types of nystagmus (e.g., optokinetic, vestibular, physiological, caloric),

depending on the stimulus involved. If inertial head rotation occurs in a completely dark environment, the resulting nystagmus is thought to be due solely to vestibular input and is thus termed vestibular nystagmus.

Nystagmus is recorded through use of an eye-position tracking system (e.g., electrooculography, videooculography, or search-coil contact lenses). Nystagmus appears on a strip chart as an oscillating pattern that is characteristic of a “sawtooth.” For example, if the head rotates in the horizontal plane to the right, the VOR will drive the eyes to compensate by moving in the opposite direction (termed a slow phase component) at roughly the velocity of the head. This leftward movement of the eyes will continue until the eye nears the edge of its orbit, at which point the eyes will rapidly reverse direction, moving back across the center of gaze (termed a *quick-phase component*). After the quick phase, the cycle is repeated as a new slow phase occurs. Slow-phase components of vestibular nystagmus are used to determine the eye velocity component of the VOR after quick phases are removed from the data.

VOR measurement generally takes place in a completely darkened room so that there are no contributing affects of visually based image-stabilizing mechanisms. A participant is either oscillated at a fixed frequency or rotated continuously around a singular axis. Participant rotations can be passive, through the use of a rotating chair, or active through self-controlled head movements. Participants usually are given a standardized task to perform during testing (such as mental arithmetic) to reduce measurement variability. Eye position (vestibular nystagmus) and head position data are recorded continuously throughout this movement. Afterward, the slow phase nystagmus components are extracted and compared to associated head movements to determine VOR gain and phase metrics. For healthy participants performing a mental arithmetic task in the dark, average nominal VOR gain is approximately 0.6 to 0.8, and average phase angle is 0 degrees, dependent on specific head-motion frequency utilized (Howard 1986b; Robinson, 1981).

3.1.3 VE-related Research on the VOR

Few studies have evaluated VOR adaptation within the context of virtual interfaces. Kramer et al. (1998) demonstrated that a VE HMD could drive VOR adaptations in both gain and phase. They presented a prerecorded visual stimulus (consisting of horizontally oscillating vertical stripes) through an HMD that was attached to a rotating chair. Participants were exposed simultaneously to the oscillating stripes and passive inertial rotation in various combinations that generated specific VOR adaptation demands. Results indicated the occurrence of VOR adaptation similar to what is observed using more conventional stimuli. This research was among the first to provide evidence that videographic images, presented through a non-head-coupled HMD, can drive VOR adaptations.

Draper (1998b) focused on the potential for VOR adaptation to occur using a head-coupled HMD, a meaningful VE, active head movements, and a short exposure period (30 min). Visual image magnification factor ($0.5\times$, $1.0\times$, $2.0\times$) was varied by manipulating geometric FOV while holding display FOV constant. The dynamics associated with the different VE image magnifications are described in Fig. 39. 4. There were significant gain adaptations when VE image magnification was $0.5\times$ (an image minification) or $2.0\times$ (an image magnification) but not for $1.0\times$ (a spatially correct image, Fig. 39. 5). Thus, VE image magnification (or more appropriately, the ratio of geometric FOV to display FOV) determined VOR gain adaptation level and direction. Variations in geometric FOV produced variations in optic flow rate in response to head movements, so Draper's results also suggest that incorrectly calibrated head tracker gain settings may influence VOR adaptation to virtual environments.

In another experiment, Draper (1998a) varied system time delays (125 and 250 msec) while VE image magnification was fixed at $1.0\times$ for a 30-min exposure period. Time delays were

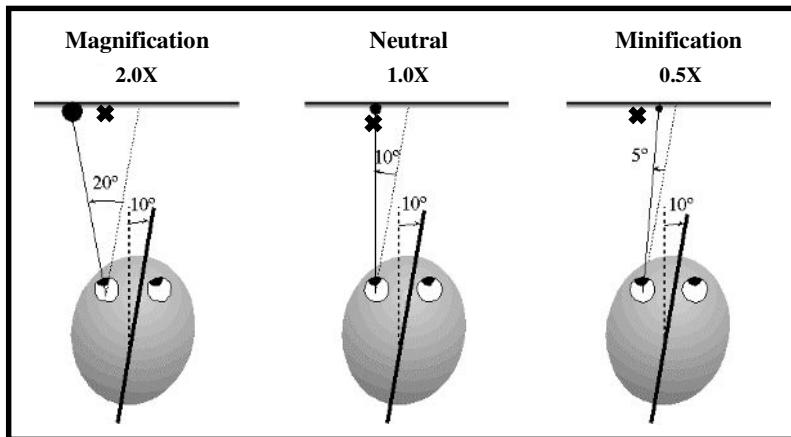

FIG. 39.4. VOR gain-change demand by VE image magnification factor, given a rightward head rotation of 10 degrees. When the VE image magnification factor is 1.0x (center graphic), the head-coupled visual scene response will be to counterrotate 10 degrees such that the VE will appear to remain stationary. A VE image magnification of 2.0x (left graphic) will result in the visual scene counterrotating 20 degrees (generating a VOR gain-increase demand), and a VE image scale factor of 0.5x (right graphic) will result in only a 5-degree counterrotation of the visual scene (generating a VOR gain-reduction demand). The “x” symbol in all three conditions marks eventual gaze location if the eyes were driven solely by the VOR with gain of 1.0.

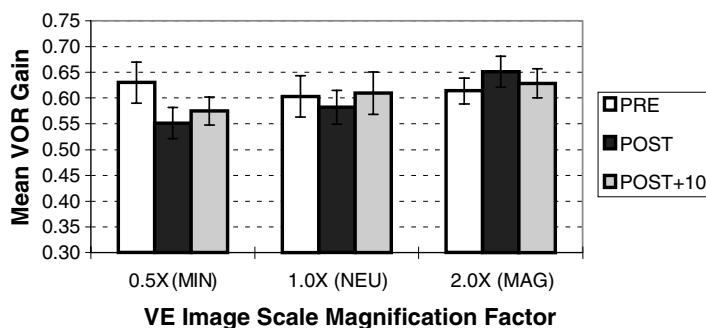

FIG. 39.5. VOR gain adaptation per VE image magnification factor (30-min exposure).

expected to influence VOR phase only. Results indicated a significant decrease in VOR gain (average 9%), in addition to an increase in phase lag of approximately 3%. Draper hypothesized that the unexpected drop in VOR gain may have resulted from the visual stimuli acting as a VOR suppression stimulus at the beginning of each head movement (due to the imposed latency).

3.2 Postural Effects

3.2.1 Overview/Description

Exposure to virtual environments, such as flight simulators, can cause postural disequilibrium in users. If the postural disequilibrium persists beyond the time an individual is within the confines of the laboratory or system site, user safety could be compromised and product liability (see chap. 27, this volume) issues could be raised. For this reason, postural equilibrium has been proposed as a means of assessing the magnitude of aftereffects associated with VE systems.

A wide variety of techniques are used for measurement of postural motion (for a review, see Riccio & Stoffregen, 1991). Among these are kinematics of the body's center of pressure, or COP (e.g., Collins & DeLuca, 1993; Riley, Mitra, Stoffregen & Turvey, 1997), whole-body kinematics (i.e., measures of head motion; Stoffregen & Smart, 1998), joint kinematics (hip and ankle; Nashner & McCollum, 1985), and muscle activity (Nashner & McCollum, 1985). These techniques can be implemented in many ways, including qualitative (e.g., Cobb, 1999), linear quantitative (e.g., Stoffregen & Smart, 1998), and dynamical quantitative (Bardy, Marin, Stoffregen, & Bootsma, 1999). Measures of the kinesthetic position sense are also to be considered. Any of these could be used to assess adaptation to VE exposure. To date, a standardized assessment procedure has not yet been developed, and thus there is considerable opportunity for the development of new tests that may confer benefits in specific situations.

Test battery construction must focus on the accuracy and applicability of the constituent postural tasks required. Each task should be relatively unobtrusive while ensuring the comfort and safety of the participants. After such considerations, the first goal should be to ensure that each task is reliable. Unreliable tasks have no utility and should be discarded. Next, one or two tasks should be chosen to assess each domain or focus area. Tasks that consistently measure similar constructs should be refined or discarded. Finally, normative data must be established to accurately gauge any adaptive change in posture.

3.2.2 Measurement Techniques

Cobb (1999) reviewed a number of studies that have used qualitative measures to assess postural stability in the context of virtual environments. The majority used techniques such as the Sharpened Romberg test. In this test, the participant is instructed to stand heel-to-toe with weight equally distributed on the two feet with the chin parallel to the floor, and with the arms folded against the chest. The dependent variable is the number of seconds that this posture can be maintained. Dynamic tests are also used, such as asking participants to walk along a rail with the dependent variable being the number of steps taken. Kennedy, Berbaum, and Lilienthal (1997) evaluated postural stability following VE exposure by recording the duration that participants could stand on one leg. Although tests of this kind are simple and convenient, the data they provide are of limited precision.

More precise data can be obtained using technology to directly record body motion. One example is video recordings of stance. A variety of simple postural tests can be used with this procedure, such as a Tandem–Romberg test. This eliminates the necessity of keeping a large walking area safe for participants to traverse, and instead restricts data collection to a small, easily safeguarded area. The Tandem–Romberg stance generally restricts the majority of postural motion to lateral sway (side to side). This arrangement simplifies data reduction from videotape records. It allows one camera (placed directly behind the participant) to capture the majority of the movement. If significant movement exists outside the lateral plane, the need exists for two synchronized cameras (or another recording technique). Alternatively, a geometric shape (a reticle) of known dimensions can be used to allow calculations that characterize movement in other planes. Placing the camera at a distance equal to the participant's height allows lateral movements to be easily characterized in angular terms because the radii of the movement from the reticle to the floor and the camera are equal. Changing the camera's distance with each participant would require recalibrating the camera so that the pixel area that the reticle occupies remains constant (i.e., the viewed size of the reticle appears constant). For this reason, it is useful to keep the camera at a fixed distance of 2 meters from participants. The advantage to this method is that a camera is the only major piece of apparatus necessary during data collection. Coupled with a frame grabber for later analysis, this method is inexpensive, requires little space, and is not influenced by magnetic fields.

A second common technology used in direct measurements of postural motion is the force platform (e.g., Collins & DeLuca, 1993; Nashner & McCollum, 1985; Riley et al., 1997). These devices are becoming less expensive and easier to use. They constitute a convenient way to measure the kinetics of standing posture. Their chief limitation is their limited spatial extent. The test participant must remain on the force platform, which typically is no more than 0.5 meters square. Another method is epidermal recording of the electrical activity of muscles, or electromyography (EMG). While this method has a long history in basic research on stance (e.g., Horak & Macpherson, 1996; Nashner & McCollum, 1985), it is of limited usefulness in applied settings. Electrodes must be attached to the skin, which can be messy, and the associated wires tend to limit both the flexibility and range of movement. In addition, the interpretation of EMG data is difficult at best. This is because there is not a constant relation between the activity of muscles and the resulting motions of the body (Horak & Macpherson, 1996; Riccio & Stoffregen, 1988).

Position-tracking sensors offer another fast, easy, and precise method of collecting sway data along several dimensions. One such apparatus is a magnetic tracker. Magnetic trackers (e.g., Polhemus, Inc.; Ascension Technologies, Inc.), record the movements of a receiver/sensor relative to a central electromagnetic transmitter. Magnetic trackers can detect movements in 6 degrees of freedom (three axes of rotation and three of translation) with great accuracy. Research has demonstrated the benefits of magnetic tracking systems for recording head motion, body sway during stance (e.g., Stoffregen Smart, 1998), or sitting (e.g., Stoffregen, Hettinger Haas, Roe, & Smart, 2000).

Though magnetic trackers are generally very accurate, accuracy dissipates with increasing distance between the transmitter and sensor and with the inclusion of additional sensors; typical systems have an effective range of little more than one meter. Additionally, magnetic interference from other equipment may influence the data, reducing the utility of such a device in small, poorly shielded settings. The cables involved with most trackers may provide participants with feedback or compromise their stability, but a small amount of planning can alleviate this problem. In short, magnetic tracking systems offer another accurate, inexpensive method of assessing postural stability, but their utility depends upon the tester's ability to eliminate from the testing area items or materials that may interfere with the magnetic field.

3.2.3 VE-related Research on Posture

As noted earlier, few VE systems include a motion base. The majority of motion-base VE systems are vehicular simulators, such as flight simulators. In such systems the collection of data on postural motion is difficult. Accordingly, at present there are few studies of postural control in response to VE-generated inertial stimulation of the vestibule.

VE-related research on posture has focused on postural responses to imposed visual stimulation. Cobb (1999) measured postural stability before and after immersion in a virtual environment, consisting of an interactive video game presented via an HMD. Several different measures of postural stability were used, including tests of stance duration (i.e., Romberg test) and direct measurements of postural motion using a magnetic tracking system. Cobb reported that only the direct measurements of postural motion revealed any change in postural motion following exposure to the VE system. The study includes a helpful review of previous research relating postural stability to VE exposure.

Kennedy et al. (1997) assessed postural stability following exposure to both fixed-base and motion-base flight simulators, each of which used an external CGI display (i.e., not head-mounted). Significant correlations were found between scores on postural stability tests and measures of the subjective experience of disorientation. However, there was not a significant relation between posture and measures of motion sickness. It should be noted that Kennedy

et al. used only qualitative measures of posture (i.e., stance duration) and did not include direct measurements of postural motion.

Stoffregen et al. (2000) measured postural motion of seated participants (i.e., torso sway) during exposure to visual stimulation in a dome-type fixed-base flight simulator. Magnetic tracking of sway was done during exposure to CGI imagery, and revealed substantial differences in postural motion between participants who later became motion sick and those who did not. The results of this study and of the studies by Cobb (1999) and Kennedy et al. (1997), suggest that indirect measures of postural instability, such as stance duration tests, are of limited usefulness in assessing postural effects caused by exposure to virtual environments. Direct measurement (i.e., tracking of body sway using magnetic or video-based systems) reveals the existence of VE-based effects on posture, which may be related to significant phenomena such as visually induced motion sickness.

3.3 Past-pointing

3.3.1 Overview/*Description*

In many cases user interaction with altered environments (including VE systems) involves manual pointing or reaching to objects and events that are presented in a display. In such systems successful performance will depend on the user's ability to point or reach accurately (which requires proper hand–eye coordination). This is an issue because changes in visual, vestibular, and haptic adaptation are known to influence the accuracy of pointing; that is, they can induce past-pointing (which was defined in section 2.2.3). For this reason, it is important to assess the extent to which VE systems are prone to induce past-pointing.

3.3.2 Measurement Techniques

Magnetic trackers may be applied to the measurement of past-pointing. The transmitter may be affixed to a participant's pointing finger via something as simple as a Velcro finger slip. This approach has the same benefits and limitations as in postural stability measurement. Magnetic trackers are small, highly accurate, and inexpensive, but may be hampered by cable placement, susceptibility to magnetic interference, and by their small range.

Another inexpensive device for measuring past-pointing changes while avoiding some of the shortcomings of magnetic trackers is a digitizing tablet with a cordless stylus. This approach involves attaching a lightweight, cordless stylus, or “pen,” to a participant's finger (possibly via a Velcro finger slip). Participants would then contact a specified point on the surface on the digitizing tablet. This technique does not involve feedback from a cable (as with the magnetic tracker), but would introduce feedback from contact with the surface of the tablet. A potential solution would be to have participants close their eyes after becoming familiar with the contact point and to record the first point of contact with the tablet as their final target.

Past-pointing is easily demonstrated, yet data analysis may be fairly complex. The simplest metric is observing the magnitude of error from an established contact point. There may be utility in categorizing the error along its component axes (i.e., horizontal and vertical). Different exposures (or exposure durations) may manifest themselves strongly along one axis, while the other axis may indicate noise. Successive administrations of the test may indicate a pattern of responding that would not lend itself well to simply averaging the magnitude of error on repeated administrations. Participants may progressively move from a large deviation along one axis, to smaller deviations, and then have deviations that increase on the other side of the origin (i.e., center point). Likewise, participants may have deviations that maintain their magnitude but change their orientation/direction with regard to the central or desired contact point.

3.3.3 VE-related Research on Past-pointing

Research utilizing past-pointing measurement has begun to be conducted in VEs (for a review see Stanney et al., 1999). Recent studies have found an increase in pointing errors and a decrease in manual task speed following exposure to see-through HMDs. This has proved to be true for a variety of VE tasks. In experiments conducted by Stanney et al., participants interacted with targets in a VE presented via an HMD. The VE was shaped like a maze, consisting of 29 rooms and 3 long corridors. Participants performed a number of locomotion and manipulation tasks, such as grasping and moving objects located on one wall. Assessment of aftereffects was conducted immediately after VE exposure, and again 20 to 30 minutes later. Past-pointing was measured via arm movements that resulted in manual contact with a digitizing tablet. Results revealed that there were significant errors in the aiming of arm movements. In two experiments, manual reaching tended to be too high. In one of the experiments, reaching was also offset to the left. This and other recent work emphasizes the need for developing and using objective measures of post-VE exposure aftereffects so as to provide a systematic determination of the conditions under which these effects may occur.

4. CLASSIFICATION OF VISUAL/VESTIBULAR STIMULATION IN VIRTUAL ENVIRONMENTS

Virtual environments encompass a wide variety of interface systems including head-coupled HMDs, head-coupled and non-head-coupled interfaces to fixed displays, various degrees of motion-based and fixed-based systems, large- and small-display field of view (FOV), and active and passive control of self-movement. Each type of VE likely has characteristic patterns of motion dynamics that stimulate vestibular adaptation processes in a unique manner. Therefore, it would be helpful to categorize VEs according to their overall motion dynamic characteristics so that one might be able to better predict when specific forms of vestibular adaptation are likely to occur.

A VE's motion dynamics can be described through exploring the visual and vestibular couplings involved. One difficulty that currently exists with VE research is the lack of an accurate and consistent characterization of vestibular and visual stimulation within specific virtual environments. To properly define the motion stimuli in VEs, both visual and vestibular components must be considered, and quite possibly the most important aspect is their interaction. Described below is a classification scheme for VEs based on visual–vestibular couplings.

The idea of classifying environments according to visual and/or vestibular coupling is not new. Reason and Brand (1975) argued that all motion sickness arises from either visual–vestibular rearrangements or canal–otolith rearrangements, each with three possible permutations of the involved variables. Another example is the practice of classifying flight simulators on the basis of their tendency to induce simulator sickness (Kennedy, Drexler, & Berbaum, 1994). Kennedy, Berbaum, Dunlap, and Hettinger (1996) have also attempted to identify and quantify provocative visual stimuli in terms of optic flow velocities and accelerations. An earlier version of the classification system presented here was created by Draper (1998a) in an attempt to better generalize simulator sickness findings across virtual environments.

A critical feature of this scheme is that these classifications reflect a qualified comparison of visual–vestibular relationships in VE and real-world settings. *These categories do not imply a comparison of “visual motion inputs” to “vestibular motion inputs.”* The choice of this type of classification is motivated by current debate about the status of nonidentities in stimulation of the visual and vestibular systems. Nonidentities in the simultaneous stimulation of the visual and vestibular systems may constitute a sensory “conflict” that needs to be

TABLE 39.1
Proposed VE Motion Dynamics Classification System

	<i>Head Movement</i>	<i>Vehicular Movement</i>
Rotation	{active} equivalent, altered, distinct	{active or passive} equivalent, altered, distinct
Translation	{active} equivalent, altered, distinct	{active or passive} equivalent, altered, distinct

resolved through internal processing (e.g., Howard, 1986b). Alternately, such nonidentities may constitute higher order information that can be picked up directly (i.e., without internal processing; Stoffregen & Bardy, 2001; Stoffregen & Riccio, 1988). Regardless of the outcome of this debate, it is a fact that patterns of visual–vestibular stimulation in VEs generally differ from those occurring in their real-world correlates, and these differences often stimulate forms of vestibular adaptation. The classification method herein proposed is focused on this fact.

There is often more than one type of visual–vestibular coupling in a given virtual environment. Therefore, a useful classification scheme must account for this possibility and give insight into the nature of the motion involved. Visual–vestibular relationships should be separated into those arising as a result of head movement and those arising as a result of vehicle movement, because it is through these two types of movements that most visual–vestibular interactions occur (see Table 39.1); (cf. Riccio, 1995). Each of these categories can be further segmented into *rotational* and *translational* motion.

The head movement category includes visual and vestibular stimuli that result from active, self-generated movements of the participant's head resulting from neck rotations, torso movements, or locomotion, such as walking. Head movements are actively controlled by the participant and are always assumed to have a corresponding vestibular signal because a working vestibular system is always stimulated by head motion.

The vehicle movement category applies in those situations where the participant experiences simulated motion of a vehicle (such as in driving and flight simulators), either actively controlled or passively experienced. In VEs, this vehicular motion can include 'flying' through an environment by means of a hand controller or other such device, as well as the changing of rotational views by means of an artificial control device. Within VEs, vestibular signals may not exist for certain instantiations of vehicular motion.

Now that the general categories of VE motion dynamics have been described, there must be some way to classify each category according to how well it reflects its real-world correlate. Note that the following classification method is subjective and necessarily ill defined to an extent, given the wide variety of VEs and associated motion dynamics involved. However, this system might assist the researcher in pinpointing those visual–vestibular couplings most likely to be implicated in instances of vestibular adaptation, and it will improve prediction of specific forms of vestibular adaptation across virtual environments.

Each cell in Table 39.1 is classified as having one of the following possible visual–vestibular couplings: equivalent, altered, and distinct, as compared to the real world correlate for that type of motion. *Equivalent* is used to imply that the pattern of visual–vestibular stimulation is considered to be very similar to that which occurs in the real world. *Altered* is used to

denote patterns of visual–vestibular stimulation having an outward appearance of similarity with the real world correlate, but lacking equivalence due to latencies, tracking inaccuracies, optical distortions, and other causes. *Distinct* indicates visual–vestibular stimulation that differs grossly from what would occur in the real world. Usually this occurs when a VE system simply does not model real-world stimulation of one of the senses. These cases generally fall into one of two categories. Vestibular stimulation that is modeled in the absence of visual stimulation is referred to as *Vest/no Vis*, while visual stimulation that is modeled in the absence of vestibular stimulation is referred to as *Vis/no Vest*. *Vis/no Vest* is more common, especially for vehicular movements. The typical case is a VE system that simulates only the visual aspects of an environment.

Finally, given the potential influence of active control of movement on adaptations, there is identification of whether vehicular movement is *actively controlled* or *passively experienced* for translation as well as for rotational motion. As mentioned earlier, the head movement category always consists of active, self-generated head movements only.

This classification system organizes the major visual–vestibular couplings of all VEs according to the four quadrants of Table 39.1. Table 39.2 gives a few examples of how specific VEs would be categorized. Note the differences in visual–vestibular couplings that exist between simulators, between head-coupled VEs, and between simulators and head-coupled virtual environments.

As an example of this classification system, fixed-base domed flight simulators (Table 39.2, row no. 1) entail visual–vestibular *equivalence* for head movements because the visual image always surrounds the pilot and therefore responds to head rotations and translations with 0 ms latency, 1.0 gain, and no phase shift (as in the real-world correlate). However, motion dynamics from vehicular movement are *distinct* from their real-world correlate, as there is no motion base to apply inertial forces associated with aircraft movements. In contrast, consider a commercially available head-coupled VE system (Table 39.2, row no. 3) that responds only to head rotations (3 DOF), with the user translating through virtual space in the direction of

TABLE 39.2
Classification of VEs according to specific visual–vestibular couplings involved
(A: actively controlled motion. P: passively experienced motion)

Virtual Environment	Head Movement (A)		Vehicular Movement	
	Rotation	Translation	Rotation	Translation
1) Fixed-base full visual field domed flight sim.	Equivalent	Equivalent	A:Distinct (vis/no vest)	A:Distinct (vis/no vest)
2) 6 DOF motion-based full visual field domed flight sim.	Equivalent	Equivalent	A:Altered	A:Altered
3) 3 DOF head-coupled (rotation only) VE (translate via hand controller in direction of gaze)	Altered	Distinct (vest/no vis)	N/A (same as head rotation)	A: Distinct (vis/no vest)
4) 6 DOF head-coupled VE (translate via hand controller in direction of gaze)	Altered	Altered	N/A (same as head rotation)	A:Distinct (vis/no vest)
5) 3 DOF (rot only) VE passive flythrough (active gaze shifts recognized)	Altered (vest/no vis)	Distinct (vis/no vest)	P:Distinct	P:Distinct (vis/no vest)

current gaze via an artificial controller. With this system, as in the flight simulator, the user actively controls the motion, but the resulting patterns of visual–vestibular stimulation are very different. Due to latencies and minor inaccuracies associated with head-tracking systems, head rotations result in visual–vestibular stimulation that is *altered* from its real-world correlate. Head translation is *distinct* (Vest/no Vis) due to the inability of the head-tracking system to record position translations. Vehicular motion is only relevant in translation and involves visual motion cues only (i.e., *distinct*—Vis/no Vest). Thus, these two VE systems (fixed-base domed flight simulator and 3-DOF HMD interface) result in very different visual–vestibular couplings, and generalization of vestibular adaptation from one to the other may be limited at best. Correspondingly, motion sickness arising from flight simulators may differ from symptoms associated with various virtual interfaces (Stanney, Kennedy, & Drexler, 1997).

The intent of this classification scheme is to provide a basis for predicting the type and magnitude of vestibular adaptation and simulator sickness between VEs, based on the relative similarity of the visual–vestibular couplings involved. It also aids the researcher in identifying visual–vestibular couplings that most likely contributed to any occurring vestibular adaptation. Given that any complete description of a human–environment system must include elements of the task, stimuli, and individual, this framework is necessarily incomplete. However, for a particular task and individual profile, this classification scheme offers a way to specify and categorize the motion dynamics associated with VEs, while also specifying the potentially salient task variable of active versus passive control of vehicular motion.

5. IMPLICATIONS FOR VIRTUAL INTERFACE DESIGN AND USE

The topic of vestibular adaptation is very relevant and possibly critical to the design of effective and safe virtual interfaces. Given the current state of VE technology, the potential exists for vestibular adaptation within VEs to continue for the foreseeable future. The question becomes, What is the impact of vestibular adaptation within virtual environments? Below is a general summary of positives and negatives associated with the occurrence of vestibular adaptation in virtual environments.

Vestibular adaptation to altered environments generally benefits the human–computer system. It allows human behavior to adjust to the novel motion environment, reducing performance errors in gaze stabilization, postural control, and hand–eye control. Therefore, the faster the adaptation process, the more quickly performance will asymptote in the virtual environment. It has also been theorized that faster adaptation reduces the potential for motion sickness (Draper, 1998b; Reason & Brand, 1975; see chap. 30, this volume).

However, vestibular adaptation does not come without costs. The requirement for adaptation implies reduced performance until adaptation is complete. Additionally, substantial adaptation to a virtual interface implies a need for subsequent readaptation to the normal environment, which may entail negative aftereffects. These aftereffects (which may include incomplete gaze stabilization, postural instability, and errors in hand–eye coordination) are of primary concern to VE designers because of safety and legal issues that are involved (see chap. 27, this volume). Lastly, altered visual–vestibular couplings have been implicated in the occurrence of motion sickness in VE systems (see chap. 30, this volume). This suggests that similar stimuli may drive both vestibular adaptation and sickness.

Given that current-technology VE interfaces will likely drive vestibular adaptations, designers may wish to concentrate on speeding adaptation and readaptation processes in seeking to minimize any adverse effects. However, a far-term goal for VE designers should be to minimize all undesired adaptations that require postexposure recovery periods.

6. CONCLUSION

With virtual interfaces, one can no longer assume that system modification only occurs on the machine side of the human–computer boundary. Vestibular adaptation as a result of exposure to VEs has been clearly demonstrated. The benefits of vestibular adaptation include an improved ability to operate within the altered motion dynamics of the VE (including gaze stabilization, postural control, and hand–eye coordination). However, vestibular adaptation may also entail important health, safety, and legal ramifications (see chap. 27, this volume), such as the occurrence of negative aftereffects (see chap. 31, this volume) following exposure and an increased likelihood for motion sickness (see chap. 30, this volume) to occur during adaptation. Therefore, a detailed analysis of how humans are influenced by virtual interfaces must occur before these interfaces can be properly designed and administered. Stimulus rearrangements that commonly appear in virtual interfaces must be evaluated for their potential to drive vestibular adaptation processes, readaptation processes (i.e., aftereffects), and induce simulator sickness. Additionally, the consequences of these adaptations and aftereffects must be better understood. Only by fully characterizing the interface in this way can designers truly understand the health and safety issues involved.

1. INTRODUCTION

Computer technology has been evolving for decades; thus, why should virtual environments (VE) be so fascinating? Undoubtedly, it is the conceived notion that one can step into a virtual environment, be transported to any desired place, and do things impossible in reality. Likely due to exaggerated portrayals in movies and books, to the general public the virtual experience appears limited only by one's imagination. Current VE technology falls short of this ideal; however, it does allow users to have unique experiences, such as standing inside a molecule, which were never before possible. Yet, current VEs are certainly not realistic enough to dupe someone into perceiving the VE as physical reality. Virtual environments take advantage of the imaginative ability of people to "psychologically transport" their "presence" to another place that may not exist in reality. This concept is demonstrated when one becomes engrossed in a book or movie and attends to it to the exclusion of one's surrounding environment. The primary characteristic distinguishing VEs from other means of displaying information is a focus on such immersion. Virtual environments add a dimension of physiological immersion by removing many real world sensations (e.g., obstructing the view of the real world via an head-mounted display [HMD]), while substituting sensations that would be imparted if the VE were real (e.g., the visual scenes of the virtual world).

Immersion, whether physiological or psychological in nature, is intended to instill a sense of belief that one has left the real world and is now "present" in the virtual environment. This notion of "presence" has been considered central to VE endeavors since its conception (Minsky, 1980). Presence is traditionally defined as the psychological perception of "being in" or "existing in" the VE in which one is immersed (Heeter, 1992; Sheridan, 1992; Steuer, 1992; Witmer & Singer, 1998). Barfield and Hendrix (1995) distinguish virtual presence from real-world presence as the extent to which participants believe they are somewhere different than their actual physical location while experiencing a computer generated simulation.

To date, the utility of the presence construct, either to enhance interactive design or human performance, has not been clearly established. This may be due to a lack of concise definitions and effective measures for this construct. This chapter commences by describing the concept of presence, then addresses types of presence, approaches of measuring presence, variables that influence presence, and the effects of presence on human performance. The latter may ultimately determine the utility of presence, for without benefits to performance this construct may have little value beyond ephemeral captivation.

2. CHARACTERIZING PRESENCE

Singer and Witmer (1997) describe presence as a perceptual flow requiring directed attention. They suggest that presence is based on the interaction of sensory stimulation, environmental factors, and internal tendencies. The psychological perception of presence in a VE is primarily thought to be the by-product of the VE's immersive and involving properties (Witmer & Singer, 1998). Kim and Biocca (1997) suggest it is fundamentally a product of two factors: (1) "arrival," or the sense of being in the VE, and (2) "departure," or the sense of not being in a virtual environment. "Arrival," or involvement in a VE, is thought to occur when one focuses energy and attention on a coherent set of stimuli or meaningfully related activities and events, presented in the virtual world. This would suggest that increasing the focus of one's attention on events portrayed in a VE enhances involvement, thereby increasing presence.

There are two differing schools of thought on what constitutes "immersion" in a virtual environment. Witmer and Singer (1998, p. 227) define immersion as "a psychological state characterized by perceiving oneself to be enveloped by, included in, and interacting with an environment that provides a continuous stream of stimuli and experiences." They also suggest that factors that affect immersion include isolation from the physical environment, perception of self-inclusion in the VE, natural modes of interaction and control, and the perception of self-movement. Witmer and Singer (1998) suggest that VEs that produce a greater sense of immersion will produce higher levels of presence.

With a different perspective, several researchers have suggested that immersion is related to the technology used to provide multimodal sensory input to users (Bystrom, Barfield, & Hendrix, 1999; Draper, Kaber, & Usher, 1998; Slater & Wilbur, 1997). For example, Slater and Wilbur (1997, p. 604) define immersion as "the extent to which computer displays are capable of delivering an inclusive, extensive, surrounding, and vivid illusion of reality to the senses of the VE participant." According to them, inclusiveness is the extent to which physical reality is shut out. Extensiveness indicates the range of sensory modalities accommodated and stimulated. Surrounding indicates the extent to which the VE is panoramic rather than limited to a narrow field of view. Vividness indicates the resolution and fidelity of stimuli for each modality and is concerned with the richness, information content, and quality of the displays. Slater and Wilbur (1997) suggest that immersion can be an objective and quantifiable description of what any particular system provides. Based on these descriptors, Slater and Wilbur characterize immersion as primarily determined by the extent to which devices and displays are capable of replicating the physiological sensations of the real world equivalent of the VE in which the person is interacting. Slater (1999) takes issue with the approach used by Witmer and Singer (1998), suggesting that their approach confounds objective, physical properties of VE technology with subjective, experiential aspects of presence. Lessiter, Freeman, Keogh, and Davidoff (2001), suggest that presence is likely related to both the subjective sense of a physical, spatial environment, as well as a personal evaluation of the appeal and naturalness or believability of the displayed environment and its content.

Regardless of how immersion is defined in regards to virtual environments, "presence" appears to be moderated by both external factors (Barfield & Hendrix, 1995; Hendrix &

Barfield, 1996a, 1996b; Prothero & Hoffman, 1995; Slater & Wilbur, 1997; Welch, Blackmon, Liu, Mellers, & Stark, 1996), as well as internal factors (Fontaine, 1992; Heeter, 1992; Witmer & Singer, 1998). Arguably, one must be afforded both technological and experiential immersion to maximize the likelihood of high levels of presence. In other words, one must be sufficiently immersed through the VE systems' hardware components and ergonomic design to enable the psychological leap of feeling "present" in the virtual environment. However, regardless of the realism of the virtual environment, if one is distracted by, or has psychological ties to, the external world, the sensation of presence may never occur and certainly will not develop to a great degree. To better understand this construct, it is important to realize that there are several different types of presence that can be elicited in a virtual environment.

3. TYPES OF PRESENCE

Heeter (1992) asserts that there are three different types of presence: environmental, social, and personal. *Environmental presence* is described as the extent to which the environment itself appears to acknowledge one's existence and react to their actions. Heeter contends that many VEs are unresponsive to users. The premise of *social presence* is simply that, if multiple people are immersed in the same VE, the presence of others provides further evidence that the environment "exists," and thus each participant is more prone to experience higher levels of presence. *Personal presence* is a measure of the extent to which, and the reasons why one feels like they are "in" a virtual environment. The degree to which individuals feel present in VEs varies tremendously and may never be fully understood or predictable without a comprehensive and accurate measure of presence. When presence is referred to it is generally in the context of personal presence.

4. VARIABLES THAT INFLUENCE PRESENCE

Just as there are several forms of presence, from environmental to social to personal, there are multiple variables that influence these forms of presence. Both individual and system variables are thought to influence the level of presence experienced in a virtual environment (Stanney et al., 1998). Some specific variables discussed include: (1) ease of interaction; (2) user-initiated control; (3) pictorial realism; (4) length of exposure; (5) social factors; and (6) system factors. Beyond these specific variables, Slater and Usoh (1993b) distinguish between internal and external factors that may contribute to a participant's sense of presence.

4.1 Ease of Interaction

Virtual environment users that experience difficulties navigating through or interacting with the environment, or while performing a task, will be more likely to perceive the VE as unnatural and may experience less presence in the environment. Billinghurst and Weghorst (1995) manipulated the design of VE systems, influencing the ease of interaction, and found those environmental designs that facilitated the "ease of interaction" increased the reported sense of presence in the virtual environment.

4.2 User-Initiated Control

Witmer and Singer (1994) suggest that the greater the level of control a user has regarding their actions in a VE, the higher the reported level of presence. Witmer and Singer explain that the immediacy of a system's response, correspondence of user-initiated actions, and naturalness

of the mode of control drive this control factor. Sheridan (1992) suggests that a user's control over the relation between sensors and the environment (e.g., the ability to modify one's viewpoint) and their ability to modify the physical characteristics of a VE are two of the principle determinants of sense of presence. Similarly, Welch et al. (1996) found that interactivity (versus passive observance) was particularly influential in enhancing perceived presence.

4.3 Pictorial Realism

Witmer and Singer (1994) suggest that presence should increase as a function of the pictorial realism of a virtual environment. Pictorial realism, in this case, relates to the connectedness, continuity, consistency, and meaningfulness of the perceptual stimuli presented. Welch et al. (1996) found limited but positive influences of pictorial realism on presence. Wilson, Nichols, and Haldane (1997) determined that realistic visual depth cues were positively related to reported levels of presence. Snow and Williges (1998) conclude that visual display resolution and texture mapping, while significant parameters, were less influential than other factors (i.e., field of view, sound, head tracking).

4.4 Length of Exposure

Preliminary data indicates that presence is not enhanced by longer exposures (Stanney, 2000). This study indicates that a given VE design appears to promote a sense of presence (or not) within the first 15 minutes of exposure. It would seem reasonable, however, to expect that extending exposure duration may increase presence because longer exposures enhance other factors thought to have an effect on presence. These factors include practice with VE tasks, extent of familiarity within the VE, and level of sensory adaptation to the intersensory and sensorimotor discordances presented by the VE (Welch et al., 1996; see chap. 31, this volume). If, as has been demonstrated, prolonged VE exposure results in increased motion sickness symptoms, presence could be negatively affected (Kennedy, Stanney, & Dunlap, 2000; Stanney, Lanham, Kennedy, & Breaux, 1999), especially since presence and sickness have been found to be negatively correlated. Witmer and Singer (1998) report that combining data from four experiments resulted in a correlation between sickness and presence of -0.426 , $p < 0.001$. Witmer and Singer (1998) suggest that symptoms accompanying sickness draw attention away from the VE and focus that attention inward, decreasing involvement in the VE and thereby reducing the sense of presence. Similarly, in a recent study using a maze shaped VE and exposures up to one hour in length, subjective presence was found to be negatively correlated ($r = -0.342$, $p < 0.001$) with sickness (Stanney, 2000). It should be noted that another study (Wilson et al., 1997) reported a positive relationship between sickness and presence using different measurement tools of sickness and presence (see discussion in Stanney et al., 1998). Stanney et al. (1998) suggested that there is the possibility that sickness and presence are both correlated (either positively or negatively) with a third factor, such asvection (see chap. 23, this volume), in that changes in one initiate changes in the other but solely via the intervening factor. Regardless of the specific relationship between them, with respect to the factors that can impede sense of presence, sickness may be one of the most deleterious. Thus, when presence is important, exposure duration should be set to minimize such adverse effects.

4.5 Social Factors

There is growing interest in the effects of social factors on presence (Heeter, 1992; Steuer, 1992). The premise of "social presence" is that if other people (i.e., representative avatars; see chap. 15, this volume) reside in a VE there is more evidence that the VE exists. Correspondingly, if other persons in a VE essentially acknowledge one's presence in the VE, it offers further

affirmation that one actually “exists” in that environment (Heeter, 1992). Social presence may result from communicating with others verbally or by gestures, interacting with others in the environment, or through confirmation that others recognize their existence in the environment.

4.6 Internal Factors

Slater and Usoh (1993b) describe internal factors as individual differences in how an individual cognitively processes information provided by a VE experience. While these factors are difficult to influence, it is important to understand their affect on presence.

Slater and Usoh (1993b) used a technique known as Neurolinguistic Programming (NLP) to assess how internal factors affect virtual presence. The NLP model suggests that subjective experience is encoded in terms of three main representation systems: visual, auditory, and kinesthetic (VAK). Practitioners of NLP claim that people have a tendency to prefer one representation system to another in a given context. The visual system includes external images as well as remembered or constructed internal mental images (see chap. 3, this volume). The auditory system includes external sounds and remembered or contrived internal sounds (see chap. 4, this volume). Also included in the auditory system is internal dialogue (i.e., talking to oneself). The kinesthetic system includes tactile sensations caused by external forces acting on the body and emotional responses (specific to internal tactile and haptic sensations; see chap. 5, this volume).

The Slater and Usoh (1993b) study suggests that visually dominant people report greater levels of presence than individuals whose primary representational system is auditory or kinesthetic and that a person who tends to process information more from the first position (e.g., “I” or “my”) is more likely to experience a sense of presence than those who process more from the second or third position. They also suggest that the higher the proportion of visual predicates and references used when describing a VE experience (e.g., “looking” or “seeing”), the greater the reported sense of presence, whereas the higher the proportion of auditory predicates and references the lower the reported sense of presence. For those individuals provided with a virtual body (VB), the greater the proportion of kinesthetic references and predicates the higher the reported level of presence. For those without a VB, kinesthetic references were inversely related to presence. It should be cautioned that these results were derived from a VE that stimulated primarily the visual system, with only a small amount of associated sound and no haptic interface. The critical issue is that subjective experience is encoded in terms of different representation systems and that people may prefer one representation system to another. Thus, it is important to consider the types of individuals who will use a given VE system and their preferred representational system.

4.7 System Factors

Slater and Usoh (1993b) describe system factors as external factors that relate to how well the system replicates the real world equivalent, how this information is presented to the user, and the how the user interacts with the virtual environment. External factors are determined wholly by the VE hardware and software that drives the display. Slater and Usoh suggest external factors that may influence reported levels of presence include high-quality, high-resolution information being presented to the participants’ sensory organs in a manner that does not convey the existence of the devices or displays. The environment being presented to the participant should be consistent across all sensory information displays. The environment should be one in which the participant can interact with objects and other actors, and one that reacts to the user. They also suggest that the self-representation of the participant should include a VB that is similar in appearance to the participant’s own body and responds appropriately to the participant’s movements.

In a study of system factors, Hendrix and Barfield (1996a) found that the addition of stereopsis positively influenced spatial realism during interaction within the VE and resulted in reports of greater presence. The same study also found that adding head tracking and manipulating the geometric field of view (GFOV) influenced reported levels of presence, with head tracking and larger GFOVs associated with higher levels of presence. Barfield and Hendrix (1995) found that presence was enhanced with increasing update rates but was approximately constant between 15 to 20 Hz. Welch et al. (1996) also encountered a negative influence on presence when a delay in visual feedback occurred. Hendrix and Barfield (1996b) found that spatialized sounds had a significant effect on presence when compared to nonspatialized or no sounds at all. Not all of these technical factors, however, are equally influential. Snow and Williges (1998) found that field of view, sound, and head tracking were nearly three times as influential on presence as visual display resolution, texture mapping, stereopsis, and scene update rate.

It has been suggested that as more sensory modalities are stimulated presence should increase (Steuer, 1992). Sadowski (1999) reviewed olfactory stimulation in VEs and the potential of incorporating odors as a means of increasing presence and performance in virtual environments. The results of this review suggest that utilizing olfactory cues in VEs may facilitate performance on some tasks, especially those demanding recall or recognition. The human

TABLE 40.1
Guidelines for Supporting Presence

	<i>Guideline</i>	<i>Issue</i>
Ease of interaction	Provide seamless interaction such that users can readily orient in, traverse in, and interact with the virtual environment.	Poorly designed interaction takes focus away from the experience and places it instead on motion/mechanics.
User-initiated control	Provide immediacy of system response, correspondence of user-initiated actions, and a natural mode of control.	Delays, discordance of users' versus effectors actions, and unnatural control devices hinder engagement in a VE.
Pictorial realism	Provide continuity, consistency, connectedness and meaningfulness of presented visual stimuli.	Poorly designed or displayed visual interactions may hinder engagement in a VE.
Length of exposure	Provide sufficient exposure time to provide VE task proficiency, familiarity with a VE, and sensory adaptation.	Avoid unnecessarily prolonged exposures that could exacerbate sickness.
Social factors	Provide opportunities to interact with and communicate with others verbally or by gestures. Provide confirmation that others recognize one's existence in a VE.	If one's presence in a VE is not acknowledged by others, it may hinder the perception that they "exist" in that environment.
Internal factors	Identify the types of individuals who will use a VE system and their preferred representational system (i.e., visual, auditory, kinesthetic).	Individual differences can render VE systems differentially effective.
System factors	Provide head tracking, a large field of view, sounds, stereopsis, increasing update rates, multimodal interaction, and ergonomically sound sensors/effectors to facilitate presence.	Poorly designed systems can degrade users' experience. Note: This does not suggest that "extreme realism" is required, but rather what is provided should be well designed and developed.

olfactory system utilizes the sensation of odors for detection, recognition, discrimination, and differentiation/scaling (Barfield & Danas, 1996). Furthermore, neuroanatomically, in comparison to the visual and auditory systems, the olfactory system has many direct connections to the limbic system of the brain where emotions and affects are regulated (Kandel & Schwartz, 1985). There is strong evidence that odors can be effective in manipulating mood, increasing vigilance, decreasing stress, and improving recall and retention of learned materials (Youngblut, Johnson, Nash, Wienclaw, & Will, 1996). Knasko and Gilbert (1990) found that even the suggestion of odors affect reported levels of pleasure and mood. Thus, the powerful influences of the olfactory system can be manipulated by incorporating odors in a VE to produce a more realistic experience, thereby increasing levels of presence and enhancing performance on some tasks.

Another system factor to consider is the interplay of the ergonomic design of the VE hardware (see chap. 41, this volume). Billinghurst and Weghorst (1995) found display comfort and quality to be predictive of reported presence. If a user is distracted by, or must focus on, the VE hardware because it is uncomfortable or burdensome, the ability to simulate “being in” the VE may deteriorate (Slater & Usoh, 1993b).

From the review of factors that influence presence, general guidelines can be provided that, if effectively implemented, should enhance users’ perceived presence within a virtual environment (see Table 40.1).

5. MEASURING PRESENCE

Although the benefits of presence have been widely discussed and touted, few researchers have attempted to systematically measure this concept and relate it to possible contributing factors. It could be that sense of presence is simply an epiphenomenon of good VE design or possibly even a distraction (Ellis, 1996; Welch, 1999). Without a valid measure of presence, however, this issue cannot be resolved. Determining how to measure presence may provide a means to establish whether presence does indeed enhance VE system interaction and a greater understanding of the factors that drive this phenomenon may result.

A valid measure of presence should be: (a) relevant—have a direct connection with presence and its components; (b) reliable—have proven test-retest repeatability; (c) sensitive—have sensitivity to variations in the variables affecting presence; (d) nonintrusive—to avoid unintentional degradation of performance and/or sense of presence; and (e) convenient—portable, low cost and easy to learn and administer (Hendrix & Barfield, 1996a; Jex, 1988).

Presence has generally been measured using subjective rating scales that require judgments comparing a VE experience to real life (Hendrix & Barfield, 1996a; 1996b; Prothero & Hoffman, 1995; Slater & Usoh, 1993a; 1993b; Slater, Usoh & Steed, 1994; Witmer & Singer, 1998), or one VE to another (e.g., Welch, Blackmon, Liu, Mellers & Stark, 1996). These rating scales generally comprise statements relating to the extent to which an individual: feels physically located in a VE; senses that a VE has become more real than the physical world; and has a sense that the VE is more than merely a mediated event and has transcended into something they have actually experienced (Lessiter, Freeman, Keogh, Davidoff, 2001). These subjective rating scales are generally relevant, sensitive, nonintrusive, and convenient. They are, however, subject to response bias and thus may be unreliable (Freeman, Avons, Pearson, & IJsselsteijn, 1999). In addition, they often assume the respondent has an understanding of the nebulous concept of “presence” (Freeman, Avons, Meddis, Pearson, & IJsselsteijn, 2000).

With the issues related to subjective rating scales, alternative forms of measurement have been investigated. Behavioral presence relates to internally measurable or externally observable responses to the VE and the presented stimuli (e.g., skin conductance, electrocardiogram

(ECG), heart rate variability). While several researchers have attempted to use behavioral or physiological measures to assess presence in virtual environments (Cohn, DiZio & Lackner, 1996; Dillon, Keogh, Freeman, & Davidoff, 2000; Wilson, et al., 1997), the results have been mixed (see section 5.2.2).

5.1 Subjective Measures of Presence

Subjective measures of presence include such psychological measurement instruments as: (a) rating scales (e.g., “On a scale of 1 to 7 rate how natural your interactions with the virtual environment seem?”); (b) subjective reports (e.g., “I really felt like I was in another place and forgot that I was actually in a laboratory.”); (c) the method of paired comparisons (e.g., “In which of the two virtual environments did you feel most ‘present’?”); and (d) cross-modality matching (e.g., “Make this music as loud as the strength of the presence you experienced in the VE with maximum music volume being equal to the highest possible presence.”).

5.1.1 Rating Scales

Subjective rating scales have been used in several VE research experiments to evaluate the amount of presence experienced by participants (Baños et al., 2000; Prothero & Hoffman, 1995; Slater et al., 1994; Witmer & Sadowski, 1998). Witmer and Singer (1998) developed the Presence Questionnaire (PQ), which measures presence along three subscales: (1) involvement and control; (2) naturalness; and (3) interface quality. Witmer and Singer (1998) have data from several experiments that indicate that the PQ is a reliable and valid measure of presence (see Singer & Witmer, 1999; Slater, 1999). The PQ also has shown evidence of meaningful relations with learning (see chap. 20, this volume), aftereffects (see chaps. 30–32, 37–39, this volume), and human performance (see chap. 35, this volume).

Schubert, Friedmann, and Regenbrecht (1999) used a rating scale to assess presence in a three-dimensional computer game. They found three main factors drive presence, including: (1) spatial presence; (2) involvement; and (3) realness (comparability of a VE to the real world). Similarly, Lessiter et al. (2001) identified via a rating scale (i.e., the ITC-Sense of Presence Inventory) four main factors driving presence, including: (1) physical space; (2) engagement; (3) naturalness; and (4) negative effects. They appear to be the first ones to formally incorporate the adverse effects of VE exposure into a presence measure. The three rating scales reviewed here (Lessiter et al., 2001; Schubert et al., 1999; Witmer & Singer, 1998) all tap on similar components of presence (i.e., the physical space, involvement, naturalness, and interface quality).

Usoh, Catena, Arman, and Slater (2000) subjected the Slater et al. (1994) and Witmer and Singer (1998) measures to a “reality test” by assessing whether or not these scales provided higher scores for real experiences as compared to the diminished experiences provided by current VE technology. Usoh, Catena, Arman, and Slater (2000) found that neither scale passed the reality test (i.e., scores for real events were not higher than VE); however, the Slater et al. (1994) scale showed some marginal differences. They concluded that the utility of rating scales, while appropriate for the assessment of a single system, is limited for comparison of experiences across diverse environments.

5.1.2 Subjective Report

Some VE experiments have also incorporated subjective reports as a means of obtaining information regarding presence (Hendrix & Barfield, 1996a; Slater & Usoh, 1993a). These studies used directed, but open-ended, questions to elicit participants’ reactions and impressions related to presence. Since these answers were formed in the participants’ own words they may serve to reduce any bias from question interpretation and Likert scale response bias. Like

any open-ended questionnaire responses, however, results from such subjective reports can be difficult to generalize.

5.1.3 Comparison-based Prediction

Schloerb (1995) proposed a paired-comparisons procedure in which the participants' task is to distinguish between a real-world scene and a VE simulating the same scene. Hence, if participants are unable to distinguish between the two environments, one could reasonably suggest that their sense of presence in the VE should be as strong as in the real world. Given the present state of VE technology it is unlikely that any participants would be unable to distinguish between a computer-generated VE and the real world. Therefore, this method may be more effective in comparing VEs amongst each other to determine which aspects of each environment, and which environment as a whole, has the greatest influence on facilitating or degrading presence.

Welch et al. (1996) used the method of paired comparison to determine the influence of three variables on participant's presence. Participants were presented with a pair of VEs that differed from each other in respect to: (a) whether the participant had an interactive or passive exposure; (b) whether the VE had high or low levels of pictorial realism; and (c) whether there was a short (200 msec) or long (1700 msec) delay of visual feedback (see Section 4.7). After participants viewed each pair of VEs, they reported which one produced more presence and indicated this difference on a scale of 1 to 100. Welch et al. (1996) found that participants indicated that interactivity (i.e., having active control over interaction rather than being a passive bystander) played a greater role than pictorial realism in judgments of relative presence. Similarly, Snow, and Williges (1998) used free-modulus magnitude estimation to examine the influence of a number of system parameters on perceived presence. In this method a participant is presented with a VE to which they assign a number based on their subjective impression of its intensity. The only restriction on the assigned number is that it must be positive (i.e., no experimenter defined constructs or rating scales). Then the participant assigns comparative values to successive VE systems. Using this method along with sequential experimentation and data bridging, Snow and Williges developed polynomial regression models to predict presence that could prove useful for VE system designers (e.g., prioritize field of view, sound and head tracking over other system factors).

Comparisons methods have the advantage that they do not require investigators to explain to participants what is meant by the concept of presence (Stanney et al., 1998). Unlike subjective reports and rating scales, which must often define or describe what is meant by terms, comparison-based prediction requires nonanalytical comparisons among alternatives, that is, reasoning by analogy (Klein, 1982). To standardize this method, a set of comparison cases could be established. Inferences about the level of presence in any one given system could then be generated based on how it compares to a select standardized comparison case. The benefit is that the response bias created by defining terms is avoided. There is an issue with this method in that the size of the difference that is detectable (known as the "just noticeable difference") will be dependent on the aspects of the stimuli (i.e., the real scene or comparison case versus the VE) that are compared. It is likely that individuals will be far more sensitive to differences in some dimensions (e.g., authentic sound simulation) as opposed to others (e.g., poor texture mapping) (Snow & Williges, 1998).

5.1.4 Cross-Modality Matching (CMM)

The scaling of sensory experiences, or psychophysics, emerged in the late 19th century. Today sensory psychophysical scales are universally used and accepted in experimental psychology and tend to be reliable and stable (Stanney et al., 1998). The premise of CMM is that a person can monotonically represent the experiences of one sensory modality through

another modality by producing a “subjectively equal” representation using a measure of the second sensory modality. This method is particularly effective when a concept does not readily lend itself to verbal scaling (such as when a definition of terms leads to response bias). For example, a person can characterize increasing or decreasing changes in a visual stimulus (e.g. light intensity) as they perceive them by matching these increases or decreases with an auditory stimulus (e.g. auditory intensity). Hence, it seems reasonable that the CMM technique could be utilized to provide an indicator of the overall presence experienced in a VE or utilized to determine which portion(s) of a VE provided the most influence on presence. Individual differences in representation of sensory modalities, however, can be problematic as it can lead to high response variability.

In general, the subjective measures reviewed here have the advantages of being easy to administer and interpret. However, the major drawback of such subjective measures is the problem of interrater reliability. Also, for some of these methods (i.e., rating scales and subjective reports), participants must understand the concept of what presence “is” and interpret questions uniformly. In addition, psychometric developers must ensure that the measurement tool is measuring “presence” as a whole and not only factors that contribute to it. Thus, objective measures of presence, such as physiological and behavioral measures, may be helpful in determining which individual and system factors influence presence.

5.2 Objective Measures of Presence

People commonly experience physiological or behavioral responses to stimuli in the real world, therefore it seems reasonable to conclude that stimuli in an immersive VE may also produce such responses. These responses may include reflexive motor acts and physiological indicators (physiometric and neurophysiological changes). Such responses could be objectively measured without participant bias and used as a primary or secondary indicator of environmental influences on perceived presence in a virtual environment.

5.2.1 Behavioral Measures

First suggested by Held and Durlach (1987, 1992), measuring behaviors, such as “startle responses” (i.e., ducking or flinching), could provide indicators of presence in a virtual environment. Wilson et al. (1997) used startle responses to an unexpected event as one method of assessing presence. Other types of behaviors such as reaching for a virtual object, greeting virtual avatars, orienting responses, head positioning, or avoiding virtual hazards (i.e., visual cliffs) may suggest that participants “believe” they occupy the virtual space. Physiological and behavioral measures may be most useful when they are tailored to the experiences participants are expected to have in a virtual environment. For example, Cohn et al. (1996) demonstrated that participants responded with an automatic motor response (used as a measure of presence) in a VE designed to induce a sense of body rotation. Slater, Usoh, and Chrysanthou (1995) developed a behavioral measure by introducing contradictory information about object properties represented in both the real (via auditory cues) and virtual world (via visual cues). The extent to which users responded to the visual cues of the VE versus the contradictory auditory cues of the real world indicated their level of presence in the virtual world.

Zahoric and Jenison (1998) suggested that presence can be defined by the level to which a VE system successfully supports user action throughout the virtual world. This implies that the sensation of presence is grounded in action rather than altered psychological states. Using this action-based approach, Slater and Steed (2000) developed a virtual presence counter that is based on the number of transitions users undergo during VE exposure between two states: presence in the VE versus presence in the real world. The premise is that presence decreases

as the number of such transitions increases. With this approach, a stochastic process is used to model the number of transitions, from which an estimate of the proportion of time spent within the “presence in the VE” state is derived. This approach is based on a number of simplifying assumptions (i.e., presence is a binary state; the stochastic model assumes discrete time; independence between transitions; reporting breaks in presence does not influence the incidence of such reports), which could hinder the validity of this approach.

5.2.2 Physiological Measures

Physiological indicators including muscular tension, cardiovascular responses, and ocular behaviors have been suggested as presence measures (Barfield & Weghorst, 1993). Bioelectric information can be obtained by electromyography (EMG), electroencephalogram (EEG), ECG, electrodermal activity (EDA), galvanic skin response (GSR), and measures of skin temperature. Measures of visual system behavior may provide a wealth of information regarding attention, alertness, and arousal. Pupilometry, eye trackers, and electro-oculograms (EOGs) have the potential to be useful tools in the isolation of presence invoking stimuli. These visual indicators may serve to identify which elements of a VE capture attention or evoke physiological changes in the person immersed. This physiological data may provide information regarding the effects of specific environmental stimuli or events experienced in a virtual environment. Strickland and Chartier (1997), although not directly investigating presence, have demonstrated the ability to utilize EEG measurements in a head-mounted display. Measuring and interpreting differences in cortical responses in real and virtual environments may lead to a better understanding of the effects of various software and hardware influences in a virtual environment.

While physiological measures are predictably related to presence, few studies have identified systematic relationships between these factors. Weiderhold, Davis, and Weiderhold (1998) found that while subjective measures indicated that flight simulations displayed via a HMD were more relaxing and higher in presence than those displayed via computer screen, there were no clear physiological relations identified. Salnass (1999) also failed to find a relationship between presence and physiological measures when assessing shared VEs with and without haptic force feedback. Conversely, Dillon et al. (2000) found greater levels of skin conductance over time using stereoscopic video presentation as compared to monoscopic presentation of a rally driving sequence; however, the stereoscopic presentation did not generate higher presence ratings. Dillon, Keogh, Freeman, and Davidoff (2001) found that heart rate is not as sensitive to manipulations in display and content design as subjective ratings of presence. These studies indicate that the drawbacks of physiological measures of presence are that collecting data can be intrusive, difficult to obtain, and the outcome is frequently unreliable. Considerable work is needed if behavioral assessment is to achieve the aforementioned criteria for a valid measure (i.e., relevance, reliability, sensitivity, unobtrusiveness, and convenience).

An objective measure of presence that can provide quantifiable differences between baseline measures, or be compared to real world situations, would be ideal. However, ensuring that physiological or behavioral responses are “directly related” to the level of presence being experienced in a VE is difficult at best. People experience varying degrees of presence while immersed in a VE, typically due to divided attention between the physical world and the virtual world (Singer & Witmer, 1997). Therefore, regardless of the technique used to measure presence, researchers must keep in mind that the point in time in which presence measures are obtained may affect the results.

Due to the inherent weaknesses in both types of measures, it may be preferable to utilize a combination of subjective and objective measures of presence to obtain a comprehensive understanding of this phenomenon. Table 40.2 provides a summary of the currently available presence measures, indicating their strengths and weaknesses.

TABLE 40.2
Measures of Presence

<i>Presence Measure</i>	<i>Type of Measure</i>	<i>Description of Measure</i>	<i>Strengths</i>	<i>Weaknesses</i>
Rating scales	Subjective	Rate level of presence experienced in a VE.	Direct perception of user.	Interrater reliability may be weak; limited utility for comparison of experiences across diverse environments.
Subjective report	Subjective	Directed, open-ended questions of reactions and impressions related to presence.	Direct perception of user.	Interpreting results may be difficult due to response variability.
Comparison-based prediction	Subjective	Distinguish between a real-world scene and a VE simulating that scene or between alternative VE systems (standardized comparison cases may be used).	No bias due to definition of terms.	Size of just noticeable difference dependent on stimulus characteristic compared.
Cross-modality matching	Subjective	Represent experience of one sensory modality through another modality.	Can be used when verbal scaling is inappropriate or difficult to quantify.	Interpreting results may be difficult due to response variability.
Behavioral measures	Objective	Reflexive physical reactions or behaviors evoked by stimuli or events occurring in a VE.	Directly influenced by the VE, no subjective bias.	May not reflect influences of stimuli or events on total presence.
Physiological indicators	Objective	Physiological responses that occur when experiencing VE stimuli or events occurring within it.	Can serve to isolate influences on presence, objectively measured.	Internal or external “noise” may affect measures, intrusiveness, and reliability problems.

6. RELATIONSHIP BETWEEN PRESENCE AND TASK PERFORMANCE

Once presence can be appropriately measured, its relation to other factors, such as task performance, can be assessed. Stanney et al. (1998, p. 164) suggest that although the necessity of presence to support performance in a VE is presently unclear, “the potential relation (1) has considerable face validity, (2) is suggested by perceptual and cognitive theories that indicate that positive transfer increases with the level of original learning as long as structurally similar stimuli and responses are available and required for both the training and transfer tasks

(Schmidt & Young, 1987), and (3) is supported by early but limited empirical evidence (Bailey & Witmer, 1994; Witmer & Singer, 1994)." These issues provide the impetus to explore this relationship more fully.

Performance on several VE tasks has been shown to be positively related to subjective presence, including tracking performance (Ellis, Dorighi, Menges, Adelstein, & Jacoby, 1997) and search task performance (Pausch, Proffitt, & Williams, 1997), as well as performance on a sensorimotor tasks (Maida, Aldridge & Novak, 1997). Some studies have found psychomotor task performance to be positively related to subjective presence (Witmer & Singer, 1994), although others have not (Singer, Ehrlich, Cinq-Mars, & Papin, 1995). Similarly, one study found spatial knowledge to be positively related to presence (Singer, Allen, McDonald, & Gildea, 1997), but another did not (Bailey & Witmer, 1994).

A recent study of performance on a battery of tasks, modeled after the Virtual Environment Performance Assessment Battery (VEPAB) (Lampton et al., 1994), found subjective presence to be positively correlated with both task performance and the amount of movement (i.e., yaw and roll) experienced throughout the VE interaction (Stanney, 2000). The results indicated that for tasks requiring VB movement (i.e., locomotion, choice reaction time, and object manipulation), presence was negatively correlated to performance time and movement distance, indicating that as performance time and distance decreased (and thus task efficiency increased) sense of presence increased. For stationary object manipulation tasks (i.e., where the VB did not move), there was no relation found between presence scores and performance measures.

Taken together, these studies provide early evidence that performance may indeed be positively related to presence. Greater study is needed, however, to fully characterize this relationship, with particular attention being warranted for task specific influences of presence. Although designers often aspire to create the ultimate in reality, VE systems should only be expressly designed to engender high levels of presence when the causal relationship between presence and a given VE task is empirically validated, or has clear experiential value, such as in entertainment-based VE applications (see chap. 55, this volume).

7. CONCLUSIONS

While there has been considerable discussion of the concept of presence, the utility of this construct has yet to be definitively determined (Stanney et al., 1998). There are even those who suggest that there is little utility to this construct and its relationship to performance. It is clear that with the current shortcoming of valid measures of presence, the fundamental research required to determine the inherent worth of this construct will be difficult to conduct properly. Stanney et al. (1998) suggest that presence may be intimately related to certain VE attributes, such as interactivity and involvement, which seem to be vital components in the creation of believable if not "realistic" virtual worlds. Thus, for certain purposes, the challenge may be to determine how best to improve the effectiveness and quality of the VE experience rather than striving for the ultimate in presence. However, for the entertainment industry (see chap. 55, this volume), increasing the sense of presence in VEs will undoubtedly continue to be a highly desirable attribute to attract consumer gamers.

1. INTRODUCTION

The growth in technical and computing capabilities have increased the ability to design complex software systems capable of producing highly immersive environments, specifically virtual environments (VEs). Although it has many definitions, a virtual environment can be described as a technologically created, immersive, and interactive space designed to invoke the sensory systems into perceiving a desired condition or situation. Advances in VE technology have created interest for applications of this technology in training, education, industrial applications and entertainment (see chaps. 42–56, this volume). The growing applications warrant ergonomic analysis, particularly as this becomes a common tool in the work environment. Just as in any work environment, it is important to understand the impact that a tool or procedure is having on users from many perspectives. Research has shown that the use of VEs is a risk in the development of ergonomic related disorders such as repetitive stress injury (Belea, 1996). Definitive techniques are available for reducing the risk of these types of injuries in the “real world,” and this knowledge can be extrapolated in the virtual world before these injuries escalate.

2. IMPORTANCE OF ERGONOMICS IN VIRTUAL ENVIRONMENTS

Virtual environments have been applied in medical, aerospace, entertainment environments, and various other industries with the hope of even broader application. As more VE applications are developed and utilized, the likelihood of injury or risk due to preventable ergonomic factors increases. Additionally, the usability of a VE system is influenced by the ergonomic strength and usability of the physical aspects of the system (Bolas, 1994). Thus, efforts to identify and mitigate the risks associated with this technology are necessary.

2.1 Background

Virtual environment applications range from personalized immersion systems to public location-based systems, from devices requiring high-performance platforms to those generating desktop and laptop virtual worlds (Noor & Ellis, 1996). In a personal immersive environment the operator may wear a stereo display system, gloves, or other handheld devices accompanied by one or more position trackers. This allows the operator to experience sensory cues primarily in the visual, auditory, and tactile senses, and sometimes olfactory, gustatory, and vestibular senses as well. Location-based systems appeal to the same sensory modalities utilizing wide projection screens to create a stereo VE for individuals or groups of people. The type and degree of ergonomic concerns are clearly dependent on the type of virtual environment employed.

Virtual environment technology poses a design situation that is different from most existing human–computer interaction (HCI) design. Thus, guidelines and principles specifically tailored to the design of VEs are necessary. Limited research has been done to address such issues. One similar design situation that has been addressed to some degree is that of wearable computer systems.

Gemperle, Kasabach, Stivonic, Bauer, and Martin (1998) have codified a number of design principles for wearable computer systems. These principles focus on treating the human body and its range of motions rather than hardware or software engineering preferences. Basically, this technique of design principles recognizes that the human body is not composed of uniform blocks. Rather, it is flexible in some places, inflexible in others, and has a variety of ranges of motions based on the underlying bone, muscle, tendon, and ligament structures. The Gemperle et al. (1998) principles also reflect the general categories and subcategories of fit, feel, and safety as relevant areas of assessment for wearability. For a system to be considered wearable, the user must be able to walk, bend, crouch, reach, and climb with the equipment on. For VE applications, the user may also need to be able to lie down and run. Military training simulations

TABLE 41.1
Ergonomic Commonalities in Wearable Computers and Virtual Environments

<i>Ergonomic Category</i>	<i>Wearable Computers</i>	<i>Virtual Environments</i>
Anthropometrics	Static and dynamic anthropometric measurements should be considered in design.	Static and dynamic anthropometric measurements should be considered in design.
Biomechanics	User mobility while wearing computer. Impact on joint and full body loading. Distribution of load.	Mobility of entire body or specific aspects of the body affected by the VE. Load mobility. Distribution of load.
Computer comfort	Design for long term wearing.	Generally, wearing time is short term.
Durability	Computer must be designed to be durable in a variety of harsh environments.	Generally, VEs do not have as harsh environments as do wearable military computers.
Cardiovascular demands	Consider weight, duration of use, task activities, and impact that these issues have on cardiovascular system.	Consider weight, duration of use, task activities, and impact that these issues have on cardiovascular system.

may require soldiers to lie down and “crawl” forward on their stomachs or run to various parts of a building they are clearing. Nevertheless, most design factors for wearable computers can be applied to VE devices. The ergonomic principles to be considered in the design of wearable computers are closely related, but not identical to those of virtual environments. Table 41.1 shows the commonalities among the areas of ergonomic concern in designing these systems.

Although wearable computers provide some insights into ergonomic issues associated with VE systems, in general, many of the principles and guidelines developed to evaluate traditional HCI will not apply to VE systems. There are, however, those that have applicability with minimal refining (Wilson, 1997). For example, from a physical ergonomic standpoint, there exists a good body of literature that can be applied to the design of VE systems. The objective of this chapter is to offer guidance on the ergonomic techniques available for application in VE system design. This guidance is developed through review of three main areas:

- Ergonomic research needs in VE system design
- Classification of physical ergonomic issues in VE system design
- Application of ergonomics in VE system design

3. ERGONOMIC RESEARCH NEEDS IN VE SYSTEM DESIGN

The continual growth of VE technology suggests that the need for ergonomic research will grow. A number of research issues have been outlined as areas for future ergonomic analysis (Wilson, 1997). In this chapter, additional areas have been identified as relevant VE system design issues in need of ergonomic research. While some of these areas have been extensively addressed from a cognitive or human factors-oriented standpoint, many of them contain a strong element of physical ergonomic research need. These areas include:

- Multiple sensory channels
- Participant representation
- Head-mounted displays (HMDs)
- Navigation and orientation
- Presence and involvement (pictorial scene and stereoscopic displays)
- Temporal constraints
- Task design within the VE system
- Biomechanics

Although each of these areas has aspects of ergonomic concern, some will be more significantly influenced through effective ergonomic application. The areas that have immediate ergonomic need include multiple sensory channels, participant representation, HMDs, task design, and biomechanics. Each of these focus areas is discussed in more detail below.

3.1 Multiple Sensory Channels

For comprehensive simulation of a referent environment, some researchers believe that all senses must be stimulated. Present-day VE systems are strongly dependent on visual stimulation with some form of auditory information. Additional research is being conducted to provide force and tactile feedback and to develop sensors of more than just body movement (Burdea, 1995; Hirota & Hirose, 1995; Wilson, 1997; see chaps. 5–6, this volume). Much participation from the ergonomic community is needed in the development of such advanced multimodal interaction because the risk of physical injury or trauma from such interaction is

of real concern (Stanney, Mourant, & Kennedy, 1998). When stimulating multiple senses, VE equipment can become cumbersome and complex. For example, when immersive technology (i.e., and HMD) is used, obstructed vision of one's natural surroundings could lead users to fall or trip over obstacles in the real world, resulting in injury. The weight of the HMD could result in body imbalance, causing a falter or fall (Thomas & Stuart, 1992). When provided with three-dimensional audio, excessive volume could lead to noise induced hearing loss. In addition, sound cues could distract users causing them to fall during immersion. Among the challenges in producing effective virtual tactile feedback is the ability to replicate the force and/or pressure that would be produced in an environment. For example, if a virtual keyboard is being used, the user should receive the feedback that is similar to that received when utilizing an actual keyboard. To accomplish this, types of reactive forces, textures and responses to varying levels of pressure must be understood and modeled in the VE system. Yet if such force feedback systems fail it could lead to a user being accidentally pinched, pulled, or otherwise harmed. Fortunately, precautions are in place, as most force feedback systems attenuate transmitted forces to avoid injury (Biocca, 1992).

3.2 Participant Representation

The representation of the user and other participants in a VE requires ergonomic consideration from the standpoint of generating realistic, occupational interaction. Generally representation of body forms and movement mechanisms in computer-aided design (CAD) modeling systems has been relatively pictorially unsophisticated. The body of ergonomic knowledge could be used to make a substantial improvement in the design of manikins and virtual body parts—or avatars within a VE (Wilson, 1997). Some of these concerns were addressed in a special issue of presence (Thalman & Thalman, 1994). More research is needed in the areas of perceptual and motor performance of participant viewing and in the ergonomics of mixed (augmented) environments. For example, if real controls are used in the VE but are required to be located via the HMD, more research is needed to improve such interactions between “worlds” so that they can be deftly performed. Additional research in this area will enhance the realism and usefulness of virtual environments.

3.3 Head-Mounted Displays

Head-mounted displays have improved considerably since they were first introduced. However, there still remains a good deal of research to be done on development of anthropometrically accommodating, comfortable HMDs that can be worn for extended periods. A fairly comprehensive summary of designing HMDs for users can be found in Melzer and Moffitt (1997). Their review indicated that lack of fit was the main complaint by HMD wearers. The lack of proper fit can cause irritation and discomfort when using the device. The discomfort is severe enough that the growth of VE applications could be impeded if HMD design does not improve. Participants today do not voluntarily spend long periods of time in VEs, which can be attributed to HMD discomfort. This discomfort can be attributed to a number of factors including inappropriate fit, movement obstruction from tethers, excessive HMD weight, and improper distribution of this weight, which can produce premature muscular fatigue and inhibit the quality of the experience in a virtual environment. To minimize the likelihood of these occurrences, knowledge of anthropometrics and biomechanics should be applied in the design of operator-friendly head-mounted displays. The weight of HMDs is very important, as it can impact comfort, duration of wearing, and overall quality of the VE system. Variation in weight across HMDs varies widely, weighing from 4 ounces to more than 5 pounds. In particular, the weight of the HMD should be kept to a minimum because greater loading on the head

and neck can lead to an increase in neck and upper extremity discomfort. Additionally, the load should be located so that it is aligned with the spine to minimize the moment acting on the neck and lower back. In one study, as neck flexion increased from less than 55 degrees to more than 66 degrees, as could occur with a heavy HMD, reports of neck pain increased from approximately 10% to more than 50% (Hunting, Laubli, & Grandjean, 1981). In addition, limits on use should be identified for current heavier HMDs, which can weigh more than 5 pounds. With this loading, it is likely that exposure durations should be kept to a minimum to reduce head and neck strain.

3.4 Biomechanics

Occupational biomechanics focuses on physical exertion, muscular exertion, quantifying forces, and torques experienced by the musculoskeletal system while working, as well as quantifying, energy expenditure. For more details on the science and application of biomechanics, see Chaffin (1999). When considering equipment used in VE, a number of biomechanical concerns may surface. The use of HMDs and restrictions imposed by gloves, suits, or sensory feedback mechanisms can impact the mobility and efficiency of a VE user. Weight is one of the foremost issues in this category. Is the equipment too heavy, improperly balanced, or awkward, and, therefore, creating too much strain on the joints and muscles of the body or fatiguing the user? As noted above, unbalanced HMD weight can create strains on muscles and eventually lead to fatigue. In order to reduce the weight and strain from an HMD, some systems are now suspending HMDs from a floor or ceiling-based master arm (Pausch, Snoddy, Taylor, Watson, & Haseltine, 1996). However, there are other types of biomechanical strain, such as unnatural forces on joints or tendons that might lead to muscle pulls and strains, tendonitis, or bursitis. Chaffin (1999) provides general design considerations regarding physical activity such as work posture, work rate, and typical ranges of movement for extremities from a biomechanics perspective. The followings should specifically be addressed from a biomechanics standpoint in VE design:

- Load weight for handheld devices and HMDs
- Load balancing
- Distribution of forces
- Joint angles
- Velocity and acceleration of movement in task design
- Load task and movements place on joints and spinal system

Proper ergonomic design of these factors may lead to improved comfort and usability of physical characteristics associated with VE systems.

In evaluating the biomechanics of the VE equipment system designers should consider the likelihood and impact in long-term use. Although some VE exposures are relatively short, others may be used for extended periods of time. Similarly, the system may also be used repeatedly over short or long periods of time. In either instance, the devices must be safe for human use and not put the user at risk for joint, muscle, tendon, or fatigue problems. To avoid these risks it is important to observe the following:

- Distribute loads appropriately across the center of gravity
- Reduce force
- Improve posture
- Reduce repetitions

Principles of handgrip design are very important in VEs that utilize DataGloves as the primary means for operator input. Sanders and McCormick (1987) discuss ergonomic principles of hand tool and device design such as maintaining a straight wrist, avoiding tissue compression stress, and avoiding repetitive finger action, which can be used to enhance the design of VE DataGloves. The hand and fingers are capable of a wide range of movements and grasping actions, which depend largely on the ability to bend the wrist and rotate the forearm. Maximum grasping force can be quadrupled by changing from holding with the fingertips to clasping with the whole hand (Kroemer & Grandjean, 1998). The power of the fingers is greatest when the hand is lightly bent upward (dorsiflexion), and in contrast, grasping strength and level of skilled operation are reduced if the hand is bent downwards or turned to either side. Inclining the hand either outward (ulnar deviation) or inward (radial deviation) reduces rotational ability by approximately 50% (Tichauer, 1975). The result of research in this area suggests that from a biomechanics standpoint, the hands should be kept in line with the forearms during task performance. Specifically, for DataGlove design the wrist should be allowed to maintain neutral posture and tasks, especially those of longer duration, should require minimal grip strength. Additionally, tasks should distribute the forces applied by the hand across the fingers, rather than allocating force application to the thumb or index finger alone.

4. CLASSIFICATION OF PHYSICAL ERGONOMIC TECHNIQUES IN VE SYSTEM DESIGN

The objective of ergonomics is to fit the task to the human. Whether the task is considered to be an occupational effort, training, or recreational there is an opportunity for application of ergonomic principles. The classification of physical ergonomic concerns for the purposes of research and analysis is often partitioned into anthropometrics, cardiovascular, musculoskeletal, and psychomotor. Seldom is an ergonomic condition solely attributable to a single area, and, thus, analysis and treatment of ergonomic conditions generally adopt a multicategory approach.

4.1 Anthropometrics

Anthropometry is the science that involves the measurement of body dimensions. By measuring body lengths, girths, and breadths, one can describe, with frequency of distributions, the population's size. Anthropometric data are useful in the design of workplaces, equipment, and products relative to people's dimensions. They have been used to develop guidelines for heights, reaches, grips, and clearances. In general, the goal is to use anthropometric measurements to make workplaces, equipment, and products fit the capacities for reach, grasp, and clearance that accommodate a majority of the workforce. Thus, this science is significant in the design and operation of virtual environments.

The essence of anthropometric application in VE system design can be summarized by the "fit" of the workplaces. Do the devices anatomically conform to the human body, appendages, and sense organs in both static and dynamic motions? There are both anatomical and hardware engineering factors to consider in developing VE equipment to fit the body and deliver appropriate sense information to the user. If the equipment does not fit properly, it will not deliver the correct information to the user or feed back accurate information into the simulation. For example, if a haptic feedback system does not fit the hand well, it could produce sensations in the wrong part of the hand or fingers and, thereby, give the user incorrect information about selected objects in the virtual environment.

TABLE 41.2
HMD-relevant Anthropometric Dimensions for the Head (Dimensions in MM)

	<i>Women</i>				<i>Men</i>			
	<i>5th</i> <i>Percentile</i>	<i>50th</i> <i>Percentile</i>	<i>95th</i> <i>Percentile</i>	<i>Standard</i> <i>Deviation</i>	<i>5th</i> <i>Percentile</i>	<i>50th</i> <i>Percentile</i>	<i>95th</i> <i>Percentile</i>	<i>Standard</i> <i>Deviation</i>
Head Circumference	523	546	571	15	543	568	594	15

Interpupillary breadth	57	62	69	4	59	65	71	4

Source: Body Space: Anthropometry, Ergonomics and the Design of Work (2nd ed.), by Stephen Pheasant

In applying anthropometric considerations to VE design, developers must understand the relationship between the equipment and the relative body component. For example, if an HMD is being designed, user population anthropometrics should be considered for relevant dimensions, such as head circumference, head length, forehead length, and distance between eyes. Obviously, no piece of equipment will accommodate every user; generally, ergonomists strive to accommodate as many users as possible. A default is to design systems to capture the anthropometric constraints of those contained within the 5th percentile female and 95th percentile male. Table 41.2 provides anthropometric dimensions for the head that are applicable to VE system design, specifically HMD design.

In VE system design, this degree of accommodation may not be necessary, depending on the anticipated user population and the likelihood that a variety of sizes of equipment will be made available (e.g., small, medium, and large DataGloves). The decision to have variable sizes can increase the probability of proper fit and reduce the cost associated with development. For a more comprehensive summary of HMD design guidelines, see *Head-Mounted Displays: Designing for the User* (Melzer & Moffitt, 1997).

In addition to the dimensions associated with the head, the hand is an area that requires anthropometric consideration in design of VE systems. Table 41.3 provides guidelines for anthropometric estimates of the hand for the American population.

4.2 Musculoskeletal Issues in VE System Design

Musculoskeletal issues are those problems that strain the muscular and skeletal systems. This is a common problem in physically intensive work places and those environments that require extensive use of a particular muscular area (e.g., hand-intensive tasks). In a VE, the likelihood for musculoskeletal problems can be increased when users are required to perform awkward movements, participate in repetitive activities, lift objects, or exert consistent muscular effort. If lifting is required in the VE, such as in picking up a rifle during a military operation, developers should be mindful of tools to measure the impact that the task is having on the operator. The National Institute for Occupational Safety and Health (NIOSH) lifting guide (Kroemer, Kroemer, & Kroemer-Elbert, 2000) is widely used in the American occupational environment to quantifying the impact of lifting and can be applied to VE system design.

TABLE 41.3
Anthropometric Dimensions of the Hands (All Dimensions in MM)

	Men				Women			
	<i>5th</i> <i>Percentile</i>	<i>50th</i> <i>Percentile</i>	<i>95th</i> <i>Percentile</i>	Standard Deviation	<i>5th</i> <i>Percentile</i>	<i>50th</i> <i>Percentile</i>	<i>95th</i> <i>Percentile</i>	Standard Deviation

The 1991 NIOSH Lifting guideline equation (NIOSH, 1992) allows, as a maximum, a “Load Constant” (LC)—permissible under the most favorable circumstances—with a value of 23 kg (51 lb). The 1991 NIOSH Lifting guideline equation is as follows:

$$\text{RWL} = \text{LC} * \text{HM} * \text{VM} * \text{DM} * \text{AM} * \text{FM} * \text{CM}$$

Where:

LC—load constant of 23 kg or 51 lb.

(Each remaining multiplier may assume a value [0,1].)

HM—the horizontal multiplier: H is the horizontal distance of the hands from the ankles (the midpoint of the ankles).

VM—the vertical multiplier: V is the vertical location (height) of the hands above the floor at the start and end points of the lift.

DM—the distance multiplier: where D is the vertical travel distance from the start to the end points of the lift.

AM—the asymmetry multiplier: where A is the angle of asymmetry, i.e., the angular displacement of the load from the medial (mid-sagittal plane) that forces the operator to twist the body. It is measured at the start and end points of the lift.

FM—the frequency multiplier: where F is the frequency rate of lifting, expressed in lifts per minute.

CM—the coupling multiplier: where C indicates the quality of coupling between hand and load.

Though lifting may not be of concern in most VE systems, there are tasks such as training or other workplace augmented reality simulations where these guidelines may apply.

When considering the risks of musculoskeletal disorder (MSD) in virtual environments, analysis suggests that the most probable risk for these injuries exists for the upper extremities,

TABLE 41.4
Risk Factors for CTDs*

<i>Occupational Risk Factors</i>	<i>Personal Characteristics</i>
Force	Previous CTD
Repetition	Habits and hobbies
Awkward joint posture	Diabetes
Hand tools	Thyroid-related problems
Length of work shift	Age
Low-frequency vibration tools	Arthritis and related joint diseases

*Adapted from McCauley-Bell & Badiru (1996b).

neck, and back. MSDs are also referred to as cumulative trauma disorders (CTDs), overuse injuries, and a variety of other names that suggest their origin is the result of aggregate impact. Specifically, cumulative trauma disorders are injuries that primarily affect soft tissues, including muscles, tendons, tendon sheaths, joint surfaces, and nerves. Recent surges in the occurrence of upper-extremity CTDs has industry concerned and has been blamed for loss in productivity, inhibition in quality, low worker morale, and soaring workers compensation costs. The application of VE technologies should make every effort to avoid the pitfalls associated with introducing an activity that has known CTD risks.

The same considerations that are applied to occupational settings should be utilized in the design of virtual workplaces. The risks are varied, as illustrated by Crumpton and Congleton (1994), who demonstrated that the risk factors for CTDs include various occupational, personal, and organizational factors (see Table 41.4). In particular, VEs can benefit from knowledge of the occupational and personal categories. For example, in the development of systems, if extensive hand movement is required, designers can distribute the task over two hands or reduce the cycle time to minimize the amount of stress that this activity produces on the musculoskeletal system of the hand.

Proactive measures should be instituted with regard to other risk factors listed in Table 41.4; however, the most significant occupational risks to avoid are excessive repetition, awkward joint posture, and excessive force. For example, if an operator in a VE is required to perform a task wearing a DataGlove, efforts should be made to limit the amount of wrist joint deviation, force required to manipulate virtual objects, and repetitions involved with such manipulation. These are the primary factors that produce musculoskeletal injuries of the upper extremities (McCauley-Bell & Badiru, 1996b). Research has demonstrated that force, repetition and awkward posture comprise a combined weight of 0.66 of the risk level associated with task characteristics (McCauley-Bell & Badiru, 1996a). Thus, efforts should be made to minimize the presence of these conditions. Table 41.5 presents guidelines to follow when attempting to minimize the presence of CTD risk factors.

The application of these principles can help reduce the likelihood for injury in real-world workplaces, and theoretically should reduce the likelihood for injury in VE systems. If a quantifiable tool is desired for risk evaluation ratings in a proposed VE system for CTD risks, a numeric model can be utilized. For a model that can be useful in quantifying the risks of CTDs see McCauley-Bell (1999).

TABLE 41.5
Guidelines for Minimizing CTD Risk Factors

-
- Reduce repetition by increasing cycle time.
 - Minimize amount of time that a person has to do a particular task.
 - Provide rest breaks.
 - Use ergonomic designs that minimize joint angle and force exertion.
 - Minimize the amount of force required for activation of tools or controls.
 - Attempt to eliminate the need for pinch strength and minimize the use of excessive grip strength.
Provide palm, wrist, and forearm supports.
 - Provide physical fitness training.
-

Guidelines for Percent of Max Aerobic Capacity in Task Performance		
Duration	Percent Max. Aerobic Capacity	Effort Level
8 hours	33%	Moderate
1 hour	50%	Heavy
20 min	70%	Very Heavy
5 min	85%	Extremely Heavy

FIG. 41.1. Guidelines for maximum aerobic capacity in task performance.

4.3 Cardiovascular

Cardiovascular areas of concern in VE may be an issue any time a user is asked to perform an action that increases the stress level on the heart by a significant margin. This margin is a function of the heart rate over a given amount of time. Figure 41.1 provides guidelines for determining the aerobic effort level in task performance. When designing a task, efforts should be made to minimize the amount of very heavy work. In cases where this cannot be avoided, providing minimal exposure time for heavy and extremely work will reduce the likelihood of operator discomfort and injury.

4.4 Cognitive

Cognitive problems arise when there is either information overload or under load during information processing. This area of VE design is covered elsewhere in this volume (see chap. 20).

4.5 Psychomotor

Psychomotor problems include those conditions that require recognition, detection, and response to stimuli with a physical movement or a reply. Although recent technology has

reduced lag time in VEs, the impact of temporal differences and perceptual lag on operator performance is an area of ergonomic consideration. Performance, user health, and acceptance of virtual technology may be at risk given the lags in current VE systems (Wilson, 1997). One of these temporal constraints includes the time lag in updating systems from a visual perspective, registering frame rate update. Richard et al. (1996) demonstrated that frame rate can have an impact on operator performance in virtual worlds. Additional temporal constraints include delay in tracking the body position or movement. Such delays could impede psychomotor performance and may be why users often experience difficulty when first trying to move about and manipulate objects in a virtual environment (Lampton et al., 1995). Thus, VE system designers cannot expect effective psychomotor performance until such technological issues are resolved.

5. APPLICATION OF ERGONOMICS IN VE SYSTEM DESIGN

This section provides an overview of the physical ergonomic issues to be considered in the design and use of VE technology. When considering the virtual environment, there are three broad, potentially overlapping categories of tools and interaction. These categories are sensors, effectors, and input devices:

- Sensors are those tools used to sense the behavior of the user, such as the head position tracker used to measure the user's head orientation.
- Effectors are used to stimulate user's senses, such as a miniature video display in a head-mounted display.
- Input devices, such as a mouse, DataGlove or joystick, complete the feedback and sensory loop in the virtual environment.

These three categories broadly categorize VE equipment and will be referenced as the application of ergonomic principles to VE technology is discussed.

5.1 Ergonomic Issues Associated With Sensors

In VEs the necessary feedback on operator status is presented through sensors. Sensors utilized in VE technology have been in the form of body suits, hand tracers, head-mounted tracers, and a host of other feedback mechanisms. These sensors detect motion and allow the system to respond with knowledge of the operator's physical state and create the illusion of presence (see chap. 40, this volume) in the virtual world. Effective application of ergonomic technology can enhance the quality of sensory information and operator comfort. The techniques for obtaining sensory feedback should not overload any sensory mode, but should instead be designed to best utilize human senses while promoting the greatest likelihood for perception and response to stimuli.

The primary means of providing sensory feedback in occupational and virtual environments are vision, audition, and tactation (i.e., touch). Some research is being done in the use of olfaction, and this can certainly be used to facilitate a more realistic environment. However, the three senses for which ergonomics consideration will be discussed include visual, auditory, and tactile.

5.1.1 *Ergonomics of the Visual Field*

Although other researchers have studied the aspects of design and presentation of visual information in virtual environments (see chaps. 3, 12, and 20, this volume), a few ergonomic factors are worth highlighting. When considering a user's response in a VE, the following should be noted given that the area measured in degrees can be seen by both fixated eyes:

- Horizontal: In the center, each eye is occluded by the nose. To the sides each eye can see a bit over 90 degrees.
- But color can only be seen about 65 degrees out; the farther you go to the periphery, shades of gray dominate.
- Upward: The visual field extends about 55 degrees and is limited by the eyelids.
- Color can be seen only to about 30 degrees upward.
- Downward: Vision is limited by the cheek at about 70 degrees.
- Color vision degradation begins at about 40 degrees.

For more in-depth review of the visual considerations in equipment development, see Kroemer, Kroemer, and Kroemer-Elbert (2000).

5.1.2 Ergonomics of the Auditory Field

To create systems that are realistic it is important to utilize, at a minimum, the visual and auditory senses. An abundance of knowledge is available and has been applied to audible issues in VE system design. The primary considerations from an ergonomic perspective would be to follow accepted occupational guidelines and use sound to add meaning to system operation. From the safety standpoint, the introduction of high levels of noise begins to be detrimental when it exceeds 90 dB(A). Guidelines for limits on exposure to noise level are shown in Table 41.6.

Thus, if the desire is to create a virtual world with noise levels comparable to an actual environment, caution should be used in the exposure of operators to db(A) levels that could produce damage.

5.1.3 Ergonomics of Tactation

The primary tactile sensors include the following:

- Mechanoreceptors, which sense tactation, i.e., contact touch, pressure
- Thermoreceptors, which sense warmth or cold relative to each other and the body's neutral temperature
- Noci-receptors, which sense pain including sharp pain, dull pain, etc.
- Electroreceptors, which respond to electrical stimulation of the skin

Depending on the type of training, all of these tactile sensory types could be used in VE system designs. Mechanoreceptors and thermoreceptors could be extremely useful in creating realism.

TABLE 41.6
Limits for Noise Exposure

<i>Duration of Exposure</i>	<i>dB(A)</i>
8 hours	90
6 hours	92
3 hours	97
90 minutes	102
30 minutes	110

Electroreceptors could be used to stimulate the vestibular system and thus create a sense of motion (see chap. 7, this volume), whereas noci-receptors could be used in military trainers that need to train pain tolerance. Clearly, however, the latter two should be avoided unless they are an explicit element of the system design.

When using mechano-receptors and thermoreceptors, efforts should be made to minimize the amount of exposure to pressure and ensure the operator does not experience thermal discomfort. To understand the impact that mechanical or load limits may be placing on body parts, a biomechanical analysis may be performed. Such analyses calculate external and internal forces as a function of load mass, joint angle, and body movement. Section 5.2.2 provides a discussion of the necessary elements for performing a biomechanical analysis.

Understanding the thermal conditions that lead to body comfort is important in creating a realistic environment. The human body has a complex control system for maintaining deep-body-core temperature very close to 37°C (about 99°F). Designers of VE systems, and the rooms that they are situated in, should be aware that thermal conditions and body comfort are a function of four physical factors: air (or water) temperature, humidity, air (or water) movement, and the temperature of surfaces that exchange energy by radiation. Additionally, level of physical exertion can influence an operator's comfort level.

Virtual environment system designs that use thermoreceptors should maintain a comfortable environmental temperature. In order to assess the comfort level associated with an environment, two approaches can be utilized: Wet-Bulb Globe Temperature (WBGT) and subjective measures of thermal comfort. The WBGT index is generated by an instrument with three sensors, whose readings are automatically weighted and then combined (Kroemer et al., 2000). In this calculation, the combined effects of climate parameters are weighted as follows:

$$\text{Outdoors: } \text{WBGT} = 0.7\text{WB} + 0.2\text{GT} + 0.1\text{DB}$$

$$\text{Indoors: } \text{WBGT} = 0.7\text{WB} + 0.3\text{GT}$$

Where WB is the wet-bulb temperature of a sensor in a wet wick exposed to a natural air current, GT is the globe temperature at the center of a black sphere 15 cm in diameter, and DB is the dry-bulb temperature measured while the thermometer is shielded from radiation. The WBGT is often used to assess the effects of warm or high climates, but it is important to understand the metabolic rate of the operator when applying guidelines for safe WBGT temperatures. Table 41.7 shows the "safe" WBGT values given a particular metabolic rate.

In the absence of WBGT measuring equipment, subjective assessments can be performed. Two of the most common scales for assessing subjective thermal comfort include the Bedford Scale and the American Society of Heating, Refrigeration and Air conditioning Engineers (ASHRAE; Kroemer, Kroemer & Kroemer-Elbert, 1997). Each of these scales is shown in Table 41.8. To apply these scales, the operator must be queried during varying levels of task performance for thermal comfort. Prior to the analysis, the operator is to be provided with the linguistic term and corresponding numeric rating. For simplicity sake, the rating scale should be posted in view of the operator during task performance or provided at each query. At specific times during task performance, the operator is asked, "What number best describes your thermal comfort?" This information is then recorded. Efforts should be made to minimize the amount of time that operators spend at the extremes of these scales as this can inhibit successful task performance.

TABLE 41.7
Safe WBGT Values*

<i>Metabolic Rate (M)</i> in Watts	<i>“Safe” WBGT (°C)</i>	
	<i>Person Acclimatized to Heat</i>	<i>Person Not Acclimatized to Heat</i>
$M \leq 117$	33	32
$117 < M \leq 234$	30	29
$234 < M \leq 360$	28	26
$360 < M \leq 468$	No air movement: 25 With air movement: 26	No air movement: 22 With air movement: 23
$M > 468$	No air movement: 23 With air movement: 25	No air movement: 18 With air movement: 20

TABLE 41.8
Scales for Assessing Subjective Thermal Comfort

<i>Bedford</i>	<i>ASHRAE</i>		
Much too warm	7	Hot	+3
Too warm	6	Warm	+2
Comfortably warm	5	Slightly warm	+1
Comfortable	4	Neutral	0
Comfortably cool	3	Slightly cool	-1
Too cool	2	Cool	-2
Much too cool	1	Cold	-3

5.2 Ergonomic Issues Associated With Effectors

When considering effectors such as HMDs, virtual caves, and augmented displays, a number of physical ergonomic considerations from anthropometric, biomechanical, and musculoskeletal perspectives must be considered. For example, the weight of any type of system for which the body is required to bear the load is important, as well the impact that the load produces on the musculoskeletal system and biomechanical abilities. The degree of impact will largely depend on the duration of task performance and characteristics of the load. The following areas are of particular ergonomic concern with respect to effectors:

- Anthropometric issues
- Biomechanical issues
- Musculoskeletal issues

Each of these areas is discussed in detail below.

5.2.1 Anthropometric Issues Associated With Effectors

When designing effectors it is important to design for the appropriate population. Such considerations include age (e.g., youth, adults, senior citizens), gender, physical abilities (e.g., handicapped issues), and the region of the body that will interface with the effector. As aforementioned, if an HMD is being designed, several linear dimensions of the head should be considered. Additional rotational anthropometric dimensions should be considered such as range of vertical and horizontal motion for the head, neck, torso, and limbs. Understanding and applying comprehensive knowledge of these anthropometric issues will result in more comfort and usability for VE systems. Anthropometric guidelines can be found in *Body Space: Anthropometry, Ergonomics and the Design of Work* (Pheasant, 1997).

5.2.2 Biomechanical Issues Associated With Effectors

From a biomechanical standpoint, effectors should be designed such that they are consistent with the natural movements of the body and do not cause excessive strain. Specific issues include designing the weight and distribution of loads in effectors so that they do not introduce inappropriate loads on the body. For example, an HMD should be designed so that it does not produce an inappropriate strain on the neck or head. The load should be distributed so that the head, neck, and upper body appropriately manage it. For VE systems design, a biomechanical analysis (see Chaffin, 1999) should be performed for the region of the body that utilizes the effector. This analysis will reveal the external and internal loads being placed on the joints. This analysis should be done for static conditions at a minimum and dynamic loading when the operator is required to move throughout the virtual environment. To perform a biomechanical analysis treating the body as a system of links, the following information is required:

- Mass of loads being handled
- Estimated weight of segments
- Segment lengths
- Joint angles

In the absence of specific segment weights, these values can be estimated using equations for estimating segment mass from total body weight (see Kroemer et al., 1997). After these values are determined for a given environment, the biomechanics analysis can be conducted. The basic steps for conducting a biomechanical analysis using the multisegment static model analysis includes the following:

- Treat each segment as a separate link in a kinetic chain.
- Start the analysis at the point of application of external loads (usually hands).
- Calculate forces and moments acting in opposing directions for adjacent segments.
- Proceed in sequence, solving equilibrium equations for each succeeding body segment.
- Continue until you reach the segment that supports the body (usually the feet).

This analysis will provide forces and moments acting on the joints and other specific locations (i.e., lower back). For additional details on static and dynamic biomechanical analysis, see Chaffin (1999).

5.2.3 Musculoskeletal Issues Associated With Effectors

Effective application of musculoskeletal concerns in effectors design should reduce the demands on the musculoskeletal system by minimizing repetition, force, and awkward posture

in effector use. In the design of effectors, an analysis of the regions of the body interfacing with the system should be performed in order to understand the impact of potential strain associated with the musculoskeletal system. Musculoskeletal issues and injuries to avoid with effectors and input devices are discussed in section 5.4.

5.3 Ergonomic Issues Associated With Input Devices

Users have many input device options to help them navigate throughout a virtual environment. Some of these devices include but are not limited to a mouse, DataGlove, or auditory commands. Similar to computer games, the traditional mouse is often used to allow users to traverse through virtual environments. The use of the mouse is therefore a positive tool to employ because most users are familiar with this equipment and have used it before. The DataGlove is a less familiar type of input device for most users, but may be familiar to video games players. Auditory commands are less frequently used as input mechanisms due to the reliability of voice command software. The defense industry is conducting research with such devices.

5.3.1 *Musculoskeletal Issues Associated With Input Devices*

During continual use of an input device such as a mouse or DataGlove, there will be an increased risk of upper-extremity musculoskeletal consequences. This increased risk is due to repetition and awkward joint postures required for maneuvering and manipulation. When designing a VE system using input devices, an analysis should be done to rate risk of cumulative trauma disorders (McCauley-Bell & Badiru, 1996a). In cases where extensive hand manipulation is required, systems should be designed to allow distribution of load over both limbs. Additional task issues in the design of VE systems and the injuries that can result are presented in section 5.4

5.4 Upper Extremity Musculoskeletal Risks for Effectors and Input Devices in VE Systems

Although there has not been an extreme prevalence of musculoskeletal disorders associated with the use of VE systems, it is important to be aware of risk factors and the types of injuries that can result. Some of the primary work related musculoskeletal disorders experienced in American industry are discussed in the following sections.

5.4.1 *Carpal Tunnel Syndrome (CTS)*

Perhaps the most widely recognized cumulative trauma disorders (CTD) of the hand and forearm region is CTS, a condition whereby the median nerve is compressed when passing through the bony carpal tunnel. The carpal tunnel is comprised of eight carpal bones at the wrist, arranged in two transverse rows of four bones each. The tendons of the forearm muscles pass through this canal to enter the hand and are held down on the anterior side by fascia called flexor and extensor retinacula, tight bands of tissue that protect and restrain the tendons as they pass from the forearm into the hand. If these transverse bands of fascia were not present, the tendons would protrude when the hand is flexed or extended. The early stages of CTS result when there is a decrease in the effective cross section of the tunnel. Subsequently, the median nerve, which accompanies the tendons through the carpal tunnel, is compressed and the resulting condition is CTS.

Early symptoms of CTS include numbness or tingling and burning sensations in the fingers. More advanced problems involve pain, wasting of the muscles at the base of the thumb, dry or shiny palms, and clumsiness. Many symptoms first occur at night and may be confined to

a specific part of the hand. If left untreated, the pain may radiate to the elbows and shoulders, causing complications such as tendonitis. Tendonitis, inflammation of tendon sheaths around a joint, is generally characterized by local tenderness at the point of inflammation and severe pain on movement of the affected joint. Tendonitis can result from trauma or excessive use of a joint and can afflict the wrist, elbow (where it is often referred to as tennis elbow), and shoulder joints.

It is important for VE system designers to understand the risk factors for CTDs, such as CTS, so that they can be minimized in their designs. In general, CTD injuries primarily affect soft tissues, including the muscles, tendons, tendon sheaths, joint surfaces, and nerves. CTDs have been referred to as repetitive motion injuries, overuse syndrome, and a host of other names that tend to imply excessive use of an area. The primary risk factors for CTDs include:

- Extensive and continuous force exertion
- Frequency or extreme repetition by a specific muscle group
- Awkward joint posture (especially awkward postures of the wrist, elbow or shoulder joints)
- Vibration (including low-frequency-vibration hand tools)
- Excessive grip or pinch strength (5 times grip)
- Extreme temperature (hot or cold extremes)
- Long work shifts without work breaks (work shifts exceeding 8 hours)

Although these risk factors are specific to the occupational environment, they have applicability in the design of VE systems, especially as they become more commonly used in training and occupational settings.

5.4.2 Tenosynovitis

Tenosynovitis is a repetition-induced tendon injury that involves the synovial sheath. The most widely recognized tenosynovitis is DeQuervain's disease. This disorder affects the tendons on the side of the wrist and at the base of the thumb. Excessive joint deviation, repetition, and twisting are known risk factors. Such postures and movements should be avoided in VE system design.

5.4.3 Intersection Syndrome and DeQuervain's Syndrome

Intersection syndrome and DeQuervain's syndrome occur in hand intensive workplaces. These injuries are characterized by chronic inflammation of the tendons and muscles on the sides of the wrist and the base of the thumb. Symptoms of these conditions include pain, tingling, swelling, numbness, and discomfort when moving the thumb. Design of end effectors should minimize the intensity of hand-related work.

5.4.4 Trigger Finger

If the tendon sheath of a finger is aggravated, swelling may occur. If the swelling is sufficient it may result in the tendon becoming locked in the sheath. At this point, if the person attempts to move his or her finger, the result is a snapping and jerking movement. This condition is called trigger finger. Trigger finger occurs to individual fingers and results when the swelling produces a thickening on the tendon that catches as it runs in and out of the sheath. Usually, snapping and clicking in the finger occurs with this disorder. These clicks occur when one bends or straightens the fingers (or thumb). Occasionally, a digit will lock either fully bent or straightened. This condition can result from overuse of a particular digit (pointer finger used to activate a trigger on a tool), and thus, VE system design should eliminate this type of risk.

5.4.5 Ischemia

Ischemia is a condition that occurs when blood supply to a tissue is lacking. Symptoms of this disorder include numbness, tingling, and fatigue depending on the degree of ischemia or blockage of peripheral blood vessels. A common cause of ischemia is compressive force in the palm of the hand. Thus, in design of end effectors, every effort should be made to reduce or eliminate the application of forces with the palm of the hand.

5.4.6 Vibration Syndrome

Vibration syndrome is often referred to as white finger, dead finger, or Raynaud's phenomenon. Excessive exposure to vibrating forces and cold temperature may lead to the development of this disorder, and thus these should be avoided in VE system design. This syndrome is characterized by recurrent episodes of finger blanching due to complete closure of the digital arteries. Thermoregulation of fingers during prolonged exposure to cold is inhibited by this condition.

5.4.7 Ganglion Cysts

Ganglion is a Greek word meaning “a knot of tissue.” Ganglion cysts are balloonlike sacs that are filled with a jellylike material. These maladies are often seen in and around tendons, in the palm of the hand, and at the base of the finger. These cysts usually occur as a result of excessive pushing, pressing, turning, or inserting motion, or as a result of forceful hand wringing. Such activity should be avoided in VE system design.

5.5 Prevention of Risks

In order to reduce risk of the previously described musculoskeletal disorders, the following considerations should be applied in design and use of VE systems.

1. Reduce repetition by increasing cycle time.
2. Minimize the amount of time for performance of a task with known risks factors in a virtual environment.
3. Provide rest breaks.
4. Design and purchase input devices that meet ergonomic guidelines.
5. Minimize the amount of force required for activation of tools or controls.
6. Attempt to eliminate the need for pinch strength and minimize the use of excessive grip strength.

As more VE applications are developed, it is important to incorporate ergonomic design considerations that reduce musculoskeletal disorders. This will minimize the extensive cost and injuries associated with many occupational environments.

6. CONCLUSIONS

Ergonomic factors to consider in VE system design can be captured through the use of ergonomic checklists. An abbreviated list, summarizing many of the ergonomic concerns reviewed in this chapter, which can be used to determine potential problems for VE system design, is presented in Table 41.9 below.

As a general reference, the International Standards Organization (ISO 9241, see <http://www.iso.ch/welcome.html>) provides standards that can be used to assess many of the ergonomic

TABLE 41.9
Ergonomic Checklist in VE System Design

1. Do sensors inhibit operator movement?
 2. Is any limb overburdened?
 3. Does task require extended latter or forward reaches beyond normal reach?
 4. Do seating conditions meet ergonomic considerations for back support?
 5. Are dials and controls easy to view and understand?
 6. Is task more than 50% repetitive?
 7. Is task performance required for more than 50% of work shift?
 8. Does layout lead to efficient motions?
 9. Are awkward postures required?
 10. Is static loading required for task performance?
 11. Is excessive force required?
 12. Is twisting and lifting required?
 13. Is forceful exertion required at awkward postures?
 14. Is noise level within ergonomic guidelines?
 15. Is sound level within ergonomic guidelines?
-

concerns of a VE system design discussed in this chapter. This standard provides design guidelines for task design, hardware and environmental factors, and software and usability concerns that could be used to guide effective ergonomic design of VE systems.

1. INTRODUCTION

Ever since the 1970s—for many the “dawn of technological proliferation”—researchers and developers the world over have taken measures to ensure that their particular field of endeavor stays very much away from the category of “a solution looking for a problem.” Very few of these measures were actually successful. The early personal computers (PCs), image processors and robots, not to mention artificial intelligence systems, speech recognition devices, and neural networks all failed to gain real-world exposure and, thus, the early application credibility they truly deserved.

For some time, the pioneers of virtual environment (VE) technologies faced similar problems. The formative U.S. attempts in the early to mid-1980s to develop immersive VE for the purposes of enhancing cockpit situational awareness (e.g., Harvey, 1987) or for astronaut training and space telepresence (e.g., Fisher et al., 1988) progressed reasonably unscathed. However, elsewhere, pioneers faced obscurity in the wake of the meteoric rise in the late 1980s and early 1990s of the immersive entertainment industry. This sector alone did more than its fair share of damage to the attempts of small, innovative companies to develop credible application demonstrators in an attempt to persuade industrialists of the power and benefits of VE and to introduce the technology into wider mainstream commercial applications. Even today, the situation is far from satisfactory, although the VE community now has an extremely exciting story to tell, as evidenced by the many applications reviewed in this chapter.

2. APPLICATIONS OVERVIEW

On Wednesday, May 8, 1991, at a hearing of the U.S. Subcommittee on Science, Technology and Space, a special session opened called New Developments in Computer Technology—Virtual

Reality. Part of Al Gore's (now famous—at least in VE circles) introductory message is reproduced below:

In the case of virtual reality [VR], . . . [recognizing and exploiting new opportunities] means providing the necessary funding for technology development, not just for military applications, but for civilian applications, like education, research, and advanced manufacturing. So far, we do not seem to be doing very well. We have small, \$1-million, \$2-million programs scattered throughout the federal government. These programs helped create virtual reality, but they are not doing very well in applying it.

—Senator Al Gore (May 1991)

Despite this gloomy early outlook, the VE community can be consoled somewhat by the fact that, uniquely, a considerable amount of first class groundwork was conducted in the early-to-mid 1990s by small innovative companies (principally in the United States and United Kingdom). Groundwork that includes projects conducted with large blue-chip or national organizations in the defense, aerospace, petrochemical, and automotive markets, producing impressive engineering demonstrations and technical/commercial results of relevance to supply chains or other related sectors. In 1993 in the United Kingdom, for example, the author's team successfully launched an industrially sponsored VE initiative called VRS (Virtual Reality and Simulation; Stone, 1996), designed to deliver applications to some 20 participating industrial sponsors, each demonstrating the potential impact of VE on their commercial and technical business practices. Groundwork included efforts on a smaller scale, such as feasibility studies with institutions dedicated to demonstrating the power of VE in communicating with and educating the general public. Just a very small sample of applications spanning these and other areas will be presented in this chapter. To set the scene:

... the research results provide clear evidence that VR technology and implementation expertise have advanced sufficiently for a wide range of commercial applications to be possible, some of which seem now to be showing the prospect of substantial business benefits.

—Cydata (1998, p. 1)

There is unmistakable evidence that VR awareness, interest and activity levels in the UK have all increased significantly during the past two years. In some sectors, VR is moving into a well-accepted mainstream role; in others, it is still being driven forward by the efforts of product champions.

—Cydata (2000, p. 14)

2.1 Engineering

The ability to convert otherwise geometrically intensive CAD data into visually acceptable, real-time interactive models capable of forming a credible input to the business process of engineering companies is a feature of VE that is now well established. Endowing those models with behavioral capabilities extracted from associated engineering databases or complex simulation code is also becoming an accepted and proven process. The applications covered by the term "engineering" are, of course, many and varied (see Fig. 42.1) and cover heavy engineering sectors of petrochemical and hydroelectric plant design or construction sites in general, to the ergonomic and aesthetic evaluation of automobile and civil aircraft interiors, from the verification of maintenance strategies for aircraft engines to the prototyping of nuclear control rooms.

One internationally active group in the petrochemical plant arena has been pushing VE technology to its limits. Fluor Corporation is one of the world's largest publicly owned consulting, engineering, and construction companies. Founded nearly 100 ago, the company now

FIG. 42.1. Example of a VE for “heavy engineering”. Image courtesy Virtual Presence.

operates in more than 50 countries worldwide and employs 50,000 staff. The corporation’s work includes the construction of major manufacturing facilities for companies such as Pepsi, BMW, and ICI, the design of refineries for, among others, Shell and Chevron, the development of gold mines, the building and maintenance of power stations, and major works for world leading pharmaceutical organizations.

After nearly 6 years of involvement in VE, Fluor has established a number of in-house VE prototyping systems in the United Kingdom, the Netherlands, and on the West Coast of the United States. Their decision to proceed with integrating VE into their business practice was taken after a number of quite intensive trials of the technology, assessing its potential impact in such processes as:

- **“Instant” Change**, whereby the virtual plant models could be modified efficiently during run-time by moving objects, resizing, altering valve locations, and so on.
- **Operator Training**, displaying plant walkways, access/egress routes, vessel interiors, vessel shutdown and access procedures, and potential hazard areas.
- **“Touch-and-Tell”** component tagging, whereby objects in the VE could be interrogated simply by touching the object with the virtual hand or cursor. Once touched, data such as item name, main plant item number, manufacturer, and so on would appear in a separate window.
- **Line and System Tracing**, highlighting (through simple touch-and-tell action, as above) a line or system route so that its path can be traced through the plant.
- **Automatic Virtual Pipe Route Production**, in a similar vein to line tracing, although generating the route data in the VE automatically from early isometric drawings and engineering tables.
- **Constructability**, demonstrating, by means of a virtual crane system, the power of VE as a tool for aiding constructors’ and contractors’ decisions in, for instance, judging the accessibility of a given area or volume during major vessel installations.

- **Internals Installation and Removal**, allowing maintenance technicians to visualize and rehearse work before entering the real vessel, for example.
- **Collaborative Working**, allowing engineers immersed within a shared virtual world to repair or maintain plant equipment cooperatively.

2.2 Micro- and Nano-technology

Among the earliest reported applications of VE to the field of microtechnology and molecular modeling were the scanning tunneling microscopy (STM) demonstrations staged by the United Kingdom's National Advanced Robotics Research Center (ARRC; *VR News*, November, 1992) and the GROPE IIIb Project of the University of North Carolina (UNC; e.g., Brooks, 1988; Brooks, ouh-young, Batter, & kilpatrick, 1990). The United Kingdom's ARRC VE program was the first to demonstrate the power of allowing scientists to visualize and explore the atomic surfaces of Angstrom-sized material samples through the direct linking of an STM with a powerful (then transputer-based) real-time VE graphics engine. GROPE demonstrated haptic interaction (see chaps. 5 and 6, this volume) with electrostatic molecule-substrate force simulations and nano-scale surfaces (generated from STM data). Early work at UNC utilized an Argonne Remote Manipulator (ARM) master, one of two donated from the Argonne National Laboratory, and a large field sequential display system.

Today, developments in micro- and nano-technologies are proceeding at a considerable pace, with much talk about the future of miniature robotic systems capable of performing surgery or other minimally invasive therapy (see chap. 48, this volume). Indeed, this provides for a perfect applications opportunity for future VE developers and links the field's historical pedigree—the early space telepresence work, for instance—with the design, manufacture, operation, and training requirements of today. As NASA, the United Kingdom's ARRC, and related establishments adopted a human-centered approach to the use of VE to control macro-scale robots for hazardous environments, future microrobots and even nanobots—such as the DNA “screw-driver” (Mao et al., 1999), designed for deployment within the human body—will need strict supervision by skilled operators, equipped with advanced VE equipment. Already one German company, MicroTEC GmbH, has demonstrated a micro-submarine (at EXPO 2000, Hannover), 4 mm long and 450 μm in diameter, powered by induction and using a tiny magnet integrated within the screw (www.microtec-d.com/; see Fig. 42.2). The company is developing new forms of motive power that avoid the use of the conventional screw or propeller concept. Miniature cameras are being deployed regularly for a variety of preoperative investigations, and one

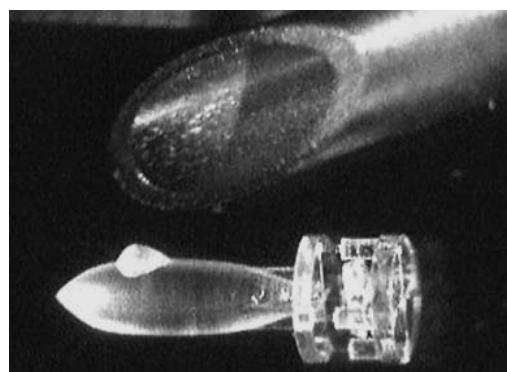

FIG. 42.2. MicroTEC's miniature submarine. Copyright micro TEC Gesellschaft für Mikrotechnologie mbH, Germany.

cannot ignore the European and U.S. developments in micro-lasers and micro-manipulators, such as Intuitive Surgical's da Vinci system (www.intusurg.com), all of which suggest a near-term revolution in the medical instrument fraternity (see chap. 47, this volume).

2.3 Aero and Space Engineering

Of the main engineering applications currently driving development and marketing efforts within VE companies, the aerospace sector probably ranks a close second to petrochemical and automotive and is on a par with naval and general defense developments. There are a number of "big-name" companies steering efforts in this field and, importantly, contributing to the development of VE products, many of which are still unable to service the complete organizational needs of the aerospace community, namely:

- Training (for maintenance, in particular, with future aspirations for collaborative training using networked VE)
- Prototyping (providing a VE interface for CAD design assessments and ergonomics; replacement of physical prototypes)
- Assembly planning and factory automation
- Engine and superstructure design and assessment (e.g., computational fluid dynamics data visualization, as with the NASA wind tunnel project)
- Marketing (interior cabin and cockpit designs; furnishings)

In 1992, Rolls-Royce (Aerospace, U.K.) conducted a short feasibility study to evaluate the role of VE in the future business of aero engine design, maintenance evaluation, and advanced training. At the outset, the project focused commercially on how VE technologies and design practices might be used to replace costly 1:1 scale physical preassemblies (PPAs). Working in tandem with the company's substantial investment in digital preassembly (DPA—Computervision CADDSS4/5X), the first engineering application of VE was demonstrated and televised across the United Kingdom early in 1993, using the Rolls-Royce Trent 800 engine geometry. This interactive visualization was made possible by an early British parallel processing (transputer-based) computer developed by Division (now part of PTC), although one year later, real-time interaction using stereoscopic head-mounted displays (HMDs) and image projectors was demonstrated with more complex converted CADDSS5X data hosted under Silicon Graphics' RealityEngine architecture.

By the spring of 1994, the virtual Trent 800 model had reached a stage whereby usability trials (see chap. 34, this volume) could be carried out (see Fig. 42.3). Potential future users from Rolls-Royce were employed as study participants and were equipped with a variety of HMDs, interactive gloves, and hand controllers. The participants were immersed in an environment that enabled them to move around and manipulate the virtual Trent geometry in a meaningful and credible fashion. Simple virtual tools were implemented, which allowed users to release bolt and bracket fittings and, with haptic (force/touch) feedback technologies in a very rudimentary state of development at that time, special visual cues were developed to assist the participants' perception of collisions between engine components.

Boeing has had an involvement with VE since 1990, the technology being a subset of the company's simulation-based design efforts. The Virtual Environments Group (Boeing Research and Technology) originally used VE for design visualization and evaluation, using a combination of CATIA with their own three-dimensional (3-D) rendering software (FlyThru). Early on, they recognized that this system (which was similar to Computervision's CADDSS5/5X and PVS, or Dassault's 4D Navigation package) did not provide designers with the capability to look freely around the designs, nor did it enable the manipulation of objects. Since then,

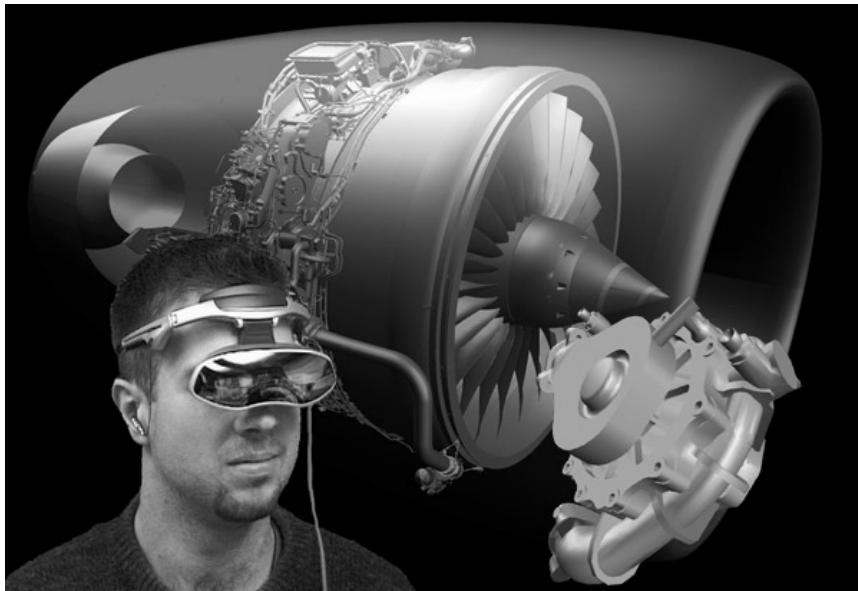

FIG. 42.3. The virtual Rolls-Royce Trent 800 Engine (1994–1995) with extracted gearbox component. Image courtesy Rolls-Royce plc and Virtual Presence.

Boeing has been evaluating and modifying proprietary VE systems. In one historic survey, the company ran a trial to assess reactions to the Boeing 777 cabin interior using VE and conventional CAD. Individuals who used the two systems manifested markedly different responses to the trials: In the CAD participants reported that they had “seen a CAD representation of the 777 interior”; in VE the report was “I’ve been in the 777 cabin and saw . . .” Other successful cabin interior designs have been reported by Airbus in Europe and Airline Services in the United Kingdom, both organizations having refitted aircraft virtually before committing to procuring real fabric.

More recently, Boeing researchers have been investigating the use of desktop and immersive VE as potential training delivery mechanisms for the Boeing Joint Strike Fighter (Barnett, Helbing, Hancock, Heininger, perrin, 2000). Using the replacement of an aircraft fuel valve as the target maintenance task, they found that immersive VE did not provide effective training. As well as poor depth perception (a common problem with narrow-field-of-view HMDs) and size distortion, participants reported difficulties with the interface itself (such as the manipulation of tools or small components). Barnett et al. (2000, p. 10) go on to state, “As a result of these unique features of the VR, four of the participants commented that *they focused more on interfacing with the VR than with learning the task*” (author’s emphasis). Desktop VE, on the other hand, delivered comparable performance to that recorded using physical mock-ups. This problem of distraction caused by immersive VE interface technologies is not uncommon and requires strict attention when designing the virtual world content for such applications as training.

The European initiative ENHANCE (ENHanced AeroNautical Concurrent Engineering) brings together the main European civilian aeronautical companies and seeks to strengthen co-operation within the European aeronautical industry by developing common working methods that govern the European aeronautical field, defining appropriate standards and supporting concurrent engineering research. One project within ENHANCE concerns an advanced VE maintenance demonstrator that links a basic virtual mannequin with PTC’s DIVISION MockUp virtual prototyping software and Sensable Technologies’ PHANToM haptic feedback system.

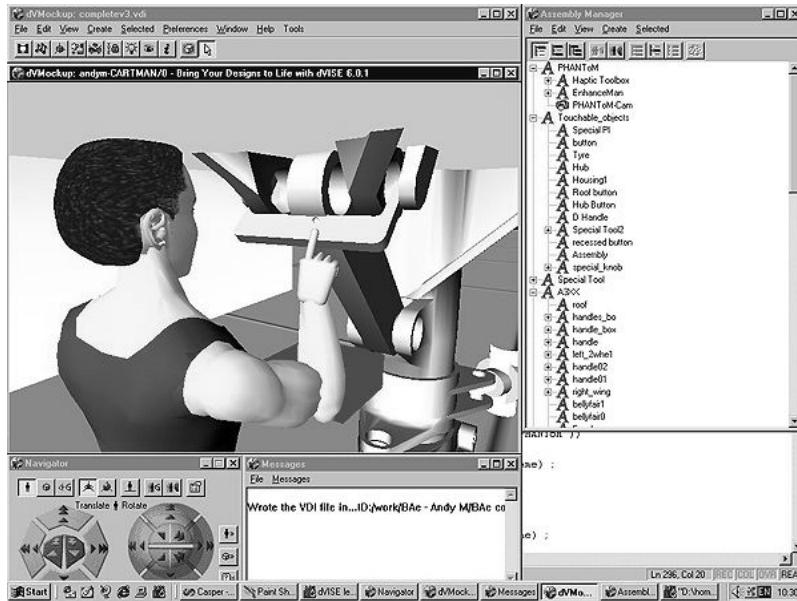

FIG. 42.4. The PTC DIVISION MockUp interface showing the PHANToM-controlled virtual mannequin interacting with an undercarriage safety lever. Image courtesy Virtual Presence.

Based on a 3-D model of a conceptual future large civil airliner, the VE demonstration involved controlling the mannequin during aircraft preparation and safety procedures (see Fig. 42.4), and in gaining access to retracted main landing gear for the purposes of wheel clearance testing.

Certain key interaction events throughout the demonstration were executed using the PHANToM. In order to define these stages clearly and to identify those procedures and events warranting the application of haptic feedback, a context-specific task analysis was carried out, as recommended in the 1999 International Standard ISO 13407 (Human-Centered Design Processes for Interactive Systems).

Turning now to space exploration, the use of VE in the U.S. space community is almost legendary, from the original NASA VIEW system, through the agency's award-winning Virtual Wind Tunnel of the early 1990s, to the use of digital panoramic and Virtual Reality Modeling Language (VRML) techniques to allow thousands to "explore" the July 1997 landing site of the *Mars Pathfinder*. It is also possible to explore the international space station on the Web, either by navigating module-by-module using digital panoramic techniques (i.e., MGI Software's Photovista; <http://spaceflight.nasa.gov/gallery/vtour/index.html>) or downloading files for use with contemporary games engines (e.g., <http://nike.larc.nasa.gov/viss.html>). The use of VE to prepare astronauts for the Hubble Space Telescope repair mission (STS-61) was itself a breakthrough, demonstrating how the technology had become a serious contender in astronaut EVA training, working alongside—and in some cases replacing—more conventional techniques based on physical mock-ups and neutral buoyancy procedures.

Indeed, NASA's history of involvement with VE technologies has served to demonstrate the successes that can be achieved when one pays full attention to the human factors issues associated with VE and associated interface technologies, including the integration of auditory cueing (see chap. 4, this volume), multisensory data representation (see chaps. 14 and 21, this volume), and speech recognition. Nowhere is this philosophy more important than in the training of air traffic controllers and NASA's most recent ATC tower simulator is exemplary in this respect (Fig. 42.5).

FIG. 42.5. NASA air traffic tower simulator. Image credit National Aeronautics and Space Administration.

Turning to Europe, in 1991, the European Space Research Technology Center, ESTEC (based in Noordwijk in the Netherlands), initiated a program of internal and contractual Research and Development to identify the suitability of VE for applications within the European space program. Toward the end of a period of research in which VE was featured in small projects dealing with telerobotics, spacecraft rendezvous, and docking (RVD) and extravehicular activity (EVA), the Simulation and Electrical Facilities Section at ESTEC set up the beginnings of a test bed that, they hoped, would link all the major technologies being developed by European contractors that boasted a simulation component. In 1992, external contracts were let to companies in France and Spain, to develop a generic VE software package and human-computer interaction (HCI), together with a high-resolution (HDTV) head-mounted display. Certainly some of the more recent demonstrations produced internally by ESTEC are quite impressive, particularly one that allows immersed users to explore the internals of the proposed Columbus Pressurized Module (Europe's "contribution" to the international space station) under visually simulated zero gravity, interacting with experimental modules using multisensory interfaces. Scientific visualization (see chap. 53, this volume) is also a key applications area for ESA's VE efforts, with visualization centers being established to deliver satellite remote sensing data to the European Community at large.

Following an early venture supported by the author's U.K. team to construct a desktop VE version of the *Mir* space station (see Fig. 42.6), Russia is also accelerating its adoption of VE in support of cosmonaut training. Despite the failure of VE (to date) to replace completely the full-size space vehicle mock-ups within the Cosmonaut Training Center (at Star City outside Moscow), networked VE workstations and PCs are being used in earnest to display real-time computer-generated orbital imagery, rather than the old practice of transmitting images of

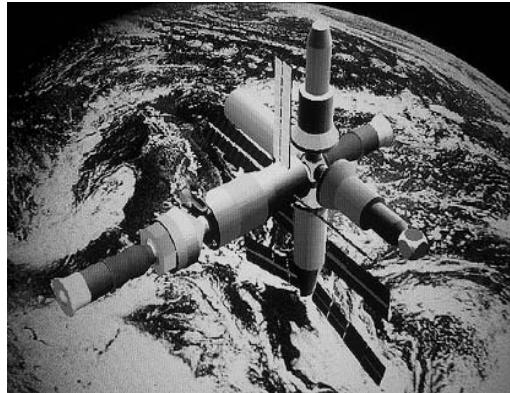

FIG. 42.6. The VE *Mir* space station. Image courtesy ASRDC and Virtual Presence.

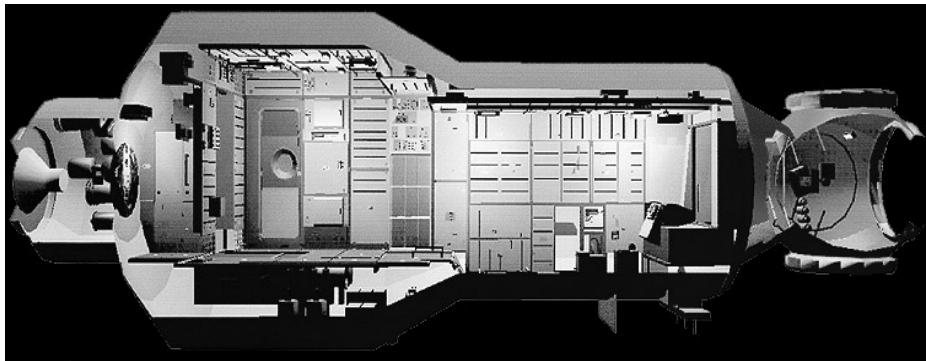

FIG. 42.7. A VE reconstruction of the Russian *Zvezda* space station module. Image courtesy Gagarin Cosmonaut Training Center (Star City).

suspended models of planets and spacecraft via TV screens located outside capsule view ports. Albatross (c. 1992) was Russia's first attempt to develop a single-channel real-time computer graphics imaging system for integration with the motion-base simulator for the *Buran* shuttle. Albatross provided a field of view of 30 degrees by 40 degrees over a simulated terrain area of 400 by 400 kilometers, with a maximum polygon count of 4,000 per scene. Although the system stood little chance of competing with Western graphics workstation developments, Albatross represented the CIS's first steps toward commercializing the many decades of mathematical modeling and simulation work for which they have become renown.

Russia's contribution to the international space station has also been the subject of a VE exercise, although the CTC still employs physical training modules, as currently exist for the *Zarya* control module and the *Zvezda* service module (both of which are in orbit at the time of writing). In cooperation with the Moscow-based Advanced Simulation Research and Development Center (ASRDC), a small group of developers within the CTC have produced a first class real-time training demonstrator of the *Zvezda* module (see Fig. 42.7), again with multiple PCs and a low-end SGI machine on a local area network. They have also been carrying out limited experiments with gestural interaction (see chap. 10, this volume) using a Polhemus Fastrak and Virtual Technologies' CyberGlove.

2.4 Ergonomics/Human Factors

As can be appreciated from the preceding subsections, ergonomics (or human factors) is playing an everincreasing role in engineering VE and simulation (see also Stone, 2001). There has been a marked rise in recent years in the number of commercial human mannequin packages, themselves endowed with anthropometric and biomechanics data, not to mention physiological libraries encompassing energy expenditure, clothing effects, psychomotor parameters, and so on. Not only do these packages provide the VE and human factors practitioner with a cost-effective assessment technique for engineering assessments, they also enable new industrial users of VE to do away with antiquated (and highly inaccurate) forms of “ergonomic” assessment based on toy figures, such as “GI Joe” or “Action Man”. The use of ergonomics knowledge to bring a methodological credibility to many engineering projects based on VE is also growing steadily. Nowhere is this more evident than in the automotive industry where, after many years of experimenting with the technology, it is now accepted that VE in both real-time interaction and offline mannequin modes has a great deal to offer in improving the information interfaces between vehicle designers, simplified, low-cost physical mock-ups (such as seating or cockpit rigs), and end users. This close linkage of technologies with users is becoming increasingly important in a number of related applications areas (and, indeed, a requirement of such standards as ISO 13407).

For example, Fig. 42.8, although based on the Rolls-Royce Trent 800 project example discussed in section 2.3, also describes well the integrated VE–ergonomics approach adopted

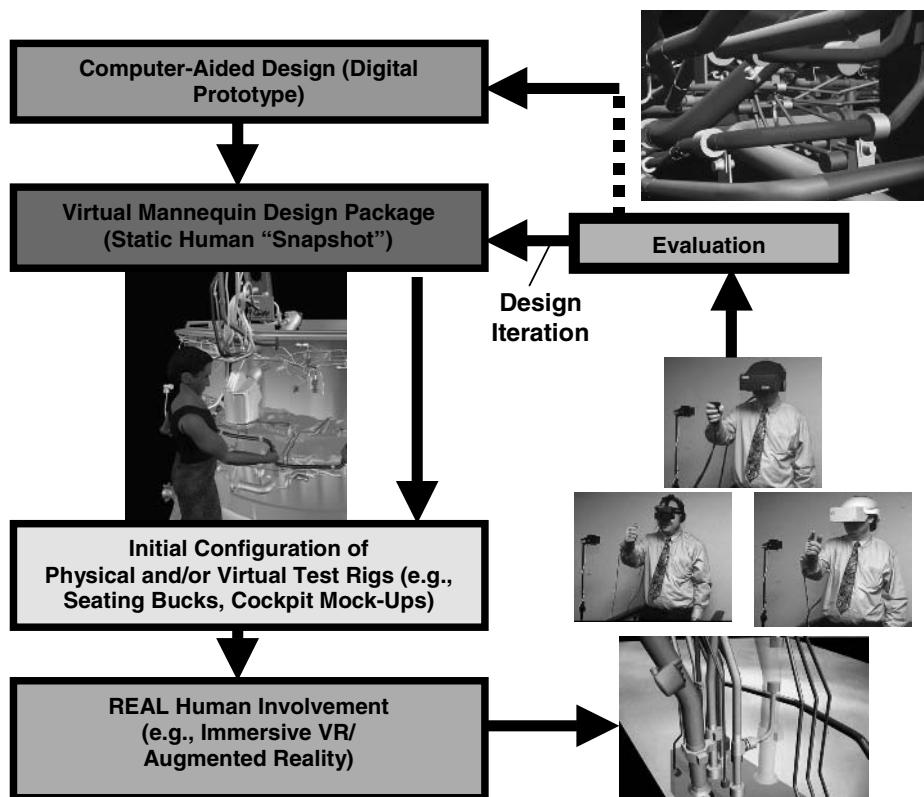

FIG. 42.8. Broad roles of mannequin simulators, physical mock-ups, and VE in the engineering design process. Image courtesy Virtual Presence.

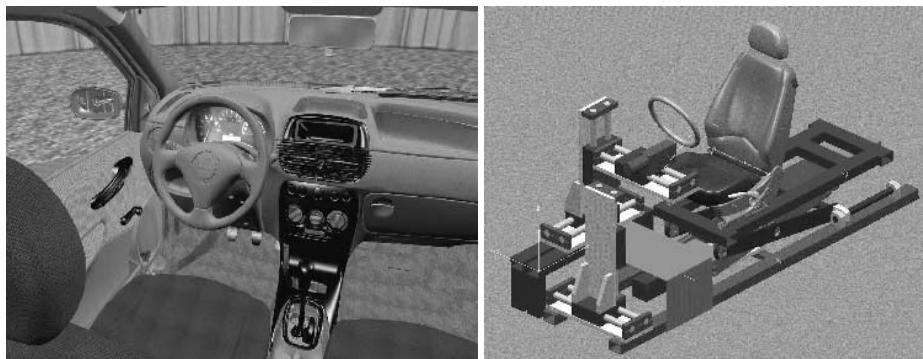

FIG. 42.9. Elasis virtual automobile interior and seat buck design concept. Images courtesy Genaro Monacelli, project manager, Elasis Pomigliano d'Arco.

for automotive design by, for example, the Virtual Reality Center of Elasis Pomigliano d'Arco, a Fiat company in southern Italy (www.elasis.com; see also Fig. 42.9).

2.5 Defense

Defense establishments and military forces across the globe have long been exploiters of VE or “synthetic environments” technology, primarily in large-scale simulators designed for such activities as operations planning, war gaming, command-control-communications and intelligence (C³I) and, of course tri-service pilot, navigator, and driver training (see chaps. 43–44, this volume). However, this has recently extended to part-task activities, such as seen with those military trainers that endow basic CAD or VE models of military platform subsystems with realistic behaviors, thereby enhancing the training of such procedures as maintenance, fault finding, and refit.

The favorable price–performance curve witnessed in recent years has stimulated defense procurement organizations to take a serious look at VE technology. Most have been impressed at the results, especially when compared to the limited and quite costly two-dimensional (2-D) computer-based training (CBT) packages they have been restricted to over the past decade. Virtual environments have been developed to create realistic military environments for such tasks as helicopter machine gun or ship close-range weapons training, parachuting experience, explosive ordnance disposal, naval helicopter deck landing, fire fighting, submarine and surface ship blind piloting, officer of the watch training, and many more. Just a few are detailed in the following subsections (see also chap. 43, this volume).

2.5.1 Airforce Avionics Training

For example, in the United Kingdom, the Avionics Training Facility (ATF) for the RAF's *Tornado* F3 aircraft was installed late in 1999 at the Tornado Maintenance School at RAF Marham in Norfolk. The ATF is based on 10 Windows NT, triple-screen simulators that enable students to explore a virtual *Tornado* and to expose, test, and repair avionics modules (“Line Replaceable Units” or LRUs) using a variety of different items of virtual test equipment (see Fig. 42.10). Only a simple mouse-function key interface is employed.

In the short time that the ATF course has been in place, instructors at Marham have been able to reduce the time taken to complete the course—from 13 weeks using physical aircraft mock-ups to 9 weeks using VE—and the amount of downtime experienced by each student (time wasted as a result of being unable to access course equipment)—from 3 weeks to zero.

FIG. 42.10. The virtual *Tornado*, rendered transparently to show LRUs. Items of virtual test equipment are also shown. Image courtesy Virtual Presence.

Feedback from the Marham trainers suggests that, in contrast to previous courses, ATF students gain enhanced spatial and procedural knowledge relating to avionics tasks nearly 40% faster than previous mock-up or CBT-based exercises.

2.5.2 Close-Range Weaponry Simulation

At the time of this writing, the U.K.'s Royal Navy is also in the process of replacing its shore-based gunnery-training outpost near Plymouth with an advanced 20 mm and 30 mm close-range weapons simulator facility near Portsmouth. The immersive VE solution equips weapon aimers, weapon directors, and course instructors with a blend of head-mounted and screen-based displays, together with virtual binoculars and tracking sensors, to create and interact with a range of target engagement scenarios—from simple sailboats and naval vessels, to drones, aircraft, and sea-skimming missiles—as if operating from a ship-based environment (see Fig. 42.11). This simulator features sea state ambient lighting and weather effects, together with own-ship pitch and roll. OpenGL has been adopted as the graphics standard, in order to deliver consistent image quality and reliable performance under the Windows NT operating system. The system will operate as a network of Windows NT workstations, each providing real-time graphics and multi-processing capabilities. The training program will be a consistent VE shared between workstations, but hosted and controlled by the main instructor consoles in a standard client-server mode.

FIG. 42.11. Early screen shot of a Royal Navy gunnery simulator environment. (Inset is view from 20 mm weapon.) Image courtesy Virtual Presence.

2.5.3 Royal Navy Submarine Qualification

As weapons platforms become more advanced, the inevitable reduction in real systems available for training means that computer-based lessons, many featuring VE, will become an essential tool of the military classroom. Nowhere is this problem more acute than is the case with future submarines. Here, smaller fleets will spend much more time at sea and less time in dock at the disposal of the inexperienced naval rating. The training of future submariners and dockyard support teams, then, is an excellent example where VE can deliver highly cost-effective alternatives to commandeering an otherwise fully operational boat.

A recent project conducted for the U.K. Royal Navy's flag officer submarines (FOSM) was based on the early training and vessel familiarization needs for submariners destined to serve on the United Kingdom's fleet of Trafalgar Class (SSN) boats. The results of the project are currently being given serious consideration for other submarine classes, and future platforms such as Astute and FASM (future attack submarine). Similar interests are being expressed within U.S. naval communities relating to the role of VE in NSSN and future attack sub programs. The overall Royal Navy's requirements for what is referred to as a submarine qualification (SMQ) system relate to the initial provision of a PC-based trainer that will enable students to become familiar with the layout of a target class of boat, including decks, compartments, key items of equipment, main service routes (e.g., high-pressure air), safety equipment, and so on (Stone, 2000).

A series of exercises are being developed which require students to locate and (where necessary) actuate shipboard components. Students can "walk" through the virtual submarine on predefined paths. At any point, they are free to turn, look around, and interact with "active" scene items, as appropriately identified on-screen. On entering a virtual compartment or zone of interest, the student is confronted with a virtual space—textured as necessary. The compartment possesses visually recognizable features—lockers, fire equipment, consoles, ladders, large-bore piping, and unique components (see Fig. 42.12).

For those compartments where additional detail and realism are required, panoramic VE techniques are implemented. Fixed nodes and viewpoints are linked to "higher realism

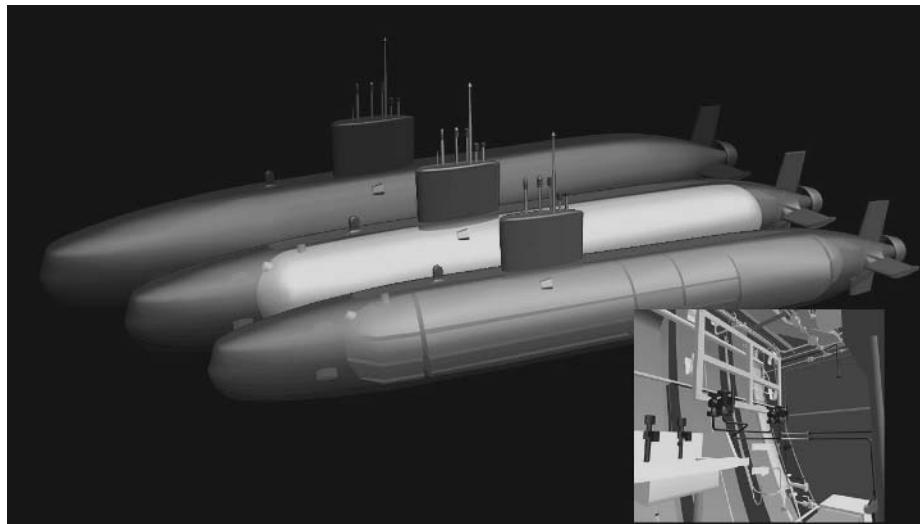

FIG. 42.12. The virtual “core” of the SMQ training system, showing compartment detail level necessary for equipment identification and system tracing. Image courtesy Virtual Presence.

databases,” such that the call-up of active scene items generates static and panoramic images, which match visually with their respective locations within the geometric compartment layout. The actual paths and times taken by students in pursuit of the set tasks are recorded and made available for replay and archiving. Finally, “hot spots” within the panorama are linked to additional 3-D geometric databases (VRML), containing recognizable models of important and safety-critical equipment (e.g., high-pressure blow valves) or digitized textual/video extracts from existing training and informational sources. In the case of the 3-D models, once the hot spot has been interrogated (simple mouse click), the VRML object appears, with textured features and labels (where relevant to the identification and operational part of the SMQ task). The student is then able to initiate any animated or interactive features to demonstrate operation and, in the case where the operation of safety equipment can originate from elsewhere in the submarine (e.g., operations compartment), warning displays are also presented.

In the aftermath of the 2000 *Kursk* Russian submarine tragedy, VE is now being seriously considered in the design process and for future training régimes for the new NATO submarine rescue system (NSRS; initial study launched in 2001). Such study is designed to address a wide range of mature subsea technologies capable of producing a submersible system to replace the rescue boats of individual nations, some of which are over 20 years old. It is believed that, by using VE in the NSRS training program, the number of “wet” training dives a trainee pilot has to undertake can be cut from five to three, or possibly two. The cost of two wet dives would actually pay for a VE system. The development of such a system (see Fig. 42.13) in parallel with the general training requirements already in place for future U.K. submarines marks the beginning of the first major integrated naval application based on VE technologies.

2.5.4 VESUB

One of the important and widely referenced VE projects to emerge from the United States is known as the VESUB (Virtual Environment for SUBmarine Officer of the Deck ship handling training) technology demonstrator (VESUB, 1998), and was conducted at the U.S. Submarine Training Facility in Norfolk, Virginia, Naval Submarine School in Groton, and Naval Air

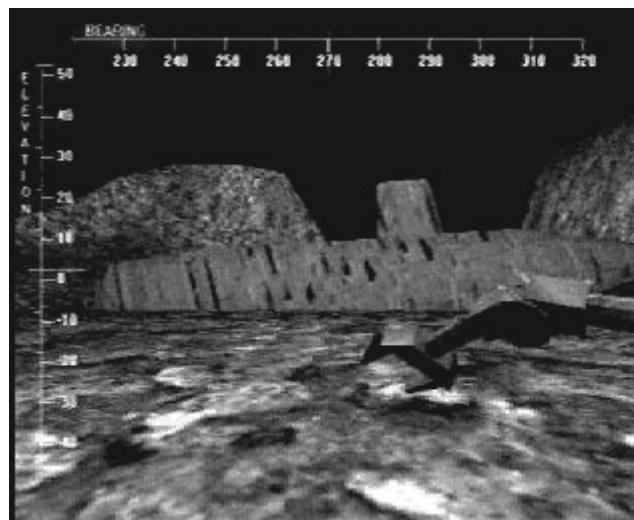

FIG. 42.13. An early immersive VE distressed submarine intervention demonstrator. Image courtesy Virtual Presence.

Warfare Center Training Systems Division in Orlando, Florida (see chap. 43, this volume). Unlike many of the CBT systems in existence today, VESUB was based on immersive VE technology, using proprietary HMDs (initially the Virtual Research VR4, later n-Vision's high-resolution DataVisor), speech recognition, and a Silicon Graphics Infinite Reality Engine computing platform. Indeed, it is interesting to note that a conscious decision was taken to move away from large-screen projection technologies and more toward an HMD implementation. The immersive facilities were used to create VE views as if the user were located on the fin of a typical U.S. submarine. Some 41 VESUB users were used in study trials, all naval personnel (involved with submarines) ranging in experience from junior officers to qualified officers of the deck and commanding officers. The participants were exposed to three scenarios in the VESUB system:

- An orientation scenario to help them become familiar with the capabilities and operation of the VE system
- A training scenario comprising several ship handling tasks, such as position determination, contact location and evaluation, getting underway, maneuvering, rudder checks, man overboard, and vessel crossing ("rules of the road")
- An actual test scenario where task improvements were recorded

Results from the latter scenario demonstrated a significant improvement in learning between training and test sessions, almost regardless of experience level. For example, students demonstrated an improvement factor of 39% in checking range markers, 33% in visually checking the rudder, 57% in contact management and 44% in reaction time in a "man overboard" event (Hays, Vincenzi, seamon, & Bradley, 1998).

The need for VE classroom trainers to familiarize incoming personnel with complex military systems and subsystem layouts is incontestable. Furthermore, the success of networked simulators, courtesy of pioneering initiatives such as distributed interactive simulation (DIS), brings a major new dimension to military VE trainers. For example, networked VE allows geographically remote infantry personnel to train together (see chap. 44, this volume) in a shared virtual theater of campaign, acting as a single, coordinated battalion, complete with

fighting vehicle backup, and other hardware support. It also provides the classroom educator with an important practical tool for assigning tasks and responsibilities to individual or collaborating trainees, not to mention providing a more quantifiable method of assessing the extent of trainees' learning (see chap. 35, this volume).

2.5.5 Virtual Land Mine Detection Training

Turning finally to land-based activities, the use of VE to train the drivers of military vehicles or operators of weapons systems is not new. However, a unique training system based on immersive VE has been developed for the French army, to help train in the detection of land mines, using the PHANToM as the primary interaction device.

The system presents the trainee with a textured cuboid representation of the ground area to be investigated and, using a standard issue military probe attached to the PHANToM, he is required to locate potential mines by gently inserting a virtual representation of the probe into the "ground."

Once a definite contact has been made, the trainee must continue probing until a recognizable pattern of penetrations has been made (see Fig. 42.14). In addition to the visual and haptic features of this trainer, a pattern recognition system is available, which matches the trainee's penetrations with known land mine geometries. Once a pattern match has been made, a schematic of the most likely mine configuration is displayed.

2.6 Medicine and Surgery

During the late 1980s, many visionaries—notably at the University of North Carolina and within the Department of Defense in the United States—were developing the notion of the surgeon or consultant of the future, equipped with an HMD and rehearsing procedures in VE, from detailed inspections of an unborn fetus, through to the accurate targeting of energy in radiation therapy, even socket fit testing in total joint replacement. For many years, the United States led the field in medical VE, and some of the early conferences and exhibitions delivered many promises about how technology would revolutionize surgery in the new millennium. Many of those promises would, even today, be hard-pushed to reach reality before 2020, let alone 2001. Nevertheless, in 1995, one of the leading practical advocates of VE in the United States, Col. Richard Satava (see chap. 47, this volume), attempted to categorize achievable applications of VE in medical and surgical domains (Satava et al., 1995). He saw developments in the fields of surgical intervention and planning, medical therapy, preventative medicine, medical

FIG. 42.14. The PHANToM system in use as part of an immersive VE trainer for land mine detection and identification. The right-hand part of the figure shows how the system's pattern recognition system can be used to present trainees with "best-fit" land mine types on the basis of ground penetration patterns. Image courtesy SimTeam.

training and skill enhancement, database visualization, and much more. Satava's original work, sponsored by the Advanced Research Projects Agency, ARPA, focused on large-scale robotic or telepresence surgery systems, using VE technologies to recreate the sense of presence (see chap. 40, this volume) for a distant surgeon when operating on, say, a battlefield casualty. However, other research efforts began to emerge across the States (and Europe) using VE in a classic simulator mode to rehearse or plan delicate operations (e.g., total joint replacement or in certain ophthalmic operations). It was then shown that one could actually use the successful virtual procedures to back up *in situ* performance (i.e., through the projection of 3-D graphics onto the operative site—"augmented reality").

Other programs saw the future not as either robot or surgeon, but as a combination of the two with the automated component of the operating theatre augmenting the skill of the surgeon, having been thoroughly preprogrammed in a preoperative virtual world (DiGioia, Jaramaz, O'Toole, Simon, & Kanade, 1995). Augmented reality took a step further when, as early as 1993, a magnetic resonance image (MRI) had been taken of a patient and overlaid onto a real-time video image of the head (Adam, 1994).

During the late 1980s and early 1990s, the application of VE and associated technologies to the field of medicine and surgery steadily increased, with pioneering (if, at that time, somewhat optimistic) companies such as High Techsplanations (HT Medical) and Cinémed becoming responsible for fueling the passion for "making surgical simulation real" (Meglan, 1996). However, more recent conferences and exhibitions suggest a plateau may have been reached, with some of the front-running concepts undergoing a period of consolidation through clinical validation. Tried and tested products, available at prices that are affordable to the greater majority of surgical teaching institutions, are still somewhat elusive. Nevertheless, the key uses of VE remain as Satava predicted, with new excursions into the realms of rehabilitation (see chap. 49 and 50, this volume), psychotherapy (see chap. 51, this volume), and support for disadvantaged individuals. Many projects have received academic grant support or national and continental funding (as one finds in Europe, during the Framework V Initiative, for example). Developments in technology continue to deliver more and more robust hardware and software at realistic prices. The surgical community has also gradually become more and more involved. In some countries, such as the United Kingdom, this is a painfully slow process, dominated by a small number of surgical (so-called) "high-flyer" personalities, who are producing somewhat fragmented developments of questionable value.

A chapter such as this cannot hope to cover all historical and contemporary aspects of VE and medicine and surgery under a single cover. However, the interested reader can obtain a more in-depth appreciation by selectively reading papers in the excellent publications of Westwood, Hoffman, Stredney, and Weghorst (1998; westwood et al., 1999).

Despite the coming of the PC/Windows era, bringing with it the capability of delivering highly interactive virtual medical environments (attractive to resource-limited surgical teaching bodies), the international academic research community (in the main) still shows a bias toward sophisticated anatomical and physiological simulations of the human body, hosted on graphics supercomputers. From the digital reconstruction of microtomed bodies of executed convicts (e.g., the National Library of Medicine's Visible Human Project, http://www.nlm.nih.gov/research/visible/visible_human.html) to speculative deformable models of various organs and vascular systems (e.g., Forschungszentrum Karlsruhe—<http://iregt1.iai.fzk.de/KISMET>, and the University of California at Berkeley's Virtual Environments for Surgical Training and Augmentation project—<http://robotics.eecs.berkeley.edu/~mdownes/surgery/>), the quest to deliver comprehensive "virtual humans" using dynamic visual, tactile, auditory, and even olfactory modes of interaction looks set to continue into the foreseeable future. The problem is, who in the real surgical world can afford to procure, operate and maintain such systems? More to the point, do they really offer trainee and consultant surgeons a career-enhancing advantage?

FIG. 42.15. The MIST surgical skills trainer. Image courtesy Manchester Royal Infirmary and Virtual Presence.

Virtual Presence's MIST (Minimally Invasive Surgical Trainer) system (see Fig. 42.15) has been subjected to worldwide testing by clinicians and applied psychologists (Stone, 1999a). Unlike many of its counterparts, MIST is an interactive skills trainer, utilizing symbolic task elements abstracted from the analyses of many minimally surgical interventions. The clinical tests have yielded a battery of positive objective results, one outcome being that the MIST system now forms a mandatory component of basic and advanced medical courses at the European Surgical Institute near Hamburg, covering a wide range of techniques, from cholecystectomy to thoracic surgery. The results include such features as improvements in surgical movement efficiency (actual/ideal instrument path lengths, past-pointing errors, and submovement corrections) and error reduction when MIST trainees are compared to control groups (e.g., Taffinder, McManus, Jansen, Russell, & Darzi, 1998a; Taffinder, McManus, Russell, & Darzi, 1998b; Taffinder, Sutton, Fishwick, McManus, & Darzi, 1998c). MIST task sensitivity to sleep deprivation has also been shown (Taffinder et al., 1998d), as have improvements in multiple incision performance, reduction of the fulcrum effect (perceived instrument reversal), and increased use of both hands in endoscopic tasks (Gallagher et al., 1998). In general, it can be stated that experimental results based on MIST tasks demonstrate statistically clear performance differences between novice, junior, and experienced laparoscopic cholecystectomy surgeons (Gallagher, Richie, McClure McGuigan, 1999). MIST is marketed by Mentice Medical Simulation AB (www.mentice.com).

2.7 Heritage

Virtual heritage may be defined as:

... the use of computer-based interactive technologies to record, preserve, or recreate artefacts, sites and actors of historic, artistic, religious and cultural significance and to deliver the results openly to a global audience in such a way as to provide formative educational experiences through electronic manipulations of time and space.

—Stone and Ojika (2000, p. 73)

Ever since the early 1990s, there has been a worldwide interest in the prospect of using VE to recreate historic sites and events for such purposes as education, special project commissions, and showcase features at national and World Heritage visitor centers. The power of VE, as described by Nynex researchers Stuart and Thomas in these formative years, lies with its ability to open up places and things not normally accessible to people from all walks of life, and to allow them to explore objects and experience events that could not normally be explored without “alterations of scale or time.” The power of the Internet now supports interaction with remote communities and interaction with virtual (historical) actors (see chap. 16, this volume). In the context of heritage, VE goes much further, however, in that it offers a means of protecting the fragile state of some sites and can help educate visitors not so much about their history, but in how to explore, interpret, and respect them. For example, VE can display the potential damage caused by the ravages of human intervention and pollution by accelerating the simulated destructive effects to monuments, even large areas of land and sea, over short periods of time (Stone, 1999).

One can trace the impetus for such interest back even further to an impressive demonstration, staged at the Imagina Conference in Monte Carlo in February 1993. An immersed member of the French clergy was joined by a simple avatar (see chap. 15, this volume), controlled by an operator in Paris who provided him with a real-time guided tour of a virtual reconstruction of the Cluny Abbey, a building destroyed in the early 19th century. This pioneering demonstration proved conclusively that a formative virtual heritage experience could be delivered over a standard ISDN communications network. Yet it was not until 1995 that the first Virtual Heritage conference was held at the Assembly Rooms in Bath, U.K., featuring Virtual Pompeii (From Carnegie Mellon University), Virtual Lowry (from Virtual Presence) the Caves of Lascaux (from the University of Cincinnati), and the fortress at Buhen, Egypt (from ERG Engineering). At the same time, a project instigated by English Heritage was announced, to develop both “large-scale” and “Web-friendly” VE models of Stonehenge. The large-scale model, complete with a mathematically accurate model of the nighttime sky and a virtual sunrise, was presented in June of the following year at the famous London Planetarium (see Fig. 42.16).

Virtual Stonehenge was also demonstrated live at the second Virtual Heritage conference held in London in December 1996. The 1996 conference was one of computing contrasts. At one end of the spectrum were such projects as Virtual Stonehenge, the Battle of Gettysburg (from TACS, Inc.), and the tomb of Menna in Thebes (from Manchester Metropolitan University), all targeting low-to-medium-range computers. At the other end was the visually stunning (and ongoing) “supercomputer”-based works of Infobyte, notably the widely referenced

FIG. 42.16. Sunrise over virtual Stonehenge. Image courtesy Virtual Presence.

FIG. 42.17. Virtual environment of Notre Dame. Image courtesy Digitalo Design.

Coliseum project. Another advanced project was announced by Miralab (from the University of Geneva), which later resulted in a stunning virtual recreation and animation of the terracotta warriors of Xian.

Since that time, there have been a small handful of heritage events featuring VE, the most notable being staged in the closing years of the 1990s by the Japanese (Gifu)-based Virtual Systems and Multi Media Organization (VSMM: www.vsmm.org). As a result of the interest generated at the international conferences, a group of the directors of the VSMM Organization went on to establish the Virtual Heritage Network (VHN) (www.virtualheritage.net), a site rich in information relating to contacts, groups, and projects. The “mission statement” of VHN is, at the time of writing, still evolving, but attempts are being made to bring together as many examples of computer-generated heritage as possible and make those examples accessible to the world through the infrastructure of the Internet and the impressive hardware technology evolving to satisfy the domestic games industry. The trends set by, for example, Digitalo Design (Virtual Reality Notre Dame Project; www.vrndproject.com; see Fig. 42.17) are exemplary in this respect. One can now harness the power of game engines using software included with the CD one has purchased from the local PC store, backed up with tutorials, patches, and 3-D model libraries from the Web. This has given rise to a whole new breed of competent VE developers, from schoolchildren age 10 and above, to small companies using the software to service the marketing and training needs of much larger corporations. Add to this the increasing availability of low-cost, even free modeling and run-time software resources from the Web, and one can appreciate why the VHN directors claim the time for global participation in Virtual Heritage is now.

2.7.1 Heritage and the Ceramics Industry

Recent developments in the British economy have prompted certain “heritage” industries to look very closely at their businesses and the prospects for improved productivity and growth in the early part of this new century. Companies such as Wedgwood and Royal Doulton, famous international, historical names in the production of quality crockery and figurines, are turning to VE in an attempt to embrace technology within their labor-intensive industries. Ceramics companies and groups, such as the Hothouse in Stoke-on-Trent, are experimenting with new haptics techniques and achieving some quite stunning results.

FIG. 42.18. An early example of the physical realization of a Hothouse trial sculpture using a Sensable PHANToM and free-form “digital clay.” Image courtesy Hothouse.

FIG. 42.19. Some of the new virtually created ceramics products in situ within a VE domestic “showroom.” Image courtesy Virtual Presence.

The importance of experiments like these, however, focuses on the people who actually produce the results. Talented sculptors—people with incredible manual skills but no background in computer technology whatsoever—have, given access to Sensable Technologies, Inc.’s, PHANToM Desktop and Freeform “digital clay” products, started to produce ornate sculptures within 3 to 4 days! Then, using local industrial resources, they have used 3-D printing and stereolithography facilities to convert these virtual prototypes into physical examples (see Fig. 42.18) and high-end VE to display them in virtual showrooms and domestic settings of very high visual fidelity (see Fig. 42.19).

2.8 Retail

Despite its poor showing in recent VE market surveys (Cydata, 1998, 2000), the retail application domain is a natural choice for implementation of VE technology. Preoccupation with international issues such as Y2K and, in Europe, the implementation of the single currency and Euro exchange rate has (in the opinion of the author) temporarily stalled developments. There is no doubt that the success of VE applications demonstrated in the 1990s by leading supermarket chains, coupled with the low price and retail information technology (IT) compatibility of today's desktop delivery machines, make the technology an attractive and viable support to the retail business process, particularly for activities in space planning, product packaging, and consumer behavior assessment. Certainly these conclusions are borne out by activities only now getting underway in the Far East and Australia.

One of the first projects demonstrating VE as a flexible design tool for store layouts began in 1993, when the U.K.'s Cooperative Wholesale Society (CWS) sponsored the development of a virtual Late Shop model. The model enabled CWS specialists to experiment with new checkout designs, evaluate store security, and assess potential ergonomics problems faced by checkout staff and customers when handling bags full of products. It was also demonstrated for the first time that it was possible to build virtual gondola and shelf models, populated with appropriate products, by automatically converting output files from proprietary rule-based space planners, such as Spaceman or Intactix.

The well-known U.K. retailer Sainsbury's then went on to demonstrate that environmental issues surrounding a proposed supermarket site development could be assessed using VE technology. This applied not only to the visual impact of the development but also to issues such as access routes, potential congestion, car park layout planning, petrol station positioning, and local transport availability. Another challenge issued by Sainsbury's came as a result of this virtual site demonstration and, in 1994, resulted in the largest virtual store interior ever developed. Users of the virtual store could reposition and resize gondolas, change fittings and replace the entire back wall with an alternative design in a matter of seconds. Then, designers, store managers, and directors could take part in a virtual design review to determine such issues as: Were the proposed department signs visible? Where were the nearest emergency exits? Were elderly or disabled shoppers catered for?

Following on from this success, Sainsbury's, in partnership with Virtual Presence Ltd., developed a PC-based space planning tool capable of being used by existing design employees called ConceptVR. In very simple terms, ConceptVR enables retail personnel to develop and modify new store and store fitting and style concepts on a "drag-and-drop" basis, organizing departments and products according to the organization's standards (see Fig. 42.20). Once developed, the virtual store concept can be distributed cheaply to other interested parties (such as shop fitting suppliers), using a 360-degree virtual "camera" system that takes panoramic digital pictures at predefined points in the virtual store model and, using a proprietary visualization software packages (e.g., QuickTime VR or Reality Studio), stores those nodes and pictures on CD (or dedicated Web sites) for real-time review on standard or laptop PCs. ConceptVR has been used in a variety of projects, most recently for gas station shop design, making sure the limited space available for groceries and other nongarage items is filled to best effect, without compromising customer comfort or through-flow.

Turning now to the products themselves, for VE to contribute to the design of new items destined for supermarket sale, the retail market demands greater attention to detail and quality than is normally evident in VE demonstrations. Products are 3-D in nature. They are housed within metallic, plastic, and cardboard containers and may be covered in cellophane or some other reflective material. They have labels that need to be read and striking designs that must create on-shelf visual impact, standing out against their competitors. Products also have to be used. More recent developments, spearheaded by Virtual Presence in collaboration with many

FIG. 42.20. Concept_{VR} in action, space planning for gas station retail area. Image courtesy Virtual Presence.

“household name” product developers—Lever, Nestlé, Procter & Gamble and Nestlé—mark a new era in the use of VE in the retail market. Using a methodology known as reality check, it is now possible to design, modify, and test product concepts thoroughly using VE to create realistic settings—virtual supermarkets, kitchens, or other household environments. Already poor packaging concepts have been intercepted using VE long before they have reached the, sometimes wasteful, prototyping stage. Virtual products can also be used by market research organizations for consumer testing (see Fig. 42.21), as first demonstrated by Lever and Procter & Gamble in the late 1990s. Courtesy of VE, one personal hygiene product even experienced a 2-year reduction in the time taken to reach the market from initial concept.

2.9 Education

Most of the inspiring and innovative developments in VE and education have happened in the United States (see chap. 45, this volume), although the United States is also home to a good number of VE educational Web sites and electronic “foundations” that do not seem to have been active since the late 1990s. Washington State University’s renowned Human Interface Technology Laboratory (HIT Lab) was one of the innovators in this field, having put in place an ambitious “peripatetic VE,” courtesy of sponsorship from U.S. West Foundation. The Virtual Reality Roving Vehicle (VRRV)—about the size of a transit van—was involved in taking immersive VE demonstrations developed by the HIT Lab to science classes in some 14 states in U.S. West’s territory. Another respected name in the field is that of the University of East Carolina, developing VE for educational heritage teaching, nursery education, and for teaching teachers how to deal with difficult classroom situations.

In Europe, one of the most impressive feats with a loose educational theme was a Cyberspace Roadshow, staged by the German Fraunhofer Institute in the late spring of 1994, and funded by the Schweizerische Bankgesellschaft. This was not just a case of putting a handful of items of VE equipment into a small van, as happened in the States. An articulated roadshow truck was completely modified to include immersive and projection equipment, a canopy extension for some 30 seated passive viewers, and desktop VE demonstrations, including a virtual tunnel

FIG. 42.21. Reality Check consumer assessment project. Image courtesy Virtual Presence.

flight, a virtual jungle, a space labyrinth, and a virtual stage with various musical and percussion instruments. One can only conclude that the budget for this, in terms of truck commissioning, equipment, development effort, power, and so on was immense. It has to be emphasized here that the Cyberspace Roadshow was carried out primarily as a special marketing event for the Swiss Bank (and the advertising agency Bosch & Butz), with the target audience being junior bankcard holders around the age of 17.

Virtual environment applications in education were in existence right at the start of popular VE activities in Europe. For example, in 1991, the late Michael Clark (then headmaster at a High School in the northeast of England), successfully canvassed local businesses to gain sponsorship for a desktop VE project he called the Intelligent City—a virtual urban scene designed to help teach schoolchildren French.

More recently, Crime Conquest was developed in the United Kingdom, using similar software to that originally procured by Michael Clark. Conquest is a desktop (PC) VE “societal trainer” that was distributed free of charge by the Greater Manchester Police Authority to some 300 schools in 10 local authorities of the greater Manchester area during September 1998. The trainer exploits VE by allowing schoolchildren to “enter the bodies” of different virtual participants. Their decisions at crime scenes involving people and property dictate what happens next. As witnesses, they have to be observant. For instance, having briefly seen the driver of a stolen vehicle, how close will their match be when invited to use the identikit computer within the VE town police station? When playing the role of a police officer, they have to make fair and just decisions. For example, are teenagers outside an elderly person’s house causing a nuisance or, worse still, exchanging drugs? Initial individual user and schools-based trials of the system have been highly successful. Indeed the software is still being used at the time of writing, despite the primitive “look-and-feel” of the real-time graphics. Although the system was

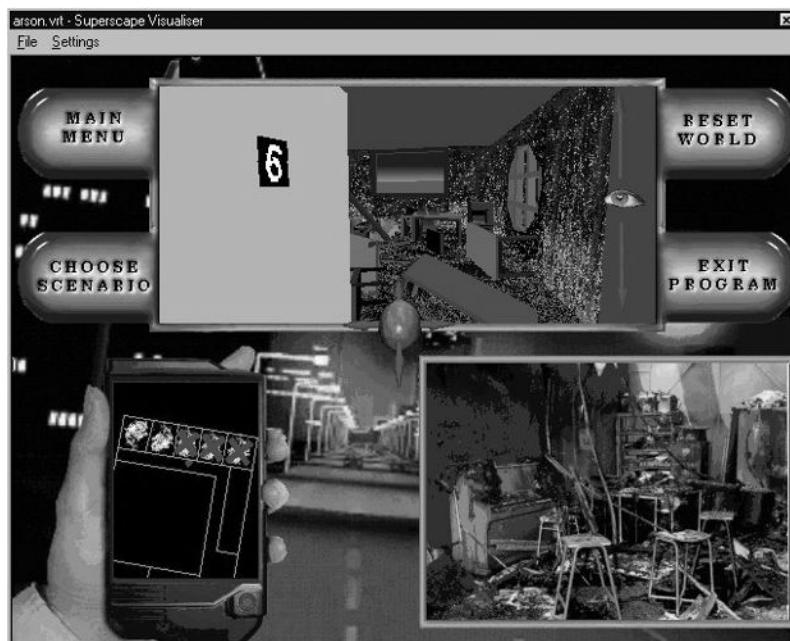

FIG. 42.22. User Interface for Crime Conquest, showing virtual schoolroom and image of real schoolroom, both subjected to arson attack. Image courtesy Virtual Presence.

originally designed for presentation to children of 11 years and older (Key Stage 3+ in the United Kingdom), children from 3 to 17 have enjoyed using the software, which has been designed in keeping with some of the aims of the IT components of the British national curriculum. Crime Conquest presents schoolchildren with 8 different scenarios—Trouble With Youths (3 variations, each escalating in severity), Shoplifting, Joyriding, Home Security, Personal Safety, and Arson (see Fig. 42.22). These can be run as individual 5- or 6-minute exercises, or as a complete “day’s experience” in around 45 minutes.

So, why are educational VE pursuits so important? The importance stems not just from the Nynex perspective described earlier for Virtual Heritage (exposing VE users to communities and actors from times gone by), although this is a key benefit of using the technology. Rather the importance relates to the future users of the technologies and practices the VE community is putting in place today. For far too long now governments have been spending quite sizeable sums of money with both academic and commercial technology organizations in the vain hope that they can attract, “kick-start,” and foster the interest of small- to medium-size enterprises (“SMEs” in Europe). In the United Kingdom (and to some extent in the United States) this has failed miserably. Put simply, employees, even directors of these SMEs simply do not have the time (nor the money) to be bothered with researching new technologies, especially those with a VE label. Even today, VE comes with a rather esoteric “prebranded” look and feel.

Can this situation be reversed? There are only two ways that change will come about. Either the companies concerned will be dragged, “kicking and screaming,” into the new millennium by the IT demands imposed on them by the blue-chip organizations they supply. Alternatively, the change will evolve from within. In other words, their future employees will, one hopes, enter employment with a raft of skills that can be tailored reasonably painlessly to meet the company’s future needs while avoiding massive organizational turmoil. This alternative depends, of course, on an appropriately educated workforce. The ability of many school children to exploit VE technologies, be it via the latest version of Epic’s Unreal (as modified and

used for the International Space Station model quoted in section 2.3) or Sierra's Half Life game engines, using Web-based 3-D modelers or even developing VRML worlds using free graphics and texture libraries is, in the view of the author, unquestionable. The potential for teachers to deliver many parts of their curricula effectively using VE techniques is also undeniable, although the perception of many educationalists that "I.T is hard" needs considerable work to quash. Most of today's youngsters have reached a stage where they are not only proficient in handling quite complex interactive 3-D databases, such as games and some CAD packages, they have come to expect a certain level of quality in the delivery of information using similar media, be it at school or in their first steps into full-time employment. Here then await members of a highly motivated, skilled community who will one day use the technologies our community is developing. Here, then, is a market worth developing.

2.10 Database and Scientific Visualization

Virtual environments have always held the potential to bring to the human eye features of living and inanimate material it would not normally see and to allow users to leave the constrained interface of the optical or digital microscope and explore such features intuitively. The future use of VE in exploring these atomic-level worlds has already been mentioned in section 2.2, in the context of micro- or nano-presence. Similarly, VE can help scientists to visualize all manner of complex artifacts and processes (see chap. 53, this volume), be they new protein chains, viral compositions, chemical drug concepts, or gaseous particles in motion (i.e., computational fluid dynamics [CFD]).

As an example of VE used for CFD visualization, NASA Ames Research Center's Numerical Aerospace Simulation Facility has developed a highly impressive facility based on VE technologies to allow users to explore numerically generated, 3-D unsteady flow fields. This award-winning facility allows users, equipped with a variety of immersive display and interaction devices (originally a BOOM [Binocular Omni Orientation Monitor] stereoscopic display and VPL's DataGlove), to view and inject smokelike virtual tracers in and around aerospace vehicles. One of NASA's sister sites (Langley) has, for international research and education purposes, now ported the concept of the Virtual Wind Tunnel on to the World Wide Web using Java (<http://ad-www.larc.nasa.gov/jvwt>). Another example of using low-cost (PC) computing technologies to deliver fully interactive VE representations of CFD processes was supported by the United Kingdom's Health and Safety Executive. This project assessed the design of chemistry laboratory fume cupboard handles and their effect on the propagation of potentially harmful particles back into the laboratory and toward the working scientists (see Fig. 42.23).

Figure 42.24 is a screenshot from an application developed using MUSE Technologies' μ uSE (Multidimensional User-oriented Synthetic Environment) software development environment (www.musetech.com). This project successfully validated new algorithms for processing industry-standard solar-weather data. This dynamic VE synthesizes multiple data sources into a single display, thereby helping scientists to understand how fluctuations in the sun's radiance affect the earth's atmosphere. In turn, this aids in the prediction of potentially adverse situations, such as the decay of satellite orbits and, by association, problems with wireless communications and other businesses reliant on integral communications and/or remotely sensed data. Clockwise from the top left of Fig. 42.24, this stage of the application includes context-sensitive images of the sun's surface, μ uSE-standard navigational instruments and a color-to-data mapping tool, context-sensitive text instruments, an image of the atmosphere's total electron content (TEC), and, finally, plots of energy content in two spectral bands coming from the sun.

Finally, VE has also proved to be an invaluable tool for displaying time-variant fused sensory data in a meaningful manner. Take for example Goodyear Tire and Rubber's application

FIG. 42.23. Immersed VE user experimenting with CFD particle visualization techniques. Image courtesy Virtual Presence.

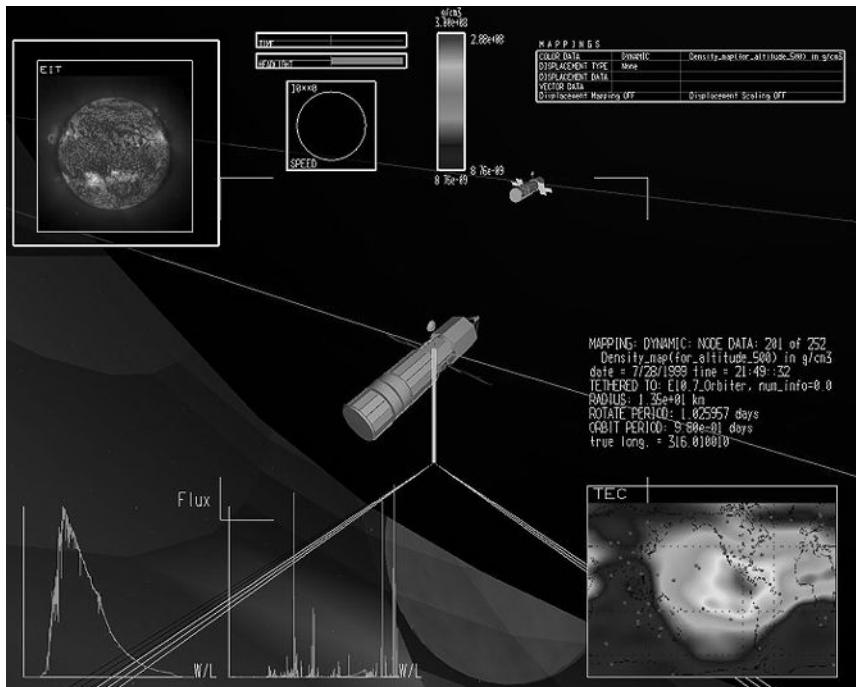

FIG. 42.24. Synthetic fused data display presenting the effects of the sun's radiance on the earth's atmosphere. Image courtesy MUSE Technologies.

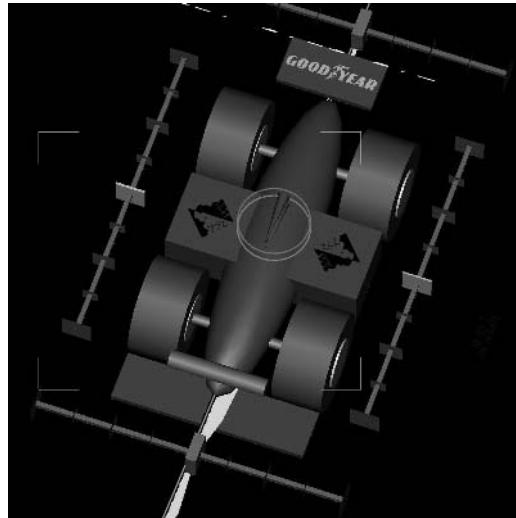

FIG. 42.25. Data fusion display depicting multiple sensor output for high-performance car and tire development. Image courtesy MUSE technologies.

for high-performance car and tire development. The real-time 3-D data display depicted in Fig. 42.25 was developed for Goodyear again using MUSE Technologies' μ SE software. The Goodyear system displays as many as 15 different types of data simultaneously, all collected at the company's test tracks.

The screenshot shown in Fig. 42.25 depicts a single racing car surrounded by instruments that help the user monitor the output of various sensors mounted on the vehicle. Users can choose any mapping of data to car component they wish. The dials at the center of the car typically show steering angle. The tires swell and shrink as the car moves along the track to indicate higher or lower pressure. The "difference bars" at the front, back, and sides of the car show load transfer across the car. The strip beneath the car is the "undertrack plot," which shows lateral acceleration.

3. CONCLUSIONS

To do real justice to the international VE community, a comprehensive overview section on applications would occupy the space normally demanded by a large reference book. This overview has only scratched the surface of an exciting and wide-ranging arena. Yet to many, the very fact that the arena is so wide-ranging is perceived to be a major problem in bringing stability to those product and service companies who are attempting to stay afloat in the VE community's turbulent waters.

No matter what commercial model or philosophy one subscribes to, it is a fact of life for the VE industry that there is no—and (for the foreseeable future) will be no—single "killer" market for VE, although education offers much potential for the future. More immediately, the absence of the killer application is a situation that has left many companies' boards of directors praying for salvation, having been preoccupied with trying to focus in on one or two market segments. After all, market consultants continuously bombard companies with the message that they must "focus, focus, focus" on specific products for specific markets. However, for the "killer-market-less" VE community, such focusing inevitably leads to stagnation, obscurity,

and termination. It is now evident that VE companies should pay more attention to how they should structure and market the abilities of their multidisciplinary skills base to provide appropriate, timely, and relevant human-centered solutions to the problems they are asked to tackle, using VE as one tool in their multimedia armory, rather than focus on the advanced technologies per se.

It was always the case that real commercial or industrial applications of VE would help to save the field of endeavor from obscurity, just like its predecessors. The truth is that there are many more success stories and, of equal importance, stories of failure or “nonadoption” by companies (for good technical, cost, or human reasons) in existence than the VE community can, or is permitted, to report. Certainly, one cannot rely too greatly on the results of recent (and rather expensive) VE market surveys, as many have questioned the validity and reliability of the community samples from which their conclusions have been drawn. One has to rely on well-documented case studies when they emerge in order to help the technology diffusion process, as described further by the author and Professor Peter Swann in chapter 28. To this end, the remaining applications chapters (see chaps. 43–55, this volume) dealing with specific applications represent only the start of what promises to become a rewarding decade of commercially meaningful VE success stories.

What is certain is that, during the closing 2 years of the last millennium, the VE community has witnessed a technological revolution that should—stress should—ensure its presence in some shape or form for at least the next 2 decades.

1. INTRODUCTION

1.1 Why Are Defense Organizations Interested in Virtual Environments?

During the last decade of the 20th century, the U.S. Department of Defense has been required to conduct an increasing number of missions while its monetary and personnel resources have been decreasing. Many of these missions represent significant departures from the services' primary warfighting mission. In addition to the combat of the Gulf War, missions have been conducted to enforce peace agreements (by enforcing embargoes and "no-fly" zones and to separate warring parties), and to provide humanitarian assistance and disaster relief. The increasing need to perform operations that require skills other than combat is illustrated by recent actions in Haiti, Somalia, and Bosnia. Missions such as these are often carried out as part of a multinational force. As a result, military units and personnel must be prepared to perform more tasks under a greater variety of conditions than ever before. In this context of having to do more with less, the use of virtual environment (VE) systems is seen as a means to enhance preparedness for a wide range of activities while reducing operating costs.

For purposes of this chapter, the definition of VE being used by the North Atlantic Treaty Organization (NATO) Research Study Group 28 is adopted. This group is investigating human factors issues in the use of VE for military purposes. Their definition of VE (they use the term *virtual reality*) is (Ehrlich, Goldberg, & Papin, 2000):

* Opinions expressed are those of the authors and do not represent an official position of the Department of Defense.

Virtual reality is the experience of being in a synthetic environment and the perceiving and interacting through sensors and effectors, actively and passively, with it and the objects in it, as if they were real. Virtual Reality technology allows the user to perceive and experience sensory contact and interact dynamically with such contact in any or all modalities.

This covers immersive VE systems that are directly perceivable by participants through their senses. It does not include training on electronic systems that use sensor (e.g., radar) data as their stimuli.

Virtual environments can enhance preparedness by providing training opportunities that cannot be made available in the real world. These systems can reduce training costs by replacing the use of actual equipment and weapons, and even aging, expensive simulators, with simulators and simulations that are relatively inexpensive to operate and maintain. Modern military weapons systems, such as planes, ships, and tanks, are expensive to operate. Sophisticated or “smart” weapons are not only so expensive that they can rarely be fired for training purposes, they are in many cases designed to be employed at such long distances that there are few locations (ranges) where they can safely be fired for training. A growing population and concern for the environment make it more difficult to continue to operate existing ranges, and in most cases makes their expansion impossible. Many military tasks, such as high-speed, low-altitude flight, are inherently dangerous. Others, such as handling ships in adverse weather, can only be practiced infrequently in the real world because the appropriate conditions rarely occur.

Many existing simulators are expensive to operate. They were designed with relatively slow computer technology and complex instructor stations. These simulators were adequate for their time, but they now are becoming expensive to support and maintain. More recent simulator designs are more efficient and effective due to improvements in computer technology, new concepts in use of spare parts, and use of intelligent tutors that reduce instructor requirements.

Effectiveness in combat results not just from soldiers or pilots fighting as individuals, but from coordinated activities of different types of units and weapons systems, such as armor, infantry, and artillery (see chap. 44, this volume). Increasingly, emphasis is being placed on training for such combined arms and multiservice operations. With the many operations the U.S. armed forces are currently engaged in across the globe, training systems need to be capable of being taken to forward areas to maintain individual and collective proficiency.

1.2 Scope of the Chapter

Because of the breadth of national defense activity in virtual simulation, the scope of this chapter must necessarily be limited to a general overview of the VE-based training programs in the U.S. Army, Air Force, and Navy in which participants have a direct view of a virtual space. The discussion will be limited to United States programs or programs that the United States is conducting jointly with other countries.

2. CURRENT AND FUTURE MILITARY APPLICATION AREAS FOR VIRTUAL ENVIRONMENTS

This section describes a variety of proposed application areas for the use of VE in the military. Each area is described in terms of the specific training challenge and way in which VE is being or could be used to meet this challenge.

2.1 Training

2.1.1 *Embedded Training*

Embedded training is training provided by capabilities built into or added onto operational systems to enhance and maintain the skill proficiency of operators and maintainers. Embedded training capabilities may be fully embedded within the operational system, or they may be designed as components that can be added and removed as required. The concept of embedded training is not new. Its use in the military dates from at least the early 1970s. However, it has become feasible in more systems as onboard computers and digital information displays become more common. An advantage of embedded training is that it provides a training capability wherever the operational system is located. With these deployable systems, soldiers can train while temporarily assigned to a foreign country, or sailors can train while onboard ship at sea. This makes embedded training especially appropriate for sustainment or refresher training. Early applications of embedded training by the army and navy have focused on embedding training on computer driven systems that utilized electronic sensor data, for example, anti-submarine warfare or Aegis system training or fire control data (Army TACFIRE Computer). Today research is under way to utilize VE technology to stimulate the direct view optics and optical sensors of weapon systems, that is, to insert virtual targets into those displays, thereby turning combat vehicles into virtual simulators.

2.1.2 *Unit/Collective Training*

In addition to the use of simulators for training individual skills, groups of simulators are being used increasingly to train team and collective skills that military operations require (see chap. 44, this volume). Collective training systems employing VE (e.g., Army Close Combat Tactical Trainer, Air Force Distributed Mission Trainer) are being employed to meet this need. Networking operational systems that possess embedded training capabilities can provide collective training.

A variation to training intact teams and units is the use of intelligent agents (see chap. 15, this volume) to simulate missing team members. The Navy Landing Craft Air Cushion (LCAC) vehicle has multiple crew stations, but a training class may not always contain members of each station. That is, a small class of four students may contain only navigators. Thus, intelligent agents can serve the role of engineer and pilot in the VE so that the navigator student can train with a full crew.

2.1.3 *Soldier and Leader Training*

The use of VE for combat training has predominantly focused on training personnel who fight from within combat vehicles, such as tanks, aircraft, and ships. However, soldiers, marines, and security personnel who operate and fight on foot can also benefit from training in VEs to meet growing responsibilities and increasing challenges. These include new missions, changing tactics, and increasingly sophisticated equipment. New noncombat missions involve more diverse types of operations and more complex and dynamic rules of engagement than do combat missions. When combined with dispersed units and a high level of media attention, this creates an environment in which the actions and decisions of small-unit leaders and individual soldiers, such as firing into a hostile crowd, can have far-reaching impacts. A variety of new equipment is being developed and evaluated to improve the effectiveness and survivability of these foot soldiers. This includes wearable computers, global positioning systems, radios, digital information displays, video capture capability, and night-vision equipment. Such sophisticated equipment will permit soldiers at lower echelons to obtain more information about

the tactical situation, command more firepower, and be separated further from their parent unit. Evolving tactics, made possible by the new communications and weapons systems, will shift information and decision making to lower level leaders. Soldiers will have to become more capable of either autonomous or small group action. They will also need to be more adaptive and flexible. Immersive VE can represent environments in which soldiers and leaders can practice these new tactical and decision-making skills. Virtual environments are also well suited to the incorporation of training strategies and techniques (such as intelligent tutoring systems), which can enhance decision-making skills.

2.2 Mission Rehearsal

While training is conducted to develop skills which will generalize to a variety of combat situations, mission rehearsals are conducted to prepare a unit to conduct a specific operation. Thus a unit might train building assault procedures with the goal of becoming more proficient in assaulting a variety of types of buildings (high-rise office building, townhouses, etc.), with the expectation that at some future time they will be assigned a similar task. The same unit might rehearse rescuing terrorist-held hostages from a specific embassy immediately before conducting that rescue. Mission rehearsal also contributes to the planning process. What is learned from the rehearsal can be used to revise the plan for the operation.

A critical element of a mission rehearsal system is representation of the physical environment in which the operation is to take place. This can be simple or elaborate. The movie *The Dirty Dozen* showed the use of scale models to rehearse an attack on an enemy-held chateau. Full-scale physical mock-ups have also been used. In Operation Desert Storm, allied forces rehearsed assaults on trench lines built from Iraqi designs. During the Vietnam War, U.S. special forces prepared for an assault on a North Vietnamese prisoner of war camp with a full-scale physical mock-up. For security reasons, the mock-up had to be disassembled whenever a Soviet reconnaissance satellite was scheduled to pass over the area. Obviously, security is another requirement for a mission rehearsal system. Desirable features include the capability to include simulated enemy and neutral forces, modify the representation as more information about the situation is obtained, and move the system to the location where the unit is based (i.e., transportability). Virtual simulations have tremendous potential to provide a mission rehearsal capability. Aircraft simulators are already being used to rehearse air missions.

2.3 Evaluation of New Concepts and Equipment

The military is constantly changing to counter new threats to national security, to assume new roles (e.g., humanitarian assistance), or to take advantage of new technology. Usually, these changes are most visible in the fielding of new weapons systems and equipment, but they may also be reflected in new or revised policy, organizational structure, tactics, or training. In an effort to speed the process of acquiring new equipment, the military is placing more emphasis on the use of models and simulations to support equipment design and evaluation. Virtual simulations make it possible to perform "human in the loop" experiments and evaluations before hardware prototypes are built. Virtual simulations can be used to replace mock-ups and prototypes to design operator interfaces. Using simulated equipment in a simulated combat setting can help identify and resolve issues such as workload and task allocation. Virtual simulations can also be used to develop and evaluate procedures for the use of the equipment. Finally, virtual simulations can be used to train operators of new equipment prior to its delivery to the receiving unit.

2.4 Performance Measurement

One of the frequent shortcomings of the real world as a training environment is that objective measurement of the conditions under which a task is performed or of the performance of the trainee is difficult. Virtual environments, on the other hand, can provide measurement opportunities that would not be possible in the real world (see chap. 35, this volume). This is because computers are utilizing movement, firing, environmental and communication data to drive the simulation. The same data is invaluable for measurement and performance assessment. Objective performance measures can be derived in judgment tasks, such as ship handling, that traditionally have eluded objective assessment. Intelligent tutoring systems can use measurement data to assess student progress in the same way an expert would and determine appropriate further instruction. The navy is building just such a system to teach shiphandling skills (see chap. 20, this volume).

2.5 Knowledge Elicitation

The conning officer of a naval vessel must make complex decisions based on the perceived motion of their own ship, as well as that of possible collision hazards around their ship. Although some of the skills required to perform this task may be articulated by an expert ship handler, studies discussed in chapter 20 (this volume) indicate that experts do not easily articulate the entire task. Perhaps this is because experts have automated the task to a degree that they are now unable to describe how they do it. Nevertheless, it may be possible to elicit knowledge about performance of the task by observing the actions of expert ship handlers, and inferring relationships between the expert's actions and outcomes of the ship-handling task. As described in the preceding paragraph, VE offers an environment in which environmental states, expert behaviors, and resulting states can be carefully measured. Then, through mathematical techniques of drawing inference, the system can extract relationships and draw conclusions about what the expert attends to and what actions he takes in performance of the task. The U.S. Navy is exploring these techniques using a VE ship-handling training system.

3. BEHAVIORAL SCIENCE CHALLENGES TO THE USE OF VIRTUAL ENVIRONMENTS

The military services have been conducting behavioral science research in the use of VE for a number of years. This section describes the major behavioral science challenges to the use of VE for the military purposes described above. It is an overview and thus is not intended to provide comprehensive reviews of either the VE research conducted by defense organizations or the research in a particular content area (e.g., cybersickness).

3.1 Management of Simulator Sickness or Cybersickness

Simulator sickness, or cybersickness, can potentially degrade training effectiveness and performance, as well as affect the well being of trainees (see chap. 30, this volume). Ensuring that symptoms do not reach a disruptive level needs to be a major consideration in the design, development, and use of military VE systems. Research conducted to date suggests some recommendations for reducing symptoms, but better guidelines are needed.

In a report summarizing 13 VE experiments conducted by the Army Research Institute during the 1990s, Knerr et al. (1998) reported that simulator sickness symptoms were sufficiently severe that 5.6% of participants withdrew from an experiment prior to its completion. Rates for

individual experiments varied from 0% to 25%. Other researchers have reported withdrawal rates of 10% (Garris-Reif & Franz, 1995) and 0% to 5% (Regan, 1995). Similar results are reported in chapter 30 (this volume).

Of particular relevance to the practical use of VE are findings indicating that, all other things being equal, an individual is most susceptible to simulator sickness during the first session with a simulator. For most tasks, the symptoms of inexperienced trainees decline during subsequent sessions. Lampton, Kraemer, Kolasinski, and Knerr (1995), Lockheed Martin (1997), and Regan (1995) have all reported fewer and less severe symptoms of simulator sickness with subsequent sessions (one or more days apart; see also chap. 30, this volume.) This suggests that trainees are adapting to the VE (see chap. 31, this volume), and that particular attention needs to be paid to the first session to avoid conditions that are likely to produce symptoms. Knerr et al. (1998) proposed that the first session should: be brief (inoculate against simulator sickness); be designed to minimize sickness-producing activities such as rapidly slewing the field of view, collisions, and viewing objects at very short distances; and avoid depicting self movement not under the participant's control. The widely used antimotion sickness drug hyoscine hydrobromide is effective in combating simulator sickness (Regan, 1995). Its effects on learning, however, have not been studied.

3.2 Presence/Immersion and Training Effectiveness and Transfer

Presence is defined as the subjective experience of being in one place or environment (the computer-generated environment), even when one is physically situated in another (the actual physical locale; see chap. 40, this volume). It has been proposed that presence can make training in simulated environments seem more realistic and increase user involvement in the tasks and situations presented in the virtual environment. This in turn should improve task performance in the VE and promote transfer of VE-acquired skills to the real world (see chap. 19, this volume). One way to improve training effectiveness and transfer, therefore, is to manipulate directly those factors that increase presence, such as interface characteristics. Although the sense of presence can be measured quantitatively (Witmer & Singer, 1998), evidence linking presence to either interface characteristics or training effectiveness is weak. In particular, there is limited evidence that a trainee who feels highly immersed in his environment learns more or faster than one who does not. However, it is necessary to make a distinction between the level of presence reported by different individuals in response to being immersed in the same environment (as represented by correlating presence scores and performance) and different levels of presence reported by the same individual in different environments. The relationship between presence and task performance in the latter case is yet to be tested.

3.3 Use of Autonomous Agents for Training

Autonomous agents and computer-controlled entities can enhance the VE training experience in a variety of ways (see chap. 15, this volume). In simulated combat scenarios, they can control the actions of enemy or other friendly "platforms" such as ships, aircraft, or armored vehicles. When coupled with the use of human avatars, they can substitute for live human role players in training scenarios that cover a range of activities from dismounted combat through peacekeeping to language training. There is a substantial history of development of forces of this type, also referred to as computer-generated forces (CGF) or semiautomated forces (SAF). Efforts are under way to develop semiautomated entities and fully automated agents that can represent both mounted and dismounted friendly and enemy ground forces (see, for example, Science Applications International Corporation and Lockheed Martin Information Systems Company, 1998). Research is also under way to make the behaviors of agents reflect more realistic human

behavior (e.g., Gillis, 1998) by incorporating cognitive models that include variables such as sleep deprivation, amount of training and experience level. Autonomous agents can also serve as automated tutors or coaches, which can provide guidance to a trainee when needed, perform tasks when so delegated, and monitor the overall training session to ensure training objectives are being met. Breaux and Stanney (1999) have discussed the use of agents as tutors for ship-handling training and spatial knowledge acquisition.

3.4 Virtual Environment Training Strategies

There is an increasing body of evidence that students can acquire in VE and transfer to the real world, both route knowledge (Bliss, Tidwell, & Guest, 1997; Witmer, Bailey, & Knerr, 1995) and configuration knowledge (Darken & Sibert, 1993, 1996; Wilson, Foreman, & Tlauka, 1997). Magee (1997) and Hays, Vincenzi, Seamon, and Bradley (1998) found that their VE simulators improved ship-handling skills, which have a spatial component. One interesting aspect of these experiments is that they did not rely on sophisticated instructional strategies or features to obtain effective training, but instead used relatively simple and straightforward approaches. Hays et al. (1998) used structured training scenarios with coaching and feedback provided by a live instructor. Magee (1997) used recording and playback of two-dimensional (2-D) and three-dimensional (3-D) views, which could include graphic display of ship tracks and alphanumeric speed, heading, and related information. Instructors also had features such as stop, rewind, and fast-forward for use in reviews. Darken and Sibert (1996) found that use of certain design features (maps and gridlines) improved configuration knowledge (see chap. 24, this volume). Beyond these few experiments, however, there has been little investigation of how VEs can be used to their best advantage in training spatial knowledge. The strategies and techniques that are best suited for maximizing the effectiveness of VE for training is an open question.

3.5 Training Geographically Dispersed Team Members

Although military VE research to date has focused primarily on training individual skills, there is a strong need for the use of VE for training collective or team skills. Small infantry units and their leaders require increased training for noncombat missions and in the tactical use of increasingly sophisticated weapons and equipment. This will require either training multiple soldiers simultaneously in a shared VE, or training one soldier (the leader) while simulating subordinates and peers, probably with computer-generated forces (agents). Effective use of VE for either of these scenarios requires resolution of a number of additional issues, including: selection and use of appropriate training features and strategies; development of VEs to facilitate human interaction necessary for team training; determining the extent of system lags (fixed and variable) and their impact on training effectiveness; identifying the requirements for avatars that are used to represent team members in VE; and determining the impact on performance and training effectiveness of reduced nonverbal communication (posture, facial expression) among team members.

3.6 Computer Recognition of Human Gestures

Many military tasks require that commands be given through gestures, either because they must be performed in high-noise environments (ground combat or the deck of an aircraft carrier), or performed in silence. Unlike gestures for signed speech, military gestures are typically expansive. For example, a leader signals his unit to increase speed by raising his clenched fist to shoulder level, then rapidly thrusting it upward until it is fully extended and returning

it to its original position. This motion is repeated rapidly several times. Military gestures must be recognizable when made from different positions (standing, kneeling, or prone) and orientations to the viewer. Computer recognition of these gestures could contribute to both training to perform the gestures correctly and training performance of the tasks that require their use. Computer recognition of gestures would allow live soldiers to control the behavior of computer generated forces through gesture commands.

3.7 Determination of Interface Requirements for Different Applications

No VE configuration replicates reality exactly. Nearly all use some “work-around” solutions, such as the use of a joystick to control locomotion, a head-mounted display (HMD) with lower resolution and smaller field of view than the human eye, or the use of enlargement or color to make distant objects visible. It is necessary to determine, for any application, the most cost-effective interface that provides the necessary cues and permits appropriate responses without using work-arounds that detract from learning and task performance by the user or trainee. Different methods of interaction, particularly of locomotion (see chap. 11, this volume), need to be evaluated in terms of the cognitive demand they place on the user and, therefore, their likely impact on training effectiveness.

For example, there are methods for self-locomotion that maintain a constant relationship between real world and VE orientation (Grant & Magee, 1997; Lockheed Martin, 1997; Singer, Ehrlich, & Allen, 1998; Templeman, 1997). The user turns in place in the VE as he or she would in the real world, and therefore receives the same kinesthetic and vestibular cues as in the real world. This aspect of the interface can be used in conjunction with a variety of techniques for moving forward, backward, or sideways. The results of locomotion experiments suggest that whereas trainees learn to move through a VE using any of a variety of well-designed interface devices, use of a “walking simulator” may produce better spatial learning than joysticks, gaze-directed, and hand-pointing controls. However, it is not clear whether this is because the walking simulator provides better cues for changes in direction, better cues for distance traveled, or because it places less cognitive demand on the trainees, allowing them to attend more carefully to other cues. There is a need for research that assesses the relative contributions of more realistic turning and movement cues to distance estimation, route learning, or configuration learning.

3.8 Effects of Prolonged or Repeated VE Use

There are numerous applications for VE that would require the user to be immersed in the VE for a long duration or for repeated sessions over an extended period. As indicated in chapter 30 (this volume) little is known about the distinct symptoms that may result from extended or prolonged use, or the rate and retention of adaptation (see chap. 31, this volume) that might be expected.

3.9 Effects of Using VE on a Moving Platform

There are applications for VE for use aboard moving platforms such as aircraft and ships. Presenting imagery derived from sensor and computer systems which is not coordinated with the perceived motions of the vessel or aircraft will eventually cause vestibular/ocular conflict and motion sickness (see chap. 30, this volume). Additionally, lag between real motions of a vehicle and the corresponding motions of virtual imagery can also induce motion sickness. Controlling a remotely operated vehicle (ROV), such as an unmanned aerial vehicle or an

unmanned underwater vehicle, while aboard a moving platform such as a ship presents a complex interplay of motion. The imagery from the ROV will be moving in accordance with its aerodynamics or hydrodynamics, yet the operator will also be experiencing motions of the platform they are riding. There is no direct research into the effects of conflicts and coordination of such VEs for operators on moving platforms.

3.10 Accurate and Fast Position- and Orientation-Tracking Systems

Systems that can track (see chap. 8, this volume) the position and orientation of body parts, weapons, and other tools accurately and rapidly are required for two purposes: computer recognition of human gestures (as discussed above) and tracking the position of weapons. Humans can respond to stimuli with speeds that vary from a few to hundreds of milliseconds, using motions that can vary dramatically in speed, range, and complexity. Technological capabilities lag human performance capabilities in this area. Moreover, some VE equipment encumbers and hampers rapid task performance. Matching human motor capabilities in this area, particularly that of skilled performers, is and will continue to be extremely challenging.

4. MAJOR VE R&D PROGRAMS

This section describes several major military VE R&D programs. It will not be exhaustive. Performing organization, objectives, and major accomplishments will be described for the lay reader.

4.1 Simulation Networking (SIMNET)/Close Combat Tactical Trainer

The traditional method for collective training of army mechanized forces had been to conduct exercises in the field with military equipment. The Defense Advance Research Programs Agency's (DARPA) Simulation Networking (SIMNET) project provided a virtual simulation alternative to field training. It was a research project designed to demonstrate simulator networking technology within a workable trainer (Thorpe, 1987). SIMNET demonstrated the capability of man-in-the-loop simulators to create a virtual battlefield on which meaningful collective training could be accomplished (Alluisi, 1991). SIMNET was an R&D system that incorporated for the first time a number of concepts that would be carried over to later virtual training systems. It was a distributed simulation, which did not rely on a central computer. Each battlefield entity maintained its own independent worldview or record of the location movement and firing of each entity on the SIMNET battlefield. These worldviews were updated by protocol data units that were generated each time an entity within the SIMNET network moved or fired. SIMNET pioneered low-cost graphics generators and a low fidelity approach to representing vehicle controls in SIMNET simulators. SIMNET aspired to an 80% fidelity solution. SIMNET also developed the first SAF. Originally SIMNET simulators on opposing sides were to see each other as enemy vehicles. This approach was dropped in favor of development of predominantly computer controlled opposing forces that employed threat, not U.S., tactics.

Two hundred and forty-seven SIMNET simulators were eventually fielded in the United States, Germany, and Korea. As a trainer, SIMNET had a number of shortcomings (Burnside, 1991). Many collective tasks could not be completely performed. The SIMNET VE was limited to daylight, and SIMNET terrain databases had limited details. SIMNET was fielded without an After Action Review (AAR) System for measuring performance and providing feedback on a unit's performance, and without training support packages consisting of task-based training scenarios. As a result of these deficiencies, the army launched a follow-on to SIMNET, the

Close Combat Tactical Trainer (CCTT). CCTT is a product of the U.S. Army's Simulation Training and Instrumentation Command (STRICOM) and its Project Manager, Combined Arms Tactical Trainer (PM, CATT).

CCTT is not an R&D project and it has met all the requirements of the army procurement process. As of this writing it has been fielded at Fort Hood, Texas, Fort Benning, Georgia, and Fort Knox, Kentucky. Fielding will continue over the next few years at sites in the United States, Germany, and Korea. Mobile CCTT vans are also being fielded for training Army National Guard units. CCTT and SIMNET are based on the same networking concept, distributed interactive simulation (DIS). CCTT improves on many of the deficiencies the army identified in SIMNET. For example, CCTT can represent day and night and weather conditions. CCTT simulators contain all of the switches and dials present in the actual vehicle (although they may not all be functional). CCTT databases are more varied and contain a higher level of detail than SIMNET databases. CCTT uses standardized DIS protocols that SIMNET did not, and CCTT SAF are based on a thorough analysis of friendly and enemy collective tasks.

CCTT provides an excellent simulation environment. Less attention was paid to upgrading the training features of SIMNET (Goldberg, Mastaglio, & Johnson, 1995). While SIMNET had no AAR System, the AAR capability fielded with CCTT is limited at best (an improved AAR system is currently being planned). Structured training support packages containing scenarios that stressed mission execution over planning were developed in response to a need for training on which to base CCTT's operational test (Flynn, Campbell, Myers, & Burnside, 1998). A structured training approach in CCTT is being institutionalized through development of a Commander's Integrated Training Tool (CITT), which allows army commanders to build new scenarios or modify old ones to meet their training objectives.

CCTT is a large distributed simulation training system. Its effectiveness and popularity as a training tool will determine how extensively VE technology will be applied to meeting a wide range of potential army collective training applications.

4.2 Virtual Environment Training Technology (VETT)

The navy has launched a multifaceted research program, Virtual Environment Training Technology, directed at furthering instructional science while at the same time providing effective training solutions. The program is currently exploring a variety of approaches for training perceptual–cognitive skills, such as ship handling.

When asked how a sailor maneuvers a ship in the ocean relative to other ships or objects a ship's captain would likely say, "They have developed the 'seaman's eye.'" This concept is described in detail in chapter 20 (this volume). Training this perceptual–cognitive construct requires a package of technologies. Visualization, metaphors, knowledge extraction, behavioral modeling, collaborative learning, and details of the human–computer interface each form a portion of the infrastructure required to fulfill the potential of VE to teach mental models that form the basis of perceptual–cognitive tasks.

Visualization (see chap. 53, this volume) provides one technique for focusing a large amount of data into meaningful relationships (Gershon, Eick, & Card, 1998). Feedback on performance, suggestions for interventions, and diagnosis of a student's weak areas are each amenable to visual presentations in a training environment. Visual display theories suggest that such feedback should be organized and displayed in a manner that it is congruent with the methods in which one scans the environment. For example, visual primitives such as texture, color, length, and slope are encoded more efficiently than shape, area, orientation, and containment (Lohse, 1997). Visual displays that differentiate by color may thus be more readily perceived than those demarcated via shape. Further, 3-D representations have been found to be differentially

superior to 2-D, with benefits in processing found with continuous as opposed to discrete data (Lee & MacLachian, 1986) and with lateral and altitude tracking accuracy as opposed to air speed (Haskell & Wickens, 1993).

Designing visualization displays according to such theories and findings may facilitate problem solving by streamlining information processing and reducing cognitive demands on users (Woods, 1984). Recent research in identifying display techniques for facilitating problem solving involves the utilization of different display modalities (i.e., visual, audio, tactile; Turk & Robertson, 2000). Mills and Noyes (1999) suggest that early studies support the notion that the multimodal aspect of VEs may result in enhanced human performance. For instance, Breaux, Martin, and Jones (1998) suggest that a primary advantage of VE technology is that it enables a training environment to be manipulated by both the instructor and the student to facilitate the integration of knowledge into an appropriate mental model, thereby enhancing learning and improving performance. It is also generally accepted that dynamic or interactive visual displays, such as VEs, facilitate a user's understanding of complex relations between represented parameters (Kalawsky, 1993). Moreover, it is theorized that VE technology may be an effective visualization tool for teaching and learning because it makes better use of the human central nervous system's ability to handle a rich set of sensory inputs (e.g., sight, sound, touch; Doyle & Cruz-Neira, 1999). There is a need to better understand the utility of extending visualizations into multimodal presentations. Doctoral fellowship studies are currently seeking to identify multimodal visualization principles that can be incorporated into design guidelines for training systems.

People naturally invoke metaphors when learning new principles by placing a new concept in the conceptual framework of something they already know about and understand (Carroll & Thomas, 1982). Based on this natural tendency, VE system designers should try to identify and adopt into their designs likely metaphorical frameworks to assist in training effectiveness. In general, metaphors have been broadly adopted into different fields of research and practice to aid learning. Physicists use metaphors to get a conceptual handle on the complexity of physics, educators make extensive use of metaphors in the classroom, and politicians are constantly in search of more powerful metaphors to position their proposals more effectively (Judge, 1993). Metaphors can provide a framework of credible associations to increase the probability that relationships in different domains will be conceived according to the patterns defined by the metaphors. In considering the role of metaphors in interactive system design, Dent, Klein, and Eggleston (1987) suggested metaphors are an aid to:

1. Systems designers as a source of organization and a decision guide about how to represent information, such as training material
2. Users or trainees as a means of directing their attention to important information needed for skilled action, especially under time pressure

Metaphors have been used in literature for thousands of years as a teaching mechanism. To see how they may work in VE, consider the "seaman's eye" training problem. Relative motion of ships at sea is somewhat analogous to relative motion of cars on a highway. Understanding overtaking and passing land vehicles may simplify explanation of the similar concept at sea and make learning faster and more efficient. If sailors can relate the tendency of ships to be drawn together due to the venturi effect at sea to the experience of passing an 18-wheeler and at the nose-to-nose point feeling that same venturi effect, then they may be able to avoid coming too close when they first "feel" the suction between two ships. The task is simplified when analogy is used, but again, students begin to focus on key relationships much quicker in the training process when cued by an analogy. That is, with the use of an analogy the concept of "slide" can be taught much quicker because there is a structure with which to link

it. An icy road may include sliding about, and ships also have that tendency. Thus, analogies build and can be linked to teach complex concepts rather quickly.

The general goal of metaphoric design is thus to develop VE training systems that are predictable based on prior knowledge and experience. Through the application of this approach, human-computer interaction has evolved into a relatively standard set of interaction techniques, including typing, pointing, and clicking. This set of “standard” interaction techniques is evolving, with a transition from graphical user interfaces to perceptual user interfaces that seek to more naturally interact with users through multimodal and multimedia interaction (Turk & Robertson, 2000). Leveraging these evolving techniques has the potential to significantly advance the design of VE training systems.

Knowledge extraction still presents a costly challenge to development of training systems. Virtual environment systems that provide rich environmental cues are becoming cheaper and cheaper. The obvious link is to capture the behavior associated with the environment as a first approximation to the knowledge and skill needed by the expert in performing a task. For example, fuzzy set theory has been used to analyze an expert ship handler’s performance within a synthetic visual environment. Relationships are derived between the commands of the human and cues available in the environment using fuzzy set theory. Those are then presented to the expert in a question and answer exploratory session to assist the expert in articulating what is important in performance of the task. This technique can save months of iterative interviews with expert performers, which is the traditional approach to knowledge extraction. Comparisons are under way between traditional cognitive task analysis and the use of fuzzy set theory for VE training systems.

Behavioral modeling can be contrasted with statistical modeling for virtual environments. That is, physics-based modeling of trajectories or impact is the standard technique used in simulation. Variation is introduced using random numbers. However, human variation is more systematic than random. For example, when one is exhausted, response time decreases. It does not fluctuate randomly but instead is generally depressed. Anxiety, fear, and stress each exert influence in a systematic way but not one describable by existing physics principles. Accurate behavioral modeling is being pursued so that as a trainee interacts with intelligent agents in a VE, it becomes difficult for the student to distinguish synthetic foe from human foe. The training session becomes more believable and more valuable. Doctoral fellowship studies are exploring insertion of anxiety and personality into VE agent behaviors.

Many complex training activities occur in groups. Expert teams are more than collections of expert individuals and exhibit certain skills such as common jargon, shared objectives, and recognition of individual differences. Some of the more subtle differences include eye contact, body posture, hand gestures, physical proximity, eye movements, and speech volume and speed. Virtual environments allow training metaphors that do just that—provide perspective from a teammate’s vantage point. Thus, certain team skills such as sharing perspective and viewing common objectives from different vantage points are a simple matter for VE systems. Application of VE to training environments requiring collaborative learning is under way.

Human computer interface characteristics weave these issues into a single VE fabric. Full immersion seems to require not only visual but also haptic, auditory, thermal, olfactory, and possibly other senses. Work on the interaction of these and their relative contribution to the sense of presence awaits an adequately complex test bed. Until it is developed, the Virtual Environment Training Program is exploring interactions based on the current state of the art and its feasibility to enhance specific training applications.

4.3 Virtual Environment Research for Infantry Training and Simulation

SIMNET and CCTT both emphasize the training of the army’s mechanized mounted force. The need for dismounted soldiers to be represented in virtual simulations and the need to

train dismounted small unit leaders in difficult environments such as built up areas led to a decision in the early 1990s to initiate a program to investigate the use of VE for training and mission rehearsal for soldiers who fought on foot. Although VE was seen as having the potential to immerse infantry soldiers directly in simulations, it was recognized that effective training requires more than just VE hardware and software. It also requires identification of: the types of tasks for which VE training is most appropriate and capable; the characteristics of VE systems that are required to provide effective training; and the training strategies that are most appropriate for use with virtual environments. In order to develop this knowledge, the U.S. Army Research Institute for the Behavioral and Social Sciences (ARI), with the support of the Institute for Simulation and Training (IST), initiated a program of experimentation to investigate those issues in 1992. Following an initial analysis of the task requirements for dismounted soldier training and a review of previous VE training research, four experiments were conducted to investigate interface effects on the capabilities of participants to perform simple tasks in virtual environments. Variables investigated included the type of control device, amount of task practice, stereoscopic versus monoscopic HMDs, and type of display device (monitor, Boom, or HMD). Three experiments were performed that addressed the effectiveness of VE for teaching route and configuration knowledge of large buildings, and the transfer of this knowledge to the real world. The results of these experiments led to a program of basic research on distance estimation in virtual environments. The next phase of the research investigated the use of VE to represent exterior terrain for training both land navigation skills (identifying landmarks and learning routes) and terrain knowledge. Finally, research was conducted investigating the use of VE for training more complex tasks. An experiment examining the effects of self-representation on performance has been completed. An experiment involving the training of two-person hazardous materials teams has been completed, and an experiment involving distributed team training is under way. Overall, the program has conducted 16 experiments involving over 600 human participants. Knerr et al. (1998) provides an overview of the results of the program.

In 1999, the army initiated a cooperative program involving ARI, STRICOM, and two elements of the Army Research Laboratory (Human Research and Engineering Directorate and the Information Systems and Technology Directorate) to address a number of critical technological challenges that prevent implementation of high-fidelity dismounted-soldier simulation. Similar to the issues identified by the navy and discussed above, these challenges include: limited field of view and resolution of visual display systems; simulating locomotion; tracking weapons and body positions; realistic performance of computer-controlled dismounted friendly and enemy soldiers; simulation of night equipment and sensor images; lack of dynamic terrain and structures; development of appropriate training strategies and methods; assessing individual and unit performance; developing training materials quickly and easily; and determining transfer of training from virtual to live environments.

The product of this effort, which will be completed in 2002, will be an integrated prototype system that includes the following components and capabilities: a locomotion platform, which provides realistic perception of movement and accurate energy expenditure; a visual system, which can simulate a variety of night vision sensors and equipment accurately; “intelligent” computer-controlled forces to represent enemy, friendly, and neutral forces; dynamic terrain, including damage to structures and rubble; and features to enhance the effectiveness of training and mission rehearsal.

4.4 Air Force–Distributed Mission Training

The U.S. Air Force is also pursuing use of VE technologies for training. Distributed Mission Training (DMT) is an aircrew training system acquisition program that evolved out of research conducted by the Air Force Research Laboratory simulation center at the former Williams

Air Force Base in Mesa, Arizona. DMT employs state-of-the-art distributed simulation technology and advanced low-cost flight simulators. The simulators are networked electronically with other aircrews located at distant bases. DMT permits pilots to remain at their home units while "flying." Pilots are learning and practicing individual and team skills in a synthetic battlespace. DMT improves the quality and availability of training, reduces aircraft operation and maintenance costs, and increases the availability of scarce resources, such as training ranges.

Crane (1999) reports on a study that defined the state-of-the-art of DMT technologies and explored their use as a synthetic training environment. The study simultaneously employed 15 virtual (human-in-the-loop) aircrews, along with dozens of constructive (computer-generated) simulations over a wide area network in order to document the technical capabilities necessary for combat mission training and to evaluate training strategies. Training missions were conducted via a secure, wide area network, using Distributed Interactive Simulation (DIS) protocols. In these missions, virtual players distributed throughout the continental United States interacted with simulated (constructive) friendly and enemy fighter aircraft, helicopters, and ground vehicles, plus enemy surface-to-air threats. Training missions were conducted for offensive air-to-air, defensive air-to-air, and close air support. At the end of 5 days of DMT-based training, participants were asked to identify the technical successes and shortfalls of the concept and to assess the potential for DMT to improve future air force training. Crane (1999) reports that overall, participants believe that aircraft and DMT-based training complement each other, with DMT being most effective for training multiship, air-to-air engagements, particularly against multiple enemy aircraft (bandits). In addition, DMT was rated as highly effective in its ability to train leadership skills. Evidently, since multiship, air combat missions are rarely practiced in fighter aircraft it is difficult for younger pilots to gain leadership experience. Instructors reported taking advantage of DMT-based training by having less experienced pilots practice their leadership skills by acting as flight leads.

DMT is a new training medium for the air force. While early studies suggest several advantages to DMT-based training, there are still challenges to full-scale implementation of DMT. Similar again to the aforementioned navy and army challenges, technical challenges of fully realizing the potential of DMT include: (a) visual-system resolution so low that it prevents trainees from determining aspect angle of friendly and enemy aircraft at real-world distances; (b) terrain databases too small to accurately represent a theater-wide environment; (c) simulator-operator stations that often constrain the way instructors want to train or make the interface with the VE much too complex; and (d) constructive entities that do not behave and respond realistically. However, despite these technical hurdles, DMT is already showing itself as the medium of choice for air warrior training.

5. FUTURE DIRECTIONS

In general, we expect that in the near future the U.S. military will continue to experience the same pressures that were discussed at the beginning of this chapter: more missions, different kinds of missions, and a continued need to constrain costs while maintaining a high level of preparedness. In addition, the U.S. military will be making increased use of digital systems to obtain and transmit more information about the battlefield to more participants than ever before. Virtual environments will be used to help design these systems, and train those who will use them. The training may well be embedded in operational systems themselves (e.g., ships, planes, and tanks).

If VE can be shown to provide cost-effective training, its use for training and mission rehearsal is likely to increase. Empirical proof of effectiveness in at least some operational training settings, not just in the laboratory, is likely to be critical to acceptance and increased use.

1. INTRODUCTION

As technological capabilities and the complexity of tasks and environments have broadened, likewise, the need for effective synchronicity and coordination of activities among members of crews, groups, teams, and collectives has increased. Decision making in these complex environments is often characterized by severe time stress, high stakes, uncertainty, vague goals, and many organizational constraints (Cannon-Bowers, Salas, & Pruitt, 1996; Orasanu & Connolly, 1995). At the core of performance success or failure is the human operator, making effective training a necessity. These factors also dictate that training for interactions among humans and between humans and machines should be conducted in a manner resembling real-life contexts (Oser, Gaultieri, Cannon-Bowers, & Salas, 1999). At the same time, growing restraints on resources have made it imperative that training methods be effective, efficient, and economical.

Virtual environments (VE) are one example of advancing technological possibilities that have allowed for expansions in training strategies. In fact, VEs are multifaceted and have the potential for individual and team training. Virtual environment technology immerses an

*The views of the authors do not necessarily represent the policy of the U.S. government.

individual or team in a perceptually realistic and interactive environment that is generated by a computer. Users are able to interact with autonomous agents (see chap. 15, this volume, i.e., virtual teammates) and/or human team members. Various combinations of multiple trainees and trainers, human or virtual, may be brought together for a training exercise in a simulated environment (Stiles, et al., 1996). This is significant, because most complex tasks require effective teamwork.

Although considerable efforts have been invested in improving VE technology, little is known about how to best use this technology for training team skills. Moreover, a strong theoretical framework to support learning in VE is lacking. Without such a framework to guide how the technology should be utilized for training, positive transfer of knowledge and skills (see chap. 19, this volume) to the job cannot be ensured (Salas & Cannon-Bowers, 1997).

The purpose of this chapter is to examine these and related issues concerning the use of virtual environments, specifically virtual teammates (VTMs) and their impact on training and learning environments. More specifically, a focus is put on an event-based approach to training (EBAT, Oser, Cannon-Bowers, Dwyer, & Salas, 1997a). Along with VE technologies, the use of a learning methodology may provide a possible solution to training in dynamic settings. This chapter initially defines related team training and technology concepts. An overview of the range of possibilities of VEs and VTMs in developing learning environments and EBAT formats follows. Finally, guidelines for the use of VEs for team training are described.

2. ASPECTS OF TEAM TRAINING

2.1 What Makes Up a Team?

Teams are a group of two or more people who work together interdependently to complete a task or to achieve a specified goal (Baker & Salas, 1997). Team members coordinate their work in a simultaneous or sequential style in order to complete a task, using specific skills and knowledge, and shared concepts or mental models of the desired goal (McIntyre & Salas, 1995; Salas, Dickinson, Converse, & Tannenbaum, 1992).

Teams and the individual members that make up teams are characterized by the level of competencies that they have, relative to what would be required to successfully complete a task or a goal. These team competencies fall into three categories. They include knowledge, skills, and attitudes (KSA). Knowledge includes the theories, principles, and concepts needed for effective team performance. Skills are the required behaviors and actions needed for thorough and successful completion of a task. Attitudes describe the team members' affective views, both individually and collectively, on their abilities and motivation to accomplish these goals (Cannon-Bowers, Tannenbaum, Salas, & Volpe, 1995). If a team's knowledge and skills are weak and their attitudes are unrealistic, the outcome will be different than expected. Thus, for effective team performance, it is important to (1) know the team's current level of competence (i.e., have clear and detailed analysis of the KSAs required for effective team functioning) and (2) design training to bridge the team's actual level of team competencies to the desired level.

Recently, Cannon-Bowers et al. (1995) have delineated an extensive list of the aspects of knowledge, skills, and attitudes necessary for effective team performance. Table 44.1 is a representative collection of some of those KSAs.

2.2 What Are Virtual Environments?

The terms *virtual reality*, *simulation*, and *modeling* are often used synonymously with virtual environments. Overall, all these terms refer to the immersion of the user into a simulated

TABLE 44.1

environment, where the user interacts with computer-generated images (Shebilske, 1993). In fact, the phrase *virtual environment* has a very general meaning. Depending on which publication is read, it may cover any simulated environment of an actual or ideal setting in which players interact with each other and/or with computerized images. These interactions may occur through written text, audio or visual communication for computer-mediated collaboration, and knowledge sharing. For the purposes of this chapter, virtual environments are defined as simulated environments creating “synthetic sensory experiences” (Kalawsky, 1993, p. 5) of an actual or theoretical physical setting in which players interact with computerized images and possibly each other through audio, visual, haptic, and computer technology for collaboration and knowledge sharing. Cognitively, VEs are supported by their multisensory representation and computerized feedback sound, graphics, and force feedback. As defined in Kalawsky (1993), VE interactions are multifaceted with three-dimensional (3-D) and real-time interactions.

Furthermore, Washburn and Ng (1997) suggest that simulations, such as VEs, must be flexible, reconfigurable, and scalable. They explain that VEs should be adaptable to the location of use and to the environment where the task is being tested. Scenarios, number of team members, and level of difficulty should be readily modifiable. Equally important, the system should be scalable for the individual or team, have local or distributed training capabilities, and wide-area networking options. Through “telepresence,” instructors should be able to observe and interact with trainees within an immersive system, allowing for training in distributed situations and within several contexts (Washburn & Ng, 1997).

2.3 What Are Virtual Team Members (VTM)?

Virtual team members (VTMs) are multifunctional autonomous agents (Stiles et al., 1996; see chap. 15, this volume) or simulated images of humans within a VE that function in the role for which they are programmed. They can work as leaders, instructors, mentors, colleagues, and teammates. They can be full-body images or disembodied images of hands and head. Their

purpose is to assist in supplying training possibilities to large-scale and possibly geographically distributed audiences.

The use of VEs and VTM can assist in supporting the necessary skills and cognitive processes needed for accurate decision making and problem solving. Trainees can work in an environment representative of the real world and interact with other teammates, both virtual and human, in real time, allowing them to train and gain experience as if being exposed to actual events and scenarios. VTM can emulate human responses and team dynamics with more realistic feedback. This opportunity is beyond what any other technology is able to contribute to training. Furthermore, through programmed instruction, skills required to effectively make decisions and solve problems in a real-life context (Cannon-Bowers & Bell, 1997) can be trained using the capabilities of VEs and VTMs.

Given that current technology is making it possible for simulated human operators to contribute in similar ways as human team members, then perhaps for training in VE it may be necessary to rethink the definition of teams to include VTMs (Zachary, Cannon-Bowers, Burns, Bilazarian, & Krecker, 1998). Traditionally, only human contributors were included in the definition; however, VTMs are likely to play an increasing, yet often inconspicuous, role in teams in the future. In terms of training, current technology has allowed for the use of both human and virtual members to make up a team, thereby expanding the possibilities and frequency of training. As such, revising this definition to include human and virtual players working together toward a common goal in VE training settings is warranted.

3. LEARNING ENVIRONMENT: ENVIRONMENTS FOR EFFECTIVE TRAINING

Although VEs have the potential to facilitate training, technology alone cannot ensure successful training outcomes (Salas & Cannon-Bowers, 1997). To effectively provide training, an environment established to promote skill acquisition and learning is necessary (Salas & Cannon-Bowers, 2000). Such environments should focus on the development of core team competencies, that is, knowledge, skills, and attitudes (KSAs; Oser, Dwyer, Cannon-Bowers, & Salas, 1998). In the design of the learning environment, several issues must be taken into account. These include the targeted training audience, task requirements, training environment, and associated interrelated components. The following framework on learning environments (see Fig. 44.1) provides a synopsis of the work of Oser, Cannon-Bowers, and colleagues (Oser et al., 1997a; Oser et al., 1998; Oser, Gualtieri, Cannon-Bowers, & Salas, 1999).

3.1 Training Audience: Who Is the Training For?

The training audience is at the center of the learning environment; thus, its needs must be clearly identified. Each team is composed of unique characteristics. An individual team's characteristics play a significant role in the manner in which a learning environment is constructed. These characteristics include: the degree to which team members hold a shared understanding of tasks and their teammates; the team's organizational structure; and the proximity of team members to each other.

More specifically, team members should have shared concepts/mental models of the process and subtasks in reaching a goal. The higher the level of shared understanding (i.e., shared mental models) between team members, the more efficient and successful goal completion (Cannon-Bowers & Salas, 1997; Cannon-Bowers, Salas, & Converse, 1993). The more team members can understand, predict, and act upon each other's and the team's needs in carrying on their responsibilities, the more efficiently the team will operate in completing a task.

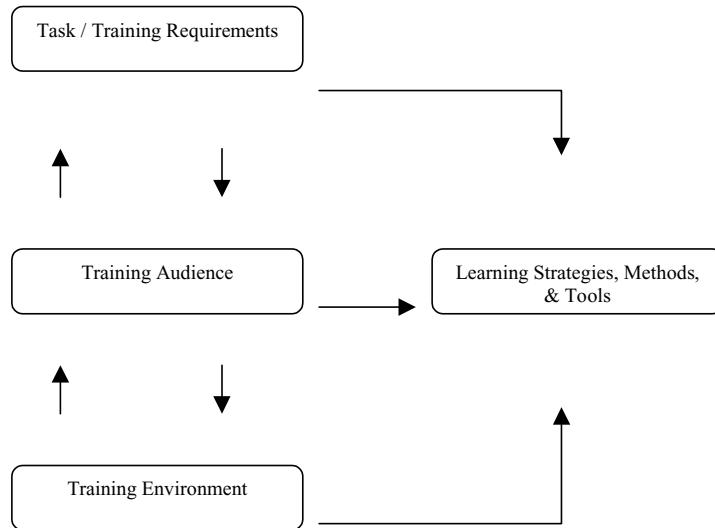

FIG. 44.1. A conceptual model of a learning environment.

Team training aiming at strengthening shared mental models has shown improvements in decision making (Blickensderfer, Cannon-Bowers, & Salas, 1998; Serfaty, Entin, & Johnston, 1998).

The team's structure is also significant in establishing the learning environment needs. The composition of team members within the team is a determining factor in how the learning environment should be designed. Different feedback mechanisms may be needed. A self-managed team may have different team dynamics than a team with a leader. In reality, organizations and institutions, and the teams within them, are hierarchical in nature. So, team-leader training may also be an issue (Smith-Jentsch, Zeisig, Acton, & McPherson, 1998). Adaptability and shared mental models are key for the members of a team to work together in an effective and efficient manner. This is especially true for teams made up of crew with diverse roles and expertise. More specifically, the methods used for information exchange and decision making are primary factors in determining the basis for the design of the learning environment. Naturally, whether team members are within the same location or have to collaborate from distributed locations influences the design of the learning environment.

3.2 Task Requirements: What Is Being Trained?

Another component in developing an effective learning environment is the characteristics that define a task. Teams must function under circumstances that often involve rapidly evolving situations, high stakes, time stress, uncertainty, vague goals, and information ambiguity. Within that context, although many factors are relevant to a task, three significant aspects include its information requirements, task length, and focus. First, however, it is important to take into consideration what type of training is required, that is, procedural versus strategic, and novel versus routine. Procedural and routine tasks are often short term and consist of planned and clearly defined steps. Novel and strategic tasks, on the other hand, often involve situational awareness, ambiguity, and problem-solving techniques. The sources of information requirements for monitoring and decision making can range from procedural to planning, management, and situation assessment. Team members need to be able to synthesize and coordinate information from a range of sources into a meaningful form.

In addition, the task may require an immediate or future focus. In time-critical situations, immediate actions are necessary and usually rely on automatic responses. Feedback is typically instant. In situations where tasks are related to future actions, necessary plans and strategies are developed over a longer time period and feedback is often not received until generated ideas are implemented. In either case, incorporation of feedback into strategy modifications is essential.

3.3 Training Environment: Under What Conditions?

The conditions of the training environment make up another variable in the learning environment design. Training environment characteristics include training frequency, length of the training cycle, level of realistic effect, and number of locations coming together in a training exercise.

How often training will take place is one component of the learning environment design. The length of the training cycle from initiation to completion is established in a learning environment to optimize the effectiveness of training. Likewise, the level of simulation should be realistic enough to allow a user to perceptually feel immersed in the setting (see chap. 40, this volume). Distracting and unrealistic characteristics should be eliminated. Yet completely realistic visuals may not be necessary, and at times counterproductive.

In considering another aspect of the training environment, distributed training (DT) has become a feasible option for convenience, economic reasons, and reliability in training. With the same training possibly being necessary in more than one location or with people in various parts of the world needing training on a specific topic, DT has certain advantages. Knowing whether the training is local or distributed plays a role in the design of the learning environment.

4. EVENT-BASED APPROACH TO TRAINING: STRATEGY FOR EFFECTIVE TRAINING

One avenue for structuring in a learning environment is an event-based approach to training. EBAT provides the strategies, methods, and tools that are essential for an effective learning environment (Salas & Cannon-Bowers, 1997) in a structured and measurable format for training and testing specific KSAs. In order to precisely control, measure, and benefit from user responses to events, a cyclical layout of EBAT has been established (Cannon-Bowers, Burns, Salas, & Pruitt, 1998).

EBAT allows for training and testing through simulated scenarios, where planned events are introduced to test specific skills that would be required in real-life situations. Systematic linkages of the strategies, methods, and tools of EBAT have been used to establish learning environments in a wide array of settings (Oser et al., 1998). Some of the competencies trained with EBAT have included situation assessment, decision making, planning, and resource management (Oser et al., 1997a; Oser, et al., 1998). At the same time, learning environments and EBAT methods have resulted in measures that are psychometrically strong and that have improved performance in a variety of settings (Dwyer, Oser, & Fowlkes, 1995; Fowlkes, Lane, Salas, Franz, & Oser, 1994; Johnston, Smith-Jentsch, Cannon-Bowers, 1997). EBAT success has been demonstrated in research of aviation events (Fowlkes et al., 1994), command and control (Johnston, Cannon-Bowers, & Smith-Jentsch, 1995), multiservice environments (Dwyer, Oser, Salas, & Fowlkes, 1999), and virtual environments (Hays, Vincenzi, Seamon, &

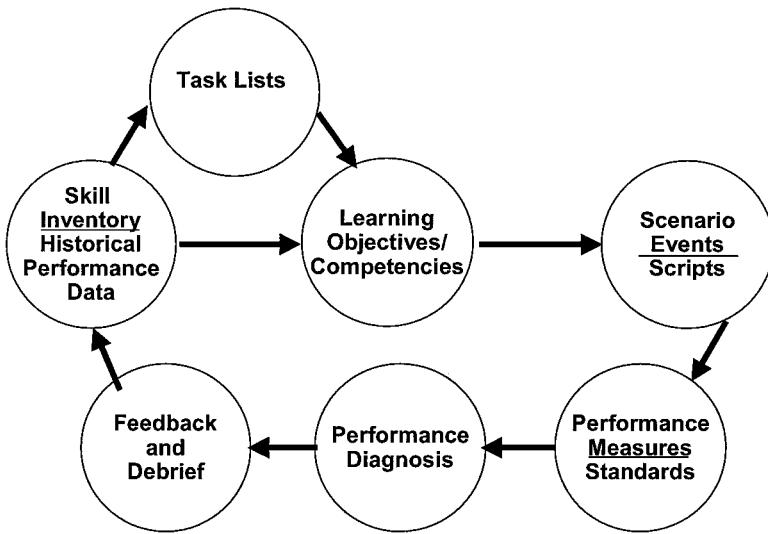

FIG. 44.2. Components of the EBAT cycle.

Bradley, 1998). Specifically, it has been shown that for effective training, performance measurements are required (Cannon-Bower & Salas, 1997) and that those measurements can provide, beyond description and evaluation, diagnostic information (Cannon-Bowers et al., 1998).

The concepts of EBAT are reviewed in this section. This review is based on research conducted by Cannon-Bowers and Salas (1997), Cannon-Bowers, Burns, Salas, and Pruitt (1998), Oser et al. (1998), Johnston et al. (1997), Fowlkes et al. (1994), Dwyer, Fowlkes, Oser, Salas, and Lane (1997), and, Dwyer et al. (1995). The seven steps of the EBAT cycle are depicted in Fig. 44.2.

4.1 Skill Inventory/Performance Data

Through techniques such as task analysis, cognitive-task analysis, and team-task analysis, a team's level of KSA core to performance are determined. Other techniques used can include knowledge elicitation procedures. Past behavioral records of trainees are used to establish the required skills for successful completion of a task and to identify typical deficiencies in those skills. It is important to know where trainees stand in comparison to behavioral representations of a realistic and desired course of action toward an event.

4.2 Learning Objectives/Competencies

Based on the skill inventory, learning objectives and required competencies are then outlined. As specific KSA deficiencies are determined, then associated learning objectives and requisite competencies become the focus of the training. These can be related to a specific task or can cover general competencies ranging over many tasks. Objectives and competencies become the root-source when developing scenario events.

4.3 Scenario Scripts/Trigger Events

Based on the task analysis, the learning objectives, and previous performance measurements, a scenario is developed. “Trigger events,” or conditions, are designed for each learning objective to test for possible deficiencies in that specific training objective. Events can vary in number, location/timing in the exercise, and in degree of difficulty. For a realistic and continuous effect and for precise data collection, the scenario must be modifiable to user’s responses in real time. The specifics of the scenario and event design are included in a master scenario event list (MSEL). For effective outcomes, the goal is to design events that will test the user’s mastery level of specific skills based on the learning objective.

4.4 Performance Measures/Standards

Performance measures and standards must be designed to assess the user’s mastery level and will assist in explaining why users performed as they did (see chap. 35, this volume). Effective measures, which are directly related to events, involve strategies and tools used and vary according to objectives being tested. Measurement methods can be through observation, semiautomated, or automated techniques. It is recommended that a multifaceted approach be used toward measurement. Examining the outcomes and processes of decision making through data collection is vital to feedback (see Fig. 44.3). Outcome measurements contribute general information on performance, whereas process measurements provide diagnostic information on the causes of performance levels. The strategies and tools used should be capable of detecting patterns and trends in performance and should provide related diagnostic feedback.

4.5 Performance Diagnosis

Based on the information obtained from performance measures and standards, it is possible to diagnose performance. These diagnoses provide insight into competencies. Causes of performance problems are examined by looking at possible deficiencies in skills, knowledge, and competencies. Diagnostic mechanisms must be based on linkages to the EBAT stages of Performance Measures and Standards (see section 4.4), Scenario Scripts and Trigger Events (see section 4.3), Learning Objectives and Competencies (see section 4.2), and Skill Inventory and Performance Data (see section 4.1), so that conclusions drawn can be relevant and mapped back to required competencies.

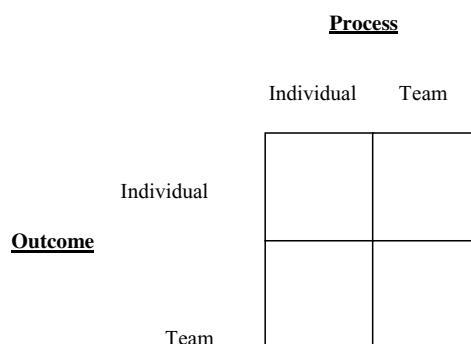

FIG. 44.3. Individual and team issues in process and outcomes.

4.6 Feedback and Debrief

Based on the diagnosis, constructive and specific feedback directly related to learning objectives must be provided, either immediately or at the completion of the task. This process will then enable users to focus on changes necessary for improved performance. The timing of feedback depends on the skill being tested and the performance level sought (Smith-Jentsch et al., 1998). After-action reviews (AAR) cover the debriefing and feedback information. By focusing on the learning objectives, events, and performance measures, the internal consistency of a training exercise is enhanced.

5. INCORPORATE INTO FUTURE TRAINING AND ARCHIVE DATA IN A MEANINGFUL MANNER

Lessons learned from the exercises can be addressed in future training exercises. Knowledge gained on deficiencies in the trainees' abilities and on their present mental model of the event can be incorporated into the training design. The focus of learning/training objectives should be on increasing user's knowledge and not merely repeating information or skills that have already been mastered. Over time, the pattern within archived data will assist in establishing a behavioral representation, or "norm," for comparisons.

The following sections discuss a vision of possible uses of VEs and VTMs in learning environments and EBAT for addressing team training issues. It is important to note that currently the technology to use VE and VTMs as fully interactive and intelligent learning tools is still at its early stages. As previously discussed, it is important for effective training to have both adequate tools and a well-structured theoretical basis. Thus, for successful merging of tools and learning theories a common vision of an intelligent, instructional VTM should be established. This chapter does not address the technical, programming, and modeling aspects of VEs and VTMs (see chaps. 12, 13, and 15, this volume). This chapter attempts to project a vision of how VEs and VTMs could be used within strong learning theories to enhance effective team training once the technology is available.

6. USING VE AND VTM TO ESTABLISH EFFECTIVE LEARNING ENVIRONMENTS

As with all educational technology, the theoretical framework for educational VEs should be based on learning theories, such as active learning, training through apprenticeship, and collaboration-based learning principles (Grant, McCarthy, Pontecorvo, & Stiles, 1991). In most contexts, these learning principles can be most fully implemented in situations where one-on-one attention or close monitoring of a group is available. For large-scale and distributed situations, these efforts are difficult, if not impossible, to achieve. As a result, the use of VTM can be advantageous. While some VTMs can be used for individual training, other VTMs or human instructors can work with groups or teams.

In order to have realistic apprenticeshiplike training, three VTM characteristics should be present. The behaviors of VTM should be responsive to changes in the VE caused by outside events or human team members or other VTMs. VTMs should be able to have an understanding of the relationships and rational of tasks, subtasks, and associated steps in order to provide appropriate direction to trainees. Lastly, VTMs should be designed with an understanding of the relationships between task roles to be able to encourage development of collaboration and cross training (Stiles et al., 1996). These aspects have implications for the design of VTMs.

Other areas that should be taken into account are the VE interactions of human to human, human to VTM, VTM to VTM, human to scene, and VTM to scene in terms of representation and visual and verbal communication (Stiles et al., 1996). The following sections delineate how VTMs and VEs affect the learning framework presented previously.

6.1 Training Audience: Who Is the Training For?

Virtual environments and VTMs can adapt to the unique characteristics and needs of a given training audience. Virtual teammates can function within and facilitate training with team issues, such as shared mental models, organizational structure, and proximity of team members in a flexible manner to meet trainees' needs. VTMs can make individual attention available for a trainee or team's unique needs. If one or few individuals or teams need further instruction in a specific area, VTMs can provide this training without slowing the overall training process for other trainees or requiring human instructors to attend to specific needs. These individuals or teams can then join the larger group when ready, which, in turn, may be led by another VTM.

As mentioned, VE and VTM technology can assist in the development of shared mental models. If the desired mental model is programmed into the VTM and the VTM requires trainees to respond accordingly, eventually the trainee should learn to make predictions and develop a similar mental model to meet expectations. Realistic features of VEs may build mental models that more accurately represent real-life scenarios and therefore better prepare the player to respond appropriately (Cannon-Bowers et al., 1993). In return, consistency offered by the VE makes it easier to pinpoint errors in players' mental models. Additionally, VTMs can play any roles assigned to them, such as functioning as team members in order to force human team members into other roles to assist cross-training and shared mental model development, or simply replacing missing human teammates.

At the same time, differences in the needs of teammates working in either close or distant proximity from each other can be addressed through VEs and VTMs. Virtual teammates and VEs can help to focus on skills required for teamwork and collaboration from distributed sites. Hence, they can help one understand, as well as train, distributed teamwork. On the other hand, VTMs can provide distributed training on a general basis while giving individuals additional instruction as needed.

6.2 Task Requirements: What Is Being Trained?

Task characteristics include information requirements, task length, and focus. Skills, such as coordinating and synthesizing information for monitoring, situation assessment, and decision making can be modeled by a VTM. The VTM can then test the trainee and provide feedback. More so, the VTM could easily be programmed to demonstrate or train for procedural, strategic, novel, or routine tasks. Communication and demonstration of desired concepts could be displayed through video, audio, or with computer messages. Moreover, the use of VE and VTM will allow for repeated training in time critical situations that may otherwise be inaccessible. Interactions with VTM would allow for continuity of information flow at real-time speed.

6.3 Training Environment: Under What Conditions?

Other than in real-life situations, no other environment can provide a more realistic training environment than simulation. With issues of locations, equipment and team member availability, safety, desire for consistency, and economical constraints, VEs and VTMs appear to be viable options. They can provide consistent, controlled, and repetitive training through their own simulated environment and equipment. The length of the training cycle, level of realistic effect, and number of locations coming together for a training exercise are easily manipulated

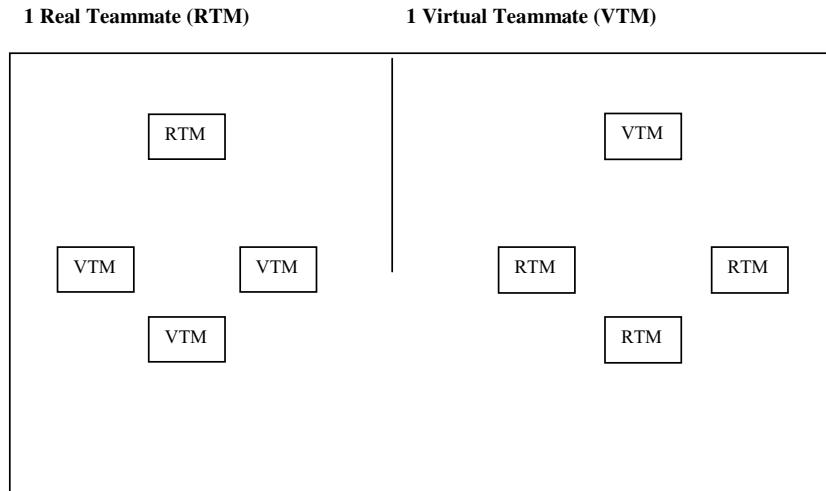

FIG. 44.4. The involvement of VTM in teams can range from one to all but one, depending on training need.

in the context of VEs and virtual teammates. For example, the STEVE (Soar Training Expert for Virtual Environments) VTM (Stiles et al., 1996), can be available in full body or with just head and hands. By allowing this option, the STEVE VTM can demonstrate a procedural task without obstructing the view of the equipment he is discussing or other relevant items (Stiles et al., 1996). In addition, advancements in VEs and VTMs can help bring people together from throughout the world to train, collaborate, and communicate. Virtual environments can provide a common location and training ground. As another advantage, VTMs can work as instructors or fill-ins for missing colleagues. The use of VTMs in a training environment can range from using only one in a team to using all VTMs and only one human trainee.

6.4 Interrelated Components of a Learning Environment: How Should It Be Trained?

The use of VE and virtual teammates technology allows more flexibility in training while at the same time providing a means to more accurately test and control for specific training strategies and related measurement methods. Specific cognitions (knowledge) and behaviors (skills) can be reinforced with VEs and VTMs. Use of VEs and VTMs gives the advantage of moving the VTM from instructor to colleague as needed to allow trainees to attempt different options and learn to self-correct when wrong. The systematic, deliberate approach provided by VEs more clearly points out proficiencies and deficiencies in an individual's or team's knowledge and abilities and the direct impact of these traits on the process and outcome of actions taken.

Within the learning environment, EBAT can be used to strategically test for and train specific required skills. The ways that VTMs and VEs could be used within EBAT are described below.

7. VE AND VTM CONTRIBUTIONS TO AN EVENT-BASED APPROACH TO TRAINING

The following sections discuss the strengths and benefits of using VTMs for training skills and building a desired knowledge base. The application of VTMs within the EBAT cycle are then described. The well-structured and consistent form and repetition of VEs and VTMs

assist in training novices to identify, categorize, and encode information. Through repeated practice in controlled environments, novices can have a number of practice opportunities on a specific situation to assist them in learning to efficiently organize information and add to their knowledge. This is supported by work by Noble, Grosz, and Boehm-Davis (1987), who found that knowledge templates are directly related to naturalistic decision making. They explain that templates develop when cues from the environment are recognized and recorded as a pattern within an individual. When cues come up again, associated and previously successful behaviors are recalled and used. Therefore, it can be assumed that the structured, repeated practice available through VEs and VTMs could assist in perfecting such templates. Moreover, Klein (1989) showed that through these organized knowledge templates, experts are more likely to successfully execute an effective solution for a given problem. This would be especially important in team situations, and in developing shared mental models of required behavior and decisions.

These same characteristics of VE and VTM can assist in precise situation assessment. Situation assessment is the capability to recognize meaningful cues, causes, and patterns in the environment (Glaser, 1986). Stout, Cannon-Bowers, and Salas (1996) defined three primary considerations for accurate situation assessment: (1) assessment of cues and cue pattern within a situation; (2) team processes for cue-related information sharing and shared mental model development; and (3) type and content of these shared mental models leading to interpretation, decision making, and action. The ability to assess a situation well could lead to reduced workload and could assist in information processing, knowledge encoding, and response facilitation (Means, Salas, Crandell, & Jacobs, 1995). According to Cannon-Bowers and Bell (1997), cue and pattern recognition is required for situation assessment. The ability to effectively link cues makes an individual or team more efficient (Means et al., 1995). Moreover, Klein (1995) points out that being able to distinguish between relevant and irrelevant cues and patterns is equally important in successful problem solving. Wickens (1984) found that internal representations of the environment and identification of causal relationships are established through underlying patterns developed from experience or training. The primary method in developing these skills is practice. By containing solution options (Cellier, Eyrolle & Marine, 1997) or through repeated practice trials (Means et al., 1995), VE simulations allow opportunity for such representations to develop.

Another decision making requirement is monitoring a system for faults. For this to be done successfully, one must understand and be familiar with the system. Because most natural settings are "fluid in nature" (Cannon-Bowers & Bell, 1997), it is vital that teams are able to collect and evaluate information from the system in a dynamic environment. Metacognition of team members, where they evaluate their own performance, is vital for self-correction and can be facilitated through appropriate feedback (Cohen, Freeman, Wolf, & Militello, 1995). Glaser (1986) suggested that these skills be developed through practice and should be encouraged in novices. These skills can be advanced in a VE or through interactions with virtual teammates by providing multiple situations in which to self-examine decisions and skills used (Oser et al., 1999). Plus, virtual environments and virtual teammates are thought to add to high interobserver reliability, internal consistency, and interexercise correlation.

While VTMs have not yet been formally used in conjunction with EBAT, the following section provides a vision of how VTMs could be used to support EBAT.

7.1 Skill Inventory/Performance Data

The initial step in the EBAT cycle is to accurately identify and define behavior and responses that trainees should develop. Information from previous databases is used to define the domain of skills and behavioral representations that would be preferable in a given scenario.

Information gained from these representations can be incorporated into databases of behavior patterns and used to comparatively evaluate trainees and teams for deficiencies and proficiencies in those behaviors. Virtual environments and VTMs could then be designed to focus on the specific information gained through knowledge elicitation procedures and cognitive task analysis.

7.2 Learning Objectives/Competencies

Given the range of potential behavioral representations and deficiencies, learning objectives can be established to support their development. As deficiencies in KSAs are determined, associated learning objectives can be targeted and programmed into VEs or through VTMs. This will enable focused training to take place. A format of the desired mental model for all trainees would be the basis of the development of the learning objectives. VTMs could be programmed to teach, test, and give feedback to the user based on the objectives. More so, the ability for consistency in repetition would ensure congruency in the repeated practice of a weak skill and in the teaching methods and strategies toward appropriate mental models. Virtual teammates could hold different positions, as team leaders or subordinates. The position of virtual teammates could change to allow for training or testing of different levels of interactions and skills. By being able to alternate the position of virtual teammates, there are greater opportunities to change team members' positions, allowing for testing of the dynamics within a group under different leadership conditions, and with various levels of expertise. Greater cross-training opportunities are also afforded, which are linked to improvements in shared mental models.

7.3 Scenario Events/Scripts

By far, one of the areas in EBAT that would most benefit from VEs and VTMs is scenario and event execution. Manipulations of VEs and VTMs would become significant components of the scenario/event itself. Complexities and inconsistencies of developing training for real-life settings can be avoided. At the same time, these technologies would have flexibility in their design so that, beyond what would be feasible in a real-life context, numerous variations to an event could be used. Consequently, the user could learn to adapt his or her skills to the inconsistencies of the real world. As aforementioned, VTMs could give individual attention to trainees as needed, while allowing others to continue forward. Likewise, VTMs could introduce events by function (i.e., novice versus expert), allowing the user to train under various circumstances, or they could be designed to work with trainees ranging in expertise. Training from embedded expert operator training models could be precisely and realistically replicated by simulated teammates and technology.

Virtual environments and VTMs can be programmed to introduce events with high time pressure and intensity by controlling for allotted time and number of subtasks required by each team member for successful task completion. Results of decisions and alternatives can more realistically be played out and witnessed through VEs and virtual teammates (Gualtieri, Parker & Zaccaro, 1995). Research shows that structured repetition and better control over the stimulus in simulation is made possible through computers (Oser, Cannon-Bowers, Dwyer, & Salas, 1997a). Moreover, manipulation of variables and other features is easier in a computerized environment (Oser et al., 1997a).

The use of VEs and VTMs establishes consistency in testing a number of trainees in a specific event and scenario. Likewise, in situations such as distributed training, consistency in testing can be held while still enabling players to affect the environment. Using VEs and VTMs allows for theoretical concepts to be more easily tested and for hands-on training and practice.

Other modes of communicating and reinforcing information beyond the visual benefits of VEs and VTMs include audio and computer message capabilities.

7.4 Performance Measures/Standards

Developing effective performance measures can also be aided by VEs and VTMs. Since a scenario event is programmed into the system, likewise, the points of desired measurement could also be programmed. Thus, at specific times, the VTM or event could signal a performance measure. More so, because behavior of the events themselves and the VTMs can be held as constants, the specific responses of users are more accurately measured. In return, VEs and VTMs can be used to guide and focus the task and to collect data from performance exercises in terms of procedures and outcomes. Because these are computerized tools, the precision of measurement itself would be higher. As data accumulates, patterns of actual behavior could be established. These then could then be compared to the behavioral representations that were the basis of the learning objectives.

7.5 Performance Diagnosis

Reliable data and the ability to directly test specific actions and outcomes may be attained through the use of VE and VTM technology. As discussed above, the system can be programmed to monitor for patterns and significant links of action to outcomes or responses to specific situations as it is recording data. An evolving inner cycle between an event, associated performance measures, and resulting diagnosis and modification permits adaptive aiding. Specifically, as performance patterns develop from gathered data, diagnosis of users' expertise is made. The VTM is then able to adapt to an individual or team's level (as is often done with many personal computers). Based on performance observation of team members and comparisons to standards, the VTM would adjust itself appropriately. For example, if trainees performed better than expected standards, the VTM could increase the level of difficulty of an exercise. One method could involve the VTM making many mistakes, placing trainees in a situation of having to use more complex and diverse skills to remedy the situation. On the other hand, a VTM could also decrease the level of difficulty if trainees fall below norm in order to allow them to strengthen basic skills and build up to standard. These modifications could continue throughout an exercise and conclude at the end of the allotted time or once an end point in the exercise was reached.

7.6 Feedback and Debrief/Link to Learning Objectives

Feedback can be immediate/real time or at the completion of an exercise and can take several forms. A VTM or the VE itself could respond to a user's actions, showing the resultant consequence or interpretation of choices made or giving an overview at the end of a scenario of all actions taken. The VTM could be used during feedback/debriefing as an instructor, mentor, or colleague. A VTM could demonstrate a task while explaining it, give further explanation and answer questions as necessary, monitor and guide the user, and then follow up with feedback on performance. Clear feedback, directly related to learning objectives, would easily be given by a VTM and virtual environment. The VTM could act as a mentor or as a teammate and give guided feedback accordingly in real time. At the completion of the exercise, feedback of the performance throughout the exercise could be given. The VTM could provide this feedback as a teammate, showing how different decisions and behaviors would have led to better outcomes. The VTM could also function as an instructor, demonstrating, discussing, asking, and answering questions to facilitate discussions between teammates.

7.7 Incorporate Into Future Training and Archive Data in a Meaningful Manner

The patterns of computerized information provided by VEs and VTMs can more precisely and easily be recorded than that of human, possibly largely subjective, data keeping. Insights and lessons learned regarding behavioral representations and patterns and mental models could be used to establish a standard from which to judge deficiencies and proficiencies.

8. APPLICATION OF VE AND VTM IN TRAINING

In summary, the use of VEs and VTMs within EBAT takes the following form. Having established desired behavioral requirements to be trained, the instructional programmer would develop and input related learning objectives and significant relationships between them. Scenarios with built-in trigger events would then be designed by the program to test for trainees' deficiencies in the learning objectives. Interactive VTMs within the VE would be able to function as tutors, collaborators, and team members, as appropriate. Their purpose would be to support trainees in learning how to perform procedural tasks by demonstrating, explaining, monitoring, and assisting the trainees. In this case, one or more human team members could participate, with the VTMs being able to observe, diagnose, and introduce suggestions. As each trainee or team interacted with the VE and VTMs, this performance would be measured and diagnosed for patterns. Based on this information, the level or type of remediation that should be presented would be determined. The VE-VTM computer technology would use adaptive aiding to adjust to the trainees' level of expertise, whether individual or team, as many personal computers have the capacity of doing. Finally, feedback during the scenario exercise and afterward would be provided based on learning objectives.

As previously discussed, VTM technology must possess some essential characteristics to be successful in the role just described. First, it is important that all actions by a team member are obvious to all other team members. In addition, to allow for VTMs to do their part in recognizing human actions and interactions, VTMs need to be developed containing models of team member's possible actions, related outcomes of those actions, and relationships between them (Johnson, Rickel, Stiles, & Munro, 1998; Rickel & Johnson, 1998).

Beyond the benefits of physically seeing VTMs through the visual component of VEs, auditory and computerized messages would contribute to communication to and from teammates. Audio messages and voice recognition technology would assist in the verbal communication component. Since the military uses specific phrases for communication during tasks, it is relatively easy to program these so a VTM may verbalize and understand this communication (Zachary et al., 1998). Nonverbal communication by VTMs is also possible through programmed gestures, facial expressions, and gazes (see chap. 10, this volume). Confirmation of understanding and turn taking continuity are two areas that benefit from these options.

VTMs would also be programmed to understand and respond to questions in various forms, communicate instructions while demonstrating a task, notice students' focus of attention, and provide redirection as needed. Communication between human trainees and VTMs could be in the form of verbal communication through voice recognition devices, digital messages, e-mail, or haptic devices (see chap. 4–6, 10, this volume). VTMs' flexibility and adaptability allow students to make mistakes, recover from them, and learn from them. With the possibilities offered by VTMs, along with the greater possibilities of VEs alone, training opportunities are increased (Johnson et al., 1998; Rickel & Johnson, 1998).

Examples of VE use and VTM behavior include Training Studio, a 3-D VE for training, and STEVE, a domain-independent, interactive VTM that can function as a mentor or as a team

TABLE 44.2
The Effects of Using VTM in EBAT

Scenario/Event-Based Approach to Training	EBAT Steps With VTMs
1. Skills inventory/performance data	<ul style="list-style-type: none"> • Take a baseline reading of current KSAs on task.
2. Learning objectives/competencies (KSA)	<ul style="list-style-type: none"> • Based on current KSA level and desired KSA level, learning objectives are established.
3. Scenario events/scripts	<ul style="list-style-type: none"> • Scripts for “trigger events” are designed to test specific KSA items based on the learning objectives.
4. Performance measures/standards	<ul style="list-style-type: none"> • Outcome and process measurements are taken through observation, automatic, or semiautomatic techniques.
5. Performance diagnosis	<ul style="list-style-type: none"> • Performance levels are examined for deficiencies, patterns, and causal relationships.
6. Feedback and debrief	<ul style="list-style-type: none"> • Feedback and debriefing should be directly related to the learning objectives.
7. Incorporate and archive lessons learned	<ul style="list-style-type: none"> • Data stored in a meaningful manner will collect to build a performance “norm” for future comparisons.
	<ul style="list-style-type: none"> • Identify and define behavioral representations from previous databases. • New information gained through VE and VTM exercises can be added to the behavioral databases. • Based on behavioral representations and related deficiencies, learning objectives can be developed and programmed into the VE and the VTM actions. This would allow for focused and consistent training, leading to greater shared mental models and skill building. • The scenario/event itself would be displayed through the VE and the actions of the VTMs. Real-life contexts and numerous variations of them would be possible while keeping consistency in exercises and measurement variables. VTMs could be used in multiple manners. Provides repeated and consistent “hands-on” training and practice involving high-intensity and time-pressure situations, multiple procedures, various expertise levels, and problem-solving and skill adaptation. • Data from trainee responses would more accurately be measured with advanced computer technology, such as that used with VEs and VTMs. Behavioral patterns could easily be compared to behavioral representations of desired behavior and to the learning objectives. • Behavioral patterns would be examined and diagnosed. Modifications to the scenario/event would be made based on the user’s expertise level. • Feedback could be immediate or at the end of the exercise by the VTM. The VTM could provide the feedback in several forms, as instructor, mentor, or teammate. • Computerized information can be easily stored to be incorporated into behavioral databases to establish a “norm” for comparisons and for future training scenarios.

member to facilitate learning of tasks that are physical and procedural (Johnson et al., 1998; Rickel & Johnson, 1998; Stiles et al., 1996).

Table 44.2 summarizes some aspects of using VE and VTM effectively in an EBAT format.

9. GENERAL GUIDELINES FOR USING EBAT

Table 44.3 provides recommendations based on the merging of EBAT, learning environment methodology, and VE technology. The guidelines are grouped into two general and nonexclusive categories, learning environment and virtual teammates.

TABLE 44.3
General Guidelines for Use of EBAT with VTMs

Learning environment characteristics

1. When establishing a learning environment to be used with VTM, a conceptual framework should be used.
2. Establish and reinforce the learning environment through EBAT learning strategies, methods, and tools and programming of VEs and VTM.
3. Use VTM in a way that allows learning strategies, methods, and tools to build systematic linkages between the EBAT steps of learning objectives, scenario/event development, performance measurement and diagnosis, and feedback.
4. Appropriate feedback of trainees' performances through VTM can be provided immediately/real time or delayed until the end the exercise.
5. Using predefined events, VTM provide opportunities for pinpointing a training audience's deficiencies and proficiencies in learning objectives and for practicing new skills or maintaining old skills.
6. Techniques used for scenario management or the use of VTM versus another human teammate should not be apparent to the trainee and should not in any way restrict decisions or actions made.

VTM characteristics

7. VTM should be designed to demonstrate and build critical competencies, such as information processing, situation awareness, and reasoning and monitoring skills.
 8. VTM should have the ability to hold different ranking positions within a team and should be able to represent various levels of expertise.
 9. VTM should have the ability to demonstrate and explain tasks and procedures. VEs and VTM may also be used to facilitate instructors with monitoring, assisting, and giving feedback to trainees.
 10. VTM can be designed to have the ability to fill in for missing team members or to provide individuals with team training. Ideally, VTM should be inconspicuous in their interactions with other teammates.
 11. Behaviors of VTM should be responsive to changes in the VE caused by outside events, human team members, or other VTM.
 12. VTM should be able to have an understanding of the relationships and rationale of tasks, subtasks, and associated steps in order to provide appropriate direction to trainees.
 13. VTM should be designed with an understanding of the relationships between the task roles to be able to encourage the development of collaboration and cross-training.
 14. Virtual environments should be adaptable to the location of use and environment where task being tested would be used.
 15. Scenarios, number of team members, and level of difficulty should be readily modifiable. The system should be scalable for individual or team, have local or distributed training capabilities, and wide area networking options. Through "telepresence," instructors should be able to observe and interact with trainees within an immersive system, allowing for training in distributed situations and within several contexts.
-

10. CONCLUDING REMARKS

Changes in the world involving global markets, geographically distributed team members, and military personnel stationed abroad have placed new demands on training. There is a greater need for effective, efficient, and economical training methods. Furthermore, training that ensures that task consistency and the integrity of learning objectives are strongly maintained is imperative. Researchers and trainers, using carefully controlled VEs depicting large scale collaborative or enemy response scenarios, can respond to these demands by being able to test one or a small number of trainees in a simulated environment depicting a real-life context.

Training, especially for dynamic and time-stressed events, is complicated. Technology alone should not be thought of as the key to successful training. Vital for effective training outcomes are consideration of the learning environment and structured methods and

strategies, as found in EBAT. Discussed in this chapter were the theories behind effective learning environments, the uses of EBAT, and the contributions of VEs and VTMs to these approaches.

Both VEs and VTMs have a number of potential advantages, such as providing a realistic representation of a scenario or location, data collection, and effective, efficient, and economical training for team synchronicity and appropriate responses to real-life events. Users are able to rehearse scenarios under varying conditions relating to intercrew communications, interdependent task completion, and team dynamics. Together, effective learning environments, structured training methodologies such as EBAT, and VE and VTM tools will be able to provide innovative and effective approaches to training.

1. INTRODUCTION

This chapter concerns itself with the use of virtual environments (VEs) for learning of the kind expected to occur in schools, colleges and universities, that is, the acquisition of general problem-solving skills, mastery of facts and concepts, and improvement of the learning process itself. The chapter systematically explores the potential of VE for education as well as potential obstacles to its use. As of mid-2001, there are no commercially available VE systems deployed for regular instructional use in K–12 or university education, so this review relies on research projects for insight. In analyzing the major experiments thus far carried out, one can discern various combinations of three basic educational approaches to VE: *exploration*, *world building*, and *world sharing*. This chapter is not a general survey of VE-based educational research. Rather, it examines in some detail six research projects, focusing on two of these projects to explore each of the approaches above. An excellent survey of the educational use of VE technology can be found in Youngblut (1998).

2. USE OF VE TECHNOLOGY IN EDUCATION

2.1 What Is VE?

Virtual environments denote a real-time graphical simulation with which the user interacts via some form of analog control, within a spatial frame of reference and with user control of the viewpoint's motion and view direction. This basic definition is often extended by provision for multimedia stimuli (sound, force feedback, etc.) by consideration of immersive displays (i.e., displays that monopolize one or more senses), and by the involvement of multiple users in a shared simulation. However, many interesting educational systems involve only the core definition.

2.2 Why Might VE Matter to Education?

Ever since the first computers, people have been suggesting that well-designed simulations could provide access to learning experiences that are simply unavailable via normal means. Virtual field trips consume no jet fuel; simulated laboratories do not explode; virtual dissection kills no animals. Many personal computer (PC)-based simulations have pursued this dream, with varying results (Weller, 1996). Virtual simulations add the specific requirements of a spatial metaphor and free viewpoint motion. Why is it believed that this structure would be superior to a more abstract presentation?

Consider a chemical experiment presented via a two-dimensional (2-D) schematic graphical rendering on a computer screen. An Erlenmeyer flask contains a basic liquid solution. As the student clicks on-screen button controls, a calibrated pipette drips acid into the flask until the dye changes color, indicating neutralization. Quantities are noted and calculations performed.

The same experiment in a virtual laboratory would be located on a realistic, perhaps scarred and beat-up countertop. The user is free to look and move around the lab. Perhaps the user has to find the Erlenmeyer flask in a drawer, set it up properly, use correct safety procedures with the acid and basic solutions, and run the risk of breaking equipment if it is handled too abruptly. In short, the virtual laboratory (like a real laboratory) is intended to teach the culture of the experience, whereas the 2-D schematic laboratory teaches the conceptual core of the experience. The culture consists of the collection of constraints, risks, and procedures that a real chemist must consider in doing the job. Real-life lab experience is usually complemented by classroom instruction to provide the concepts, precisely because the cultural lab experience is so information rich that the conceptual core is obscured.

The story about the chemistry experiment obviously added more than free viewpoint motion to the abstract example. It added a world worth moving through, a context in which the user has choices. These options range from the simple selection of the correct glassware, to the decision to wander away from the lab counter and see what else is in the virtual world.

In a real lab, students make some choices based on learning styles (Gardner, 1993). Some students need to experience direct consequences of manual actions to grasp causal relationships. Others need to say what they see. Still others need to hear or read explanations. The virtual lab is intended to provide a rich set of such choices and to make them accessible in natural ways.

But if all this could be accomplished, would it actually improve education?

2.3 Why Might VE Be a Red Herring for Education?

There are two essential obstacles to the rosy vision described above: design and pedagogy. Let us assume the existence of affordable, reliable VE software and hardware. The creation of richly detailed virtual worlds must still somehow be supported, in which the glassware clinks, the wooden desktop thunks, and, most importantly, when a user does something unexpected (e.g., drops a paper clip into a beaker of liquid), something plausible happens. There are several dilemmas:

- Building richly detailed worlds is very expensive (see chaps. 12–13, this volume). Commercial video games currently cost over \$1 million to produce, and they set the standard by which kids will judge virtual worlds.
- If a fascinating, complex world is built, is it actually helping or hindering the kids' learning? Is all this intriguing simulation really bribery, or does it pay its way?

There are those (e.g., Postman, 1985) who stoutly assert that television, even the best educational television, is destroying our kids' ability to deal with abstraction. The written word

requires a continuous positive act of the imagination as one reads. Television, and possibly high-fidelity VE as well, do most of the work for you. Thus, Postman would probably assert that the better (and more appealing) a design gets, the further one moves from an ideal learning environment. From a slightly different perspective, Wickens (1992) argues that natural and easy-to-use interactions may reduce a student's retention because less effort is expended.

On the other hand, there is a substantial body of scholarship (described below in more detail) that asserts the value of "situated learning," of providing tasks within a realistic story, with appealing characters and situations. Humans emulate heroes and want to be admired as new heroes. Virtual environments may provide enough story structure and detail to enable learners to remain engaged with tasks, which they would have abandoned in other forms. It may empower learners whose cognitive styles will never resonate with traditional, linear book culture. Active engagement with rich simulated worlds may help students to construct their own mental models.

The following section establishes some essential principles and terminology for discussing kinds of learning, and educational theories such as constructivism and situated learning. Sections 4 through 6 explore, respectively, the following domains:

- Exploration of prebuilt worlds as a *constructivist* learning activity
- Creation or modification of worlds as a *constructionist* learning activity
- Role-playing by multiple participants as a *situated learning* activity.

Each section includes a description of two experimental projects. A final section then summarizes the state of knowledge and poses challenges for the future.

3. A CONCEPTUAL FRAMEWORK

A commonly cited taxonomy for learning (Gagné, Briggs, & Wager, 1988), describes five categories of learning outcomes:

- Intellectual skills and procedural knowledge
- Verbal information
- Cognitive strategies
- Motor skills
- Attitudes

The Gagné taxonomy is one of the standard tools for instructional design; its structure reflects the traditional academic focus on reading and writing. Others give more attention to nonverbal domains. Gardner (1993) describes seven kinds of intelligence (among many):

- Verbal
- Mathematical-logical
- Spatial
- Kinesthetic
- Musical
- Interpersonal (dealing with others)
- Intrapyschic (dealing with one's own self)

These two classification systems are not easily compared. For instance, Gagné's "motor skills" denotes specific behaviors such as typing or playing golf, whereas Gardner's "kinesthetic

intelligence” refers to a way of understanding systems of concepts that is based on physically manipulating and interacting with objects. For instance, Papert (1980) describes a childhood epiphany in which his manipulation of the differential axle of a toy vehicle revealed to him the nature of functional relationships.

And where in Gagne’s terminology does one account for knowledge of the fact that Germany lies north and east of France? Calling this “verbal information” reflects a behaviorist focus on the traditional means of reporting knowledge by writing, but students are often asked to draw maps or otherwise indicate their mastery of spatial information. It seems necessary to generalize Gagne’s category of verbal information by renaming it as “factual information.”

Multisensory integration (see chaps. 14, 21–22, this volume) is integral to VE’s affordances for learning and motivates many of the projects discussed below. To deal with this issue, an attempt is made to use both Gagne’s and Gardner’s terms to describe the kind of learning under study in each project.

3.1 Constructivism, Constructionism, Situated Learning, and Role-playing

The concepts of constructivism, constructionism, and situated learning drive many innovations and experiments in education, ranging from individual lesson modules to entire school reform movements (Cusick, 1997; Wang, 1998). Role-playing can serve as an intense form of situated learning. In most of the experiments in VE for education, several of these learning strategies are involved. For the purposes of this chapter, two research projects have been selected to highlight each concept.

3.1.1 Constructivism

A substantial body of literature (Dede, 1995; Duffy & Jonassen, 1992; Windschitl, 1998) has established the principle that students actively build their internal models of the world rather than passively accepting data. In constructivist theory, all useful knowledge is procedural knowledge. Thus, constructivism serves as a theoretical justification for discovery learning and exploratory systems. Section 4 below explores two constructivist VE projects: ScienceSpace and the Virtual Gorilla Exhibit.

3.1.2 Constructionism

Constructionism is an extension of constructivism, that latter of which is usually associated with MIT’s S. Papert (Harel & Papert, 1991; Kafai & Resnick, 1996), in which students must actively create artifacts—preferably interactive ones—to fully integrate their models of the world. Papert invented the well-known LOGO language for children and continues to evangelize the doctrine of constructionism. Not all authors use Papert’s terminology; the creation of virtual worlds is sometimes referred to as constructivist activity. We find the distinction useful. Section 5 reviews two constructionist VE projects the VRRV project, and the NICE virtual gardening project.

3.1.3 Situated Learning

Situated learning (Cognition and Technology Group at Vanderbilt, 1993) is oriented around the idea that learning takes place best in story-based, human-centered circumstances. Rather than just computing the area of a triangle, learners are asked to help characters in a story solve an extended problem such as building a house. Many individual problems naturally arise in such a story; their solution is motivated by the normal needs of the characters in the story.

Role-playing takes situated learning one step further by involving multiple learners who are identified with specific characters in the story. Simulated situations may be competitive, cooperative, or both. Introducing multiple learners raises many challenging problems of synchronization, tasking, discipline, and resource management, but offers the potential of unleashing for educational use one of the most powerful forces in the human psyche: social interaction. Section 6 profiles two role-playing experiments, the Round Earth Project and ExploreNet.

4. PREBUILT WORLDS, DISCOVERY LEARNING, AND CONSTRUCTIVISM

4.1 ScienceSpace

One of the most thorough and extensive studies of VE in education has been underway since 1994. Led by C. Dede of George Mason University (Now at Harvard University) and B. Loftin of the University of Houston (Now at Old Dominion University), the ScienceSpace project (Dede, Salzman, Loftin, & Ash, 1999a, Dede, Salzman, Loftin, & Sprague, 1999b; Salzman, Dede, Loftin, & Ash, 1998; Salzman, Dede, Loftin, & Chen, 1999) has used high performance technology to examine the educational potential of immersive VE systems. Loftin created and directs the University of Houston's Virtual Environment Technology Laboratory, and so had access to state-of-the-art VE technology used in astronaut training programs.

4.1.1 *Purpose*

The focal purpose of ScienceSpace was to identify the key affordances of immersive VE and evaluate their effectiveness as means of learning complex, abstract concepts such as mass, density, and momentum. Three key affordances were of principal concern:

- Immersion
- Use of multiple frames of reference
- Multisensory cues

4.1.2 *Setup*

Immersion was provided by the use of a state-of-the-art Silicon Graphics RealityEngine2 image generation system, a Virtual Research VR4 head-mounted display (HMD), and Crystal River audio localization equipment. Multiple frames of reference were provided by a variety of means, the principal one being that students could either move through the world coordinate system with the object whose behavior was being studied or remain fixed in the world coordinate system, and observe the phenomena. Multisensory cues were provided by the sound system and also by the use of a special vest. The vest, originally designed for multiplayer "shoot-em" games, was capable of delivering a vibrating stimulation to the user's chest. The learner held a control device in one hand and a reference device in the other hand; both were tracked by 6 degrees-of-freedom magnetic trackers.

4.1.3 *Experiments*

The ScienceSpace experiments consisted of three phases. The first phase (Newton World) represented basic Newtonian mechanics. The second phase (Maxwell World) concerned electrostatic forces and fields. The third phase (Pauli World) concerned quantum phenomena. During each phase, a series of experiments began with simple pilot activities and continued

through formal evaluations of learning effects. Detailed documentation is available on the first two experiments, and so they are described here.

Newton World focused on the motion of spherical masses along a one-dimensional axis. The axis was visualized as a corridor passing between two rows of columns. The columns were used in a variety of ways to help the user measure and perceive the motion of masses. For instance, the columns might change color as a mass passed by, or sounds might occur. Students controlled the action in the world using three-dimensional (3-D) tracking devices or a voice control system.

When studying energy, it was necessary to devise means of concretely rendering the quantities of kinetic and potential energy. A coiled spring was used to represent potential energy; when it was compressed, vibration in the vest increased. An artificial shadow of the mass was used to represent kinetic energy; the shadow's area represented the amount of kinetic energy the object currently possessed with respect to the fixed reference frame. (The radius of the shadow would therefore be proportional to the velocity.) Learners could either travel with one of the moving masses or view the motion from various points outside or within the corridor.

A pilot experiment yielded a series of improvements in the user interface and experimental technique. It was discovered that the affordance of multiple viewpoints was crucial to learning success. A variety of methods of selecting the next action were used (e.g., picking from menus attached to the fixed reference frame, attached to the user's other hand, or via voice commands). Voice selection was found to be the most preferred means of control. Users liked the multisensory feedback modalities and found the world easier to use when multisensory feedback was presented (see chaps. 14, 21–22, this volume).

In a second experiment, 30 high school students helped to evaluate Newton World's potential for learning. The students were pretested, and it was found that most of them confused the concepts of velocity and acceleration, and that most had trouble predicting what would happen when two masses collided.

After a session of approximately an hour's use of Newton World, students' conceptual understanding was again tested. No significant improvement was measured, suggesting that a single visit to Newton World was insufficient to transform users' mental models. However, multiple improvements in experimental technique and virtual world design were carried forward to the next phase.

In the Maxwell World experiments, learners again had the opportunity to use multiple frames of reference and multisensory feedback. Learners could see electrostatic fields in the form of equipotential lines. A "force meter" represented the magnitude and direction of force that would be applied to a charge at any point in the field as the student moved the force meter around. Using the meter, a user could release a charge and watch it move through space, or "become" the charge and go for a ride.

In the first experiments, students' length of exposure to the system was increased. Fourteen students had from one to three sessions, each of 2 hours duration. As a control, a 2-D commercially developed educational software system, EMfield, was taught. The features of Maxwell World were restricted to correspond to those available in EMfield. Pre- and posttesting indicated that users of Maxwell World developed significantly better understanding of electric fields' 3-D aspects than users of EMfield. In 2-D tests (such as the drawing of sketches related to potentials) the results were mixed. However, the overall results for Maxwell World were significantly better than those for EMfield.

4.1.4 Experimenters' Conclusions

In the later experiments, significantly more learning occurred with VE than without it. Students in all the systems were enthusiastic about their use and remained motivated throughout

the experiments. However, motivation did not turn out in the statistical analyses to be a predictor of learning. Some simulator sickness (see chap. 30, this volume) was experienced, with incidence and severity increasing with the longer exposures used in Maxwell World.

4.1.5 Analysis

In terms of the learning taxonomies, ScienceSpace provided a new experiential domain in which students were expected to develop novel cognitive strategies in order to establish procedural knowledge about spatial and mathematical-logical relationships in physics. Despite the lack of force feedback, the investigators hoped that kinesthetic learning would contribute to students' development of physical intuition.

The project made substantial progress in determining how to build effective virtual learning environments for physics, how to enrich multisensory feedback, and how much exposure was necessary to achieve measurable effects.

4.2 The Virtual Reality Gorilla Exhibit

A team of researchers at Georgia Tech developed a VE simulation of a new gorilla habitat at Zoo Atlanta. A basic dimension of this project is a concern with how a virtual experience must be coupled with background information, reflection, and various forms of information accessible during the simulation itself in order to achieve useful educational outcomes.

4.2.1 Purpose

The initial experiments (Allison, Willis, Bowman, Wireman, & Hodges 1997) were designed to teach middle school students about gorilla's social interactions by letting the students play the role of an adolescent gorilla. Subsequent experiments (Bowman, Wireman, Hodges, & Allison, 1999) focused on the design of the zoo's gorilla habitat, with the intention of teaching college students about principles of design.

4.2.2 Setup

The experiment is hosted on Silicon Graphics equipment, using a Virtual Research HMD and Polhemus tracking equipment. A single user experiences the simulation and interacts with the exhibit via a "stylus and tablet" virtual control device. Motion is controlled either by pointing the stylus in the direction of intended travel or by dragging a dot on a map displayed on the tablet. Software was implemented using the Simple Virtual Environment (SVE) software system developed at Georgia Tech (Kessler, Kooper, & Hodges, 1998). Animal sounds are provided through external speakers.

4.2.3 Experiments

In the first series of experiments, students were provided with an experience that could be dangerous in real life, taking middle school students on a visit inside a functioning gorilla society. After initially viewing simulated gorillas through a simulated viewport, the learner "moves inside" the habitat and takes up the role of an adolescent gorilla. When the learner moves about, the other gorillas react by moving away or by watching the visitor. If the visitor moves too close to a male silverback (dominant individual) or stares too long at it, the silverback becomes annoyed and will ultimately carry out a "bluff charge" and beat on his chest.

The experimenters observed that most students needed help to understand the gorilla's behavior. Initially a live human guide would stand next to the student and explain what was happening; subsequently explanatory material was built into the audio portion of the experience.

The system was also modified to include explicit “mood indicator” icons to show the emotional state of each gorilla.

The second series of experiments concerned teaching college students about habitat design. The design profession is based on well-established principles and also includes a substantial aesthetic component. The experimenters’ intention was to provide a series of design examples, with annotation, somewhat like a guided visit to a Frank Lloyd Wright project. A series of audio clips are embedded in the virtual gorilla exhibit. Annotations are marked by cubical signs that play the audio annotation when selected. A few fixed signs occur in places where signs might appear in a real zoo habitat.

The map that is displayed on the virtual tablet (corresponding to the real tablet the user is holding) provides additional spatial information. The map situates the exhibit among several others in the zoo and teaches the principle of bioclimatic zones, by which exhibits from similar climates and ecosystems are located close to one another. The exhibit also includes photographs of gorillas in locations they typically occupy. These help the viewer to establish the scale of the exhibit. The virtual gorillas are not active in the design experiment because their behaviors would distract from the design lesson being taught. Also, the gorilla’s automated behaviors do not include the full spectrum of activities (eating, sleeping, mating, etc.) that must be accounted for in habitat design.

4.2.4 Experimenter’s Conclusions

In the first series of experiments with schoolchildren, the principal lessons learned concerned the user interface and the need for explanatory support. Students tended to be concerned with specifics of navigation (see chap. 24, this volume) and could be overwhelmed by the sights and sounds of the simulated animals. The experimenters found it necessary to provide a live gorilla expert to comment on what the students were experiencing.

The system was subsequently used in a Georgia Tech class on the psychology of environmental design. The system was found easy to use. However, students did not strongly relate the audio material to the environment as was intended. As expected, the groups that used the system performed as well as or better than a control group. However, the differences were not significant, probably due to the small size of the samples. A group that experienced the annotated VE without a corresponding lecture received very little benefit.

4.2.5 Analysis

This project aimed to develop factual and procedural knowledge about how gorillas live and interact, as well as about how to design habitats for zoos. It used visual, verbal, and kinesthetic modes of interaction.

The experiences with schoolchildren (needing a live expert to facilitate their learning) and with the university students (needing a lecture to exhibit measurable learning) serve as a strong cautionary note to advocates of VE as a primary means of instruction. The Georgia Tech team advocates VE as a supplementary tool to be used alongside other means of teaching.

5. BUILDING VIRTUAL WORLDS AS A CONSTRUCTIONIST ACTIVITY

In this section two projects are described in which the learner’s major activity is to construct or extend the features of a virtual world.

5.1 The VRRV Project

At the University of Washington's HIT Lab (Human Interface Technology Laboratory), a team led by William Winn carried out an extensive project titled VRRV (Virtual Reality Recreational Vehicle). The basic premise was to have students in schools participate in extended world-building exercises using conventional computers. Then an "RV" (originally intended to be a motor home or recreational vehicle, but actually a van) visited the school with immersive VE equipment, so the students could experience the worlds they built. The project is described in Winn et al. (1999). This report describes one component of the VRRV project.

5.1.1 Purpose

The VRRV Project was intended to explore the educational utility of students' building virtual worlds within the constructionist paradigm. The investigators analyzed several previous constructionist VE projects in order to choose experimental parameters. The key questions concerned:

- How students would choose to represent objects and processes
- How students would design spaces to help their peers understand subject matter

5.1.2 Setup

Teachers from 14 schools volunteered their elementary, middle, and high schools as test sites. The teachers were trained in the use of Macromodel software, and it was concluded that the software was too difficult for elementary and some middle school students. Consequently, it was decided to have the project staff build a common world and let the younger students construct auxiliary but nonessential objects. Most of the middle schools and all the high schools designed and built worlds. In these cases the students modeled the objects and specified how they should fit into the world and interact. Project programmers then assembled the worlds and programmed necessary interactions.

Portable (PC-based) VE equipment built by Division was brought to each school so that the students could visit their own worlds. The systems included Division HMDs and magnetic tracking equipment. The project involved 365 students.

5.1.3 Experiments

Except for the elementary schools and one middle school, each school designed and implemented its own world. During the planning phase, students worked in groups. They selected content, specified objects and metaphors to represent invisible objects and relationships. During the modeling phase, students drew their objects on paper and then built them with the Macromodel software. Project staff assembled the worlds and programmed behaviors. The elementary children explored and manipulated a prebuilt world, to which they had contributed some auxiliary objects. Finally, students visited the worlds they had created, performed specified tasks, and filled out questionnaires about the experience.

In a few schools, the projects related to academic subjects being studied in the schools. Thus, data was gathered to see if VE students had better knowledge of the subject matter than students in other non-VE-supported classes.

5.1.4 The Worlds

Tree World (shared by the elementary schools) consisted of a tree that needed sunlight, water, and nutrients. Students pushed aside a virtual cloud to let in sunlight, pushed aside a

boulder to let in a river, and fed a cow so that its manure would fertilize the tree. Students provided insects, squirrels, and birds. In this world, the students' activities could be described as constructivist but not constructionist. The purpose was to make the tree look healthier by providing for its needs, and thus to learn about biological resource cycles.

Here a few typical constructionist worlds are described. Medieval Castle World represented a number of rooms of a classic castle, with a drawbridge. Rain Forest World tells a story in which bulldozers destroy the forest; cattle are introduced and become hamburgers. Finally, the earth is replaced by a big dollar sign. Endangered Species World has animals that turn into skeletons when handled. Washington World presented a maplike visitable model of the state, with many correctly located features that revealed textual annotations when selected. Tide World was intended to show how the sun and moon produce tides.

5.1.5 Experimenter's Conclusions

The authors observed two kinds of metaphor in use: objects could stand for other objects or for invisible objects or processes. Hamburgers stood for the end product of clearing the forest. Skeletons stood for the (unobservable) process of extinction. Students showed the ability to construct valid metaphors but tended to undergeneralize principles. For instance, the elementary students, when asked about plant nutrients, reported that they came from cow poop.

Similarly, students showed the ability to define processes, but when asked about the underlying principles would often cite the process itself (e.g., hamburgers are not the problem, habitat destruction is). The Washington World and Tide World showed mastery of spatial relations and of scale as a dimension of design.

Student designers had to anticipate the need for interactions (e.g., feedback for successful actions) and specify them. This required that students anticipate the errors of others.

Numerical results of posttests were analyzed to investigate enjoyment, ability to navigate, and VE sickness, as well as correlations among these measures. Those who found it easy to navigate also enjoyed the experience. Separate (teacher-designed) testing of knowledge of content indicated that less able students learned a significant amount about the world's subject matter from the VE-building experience, whereas higher performing students did not.

5.1.6 Analysis

VRRV's constructionist experiments spanned a wide range of subject matter and included both factual knowledge and procedural knowledge. The procedural knowledge involved phenomena within the simulation (such as flow of resources through the nutrient cycles of the tree) and processes involved in building virtual worlds. The principal cognitive strategy involved was meta-learning (thinking about the learning process itself), in the form of explicit instructional design for the benefit of other students.

In Gardner's terms, mathematical-logical (causal loops), spatial, and kinesthetic intelligences were involved in the project. Of course, verbal skills had an essential role in planning and specifying the worlds before they were built.

In common with most other VE based projects, the VRRV experiments increased the authors' understanding of the user interface and didactic issues involved, but exhibited relatively little in the way of measurable learning.

5.2 The NICE Project

At the University of Illinois at Chicago, the Electronic Visualization Laboratory has developed a unique immersive VE system called the CAVE (Cave Automatic Virtual Environment;

Cruz-Neira, Sandin, DeFanti, Kenyon, & Hart, 1992; see chap. 11, this volume). Rather than using an opaque HMD, the CAVE uses large projected images on three walls and the floor. A viewer wearing stereographic glasses and a tracking device has the experience of being inside a high-resolution virtual space, but without most of the motion sickness problems (see chap. 30, this volume) associated with head-mounted displays. A handheld control device is also provided. Multiple users can simultaneously see images, although only the one with the tracking device has correct perspective and parallax.

5.2.1 Purpose

Using the CAVE, the NICE (Narrative Immersive Constructionist/Collaborative Environments) project explored both constructionism and collaboration by having students design, build, and “nurture” a virtual garden (Roussos et al., 1997, 1999). In this review, the focus is on the constructionist aspects of the project. The specific learning outcomes being sought were an increased understanding of the relationships between environmental conditions and plant growth. In addition, the experimenters focused attention on the suitability of the CAVE user interface for learning by children of various ages.

5.2.2 Setup

Software was provided that supported the simulation of plant life in a garden. Using a handheld controller, or “wand,” students dropped a seed and a plant grew on that spot. If the plants were too close together they would not grow well. Students could grab a rain cloud, “water” a plant, or provide sunlight. Weeds could be removed to a compost heap. The garden continued to evolve, with weeds growing and animals eating plants, even if no users were present. NICE is accessible not only through the CAVE, but also through desktop 3-D VE systems and a 2-D Web-accessible interface.

Two features of VE technology of particular educational interest are its ability to reveal hidden phenomena and help users interpret them. In NICE, for instance, users can go underground to see what is happening there as well as control the flow of time. In addition, a plant that is receiving too much water is shown holding an umbrella.

An unusual feature of the NICE system is that a story is automatically constructed, which describes each action of the learner. This story is expressed in simple English sentences, with some words (e.g., sun) replaced by colorful icons. The story is printed for the child to take home.

5.2.3 Experiments

The basic premise of NICE was to allow self-directed exploratory activities and to carefully observe and analyze what happened. There was some guidance provided by teachers who helped students stay on task and contain their excitement. The experimenters gathered observations in five areas:

- Technical: usability of the interface, system hardware and software
- Orientation: navigation, presence
- Affective: engagement, confidence, interest level
- Cognitive: improvement of knowledge and understanding
- Pedagogical: how did student–student and student–teacher collaboration work?

Fifty-two students between 6 and 10 years old participated in the NICE experiments. The usual experimental setup was to have two groups of four students using two CAVE systems, coupled

by a bidirectional audio link. In each group, a leader was designated to wear the tracking device and to appear in the NICE world as an avatar. The other team's avatar, and that of a third person (actually a teacher), appeared in the world to act as a guide.

Each group planned a garden before they entered the CAVE. The group then directed their leader as he or she carried out the design. The group could see the other group's avatar. Sessions lasted about 40 minutes; they were preceded by a set of pretest questions, and followed by interview questions. Students then made drawings and wrote essays.

5.2.4 Experimenter's Conclusions

With regard to usability: the stereo glasses and control wand, being adult-sized, did not work optimally for smaller children. Fatigue (see chap. 41, this volume) and simulator sickness (see chap. 30, this volume) were minimal, but some difficulty with orientation (see chap. 24, this volume) was reported. With regard to affective issues, students enjoyed the activity and particularly liked reading the stories that chronicled their adventures. The student leaders were more engaged with the learning task than the passive observers; the observers were more engaged with the medium itself. Improvement of knowledge and understanding was correlated with control; that is, the students who directly controlled the environment learned more than the passive observers.

Before the experience, 12% of the participants had a good understanding of environmental concepts; afterward, 35% met the same criterion. Most (73%) of the successful students were group leaders.

The project team plans to develop scalable models so that younger children can experience simplified biological phenomena and older ones can explore a richer set of interactions.

5.2.5 Analysis

In Gagne's terms, the NICE experiment helped students build their "procedural knowledge" about caring for plants and their "verbal information" about how plants live. In Gardner's terms, the project was directed at helping students develop their understanding of "mathematical-logical" and "spatial" relationships between growing plants and their environment.

The experiment's cognitive measures would seem to indicate that the educational efficacy of passive observation/participation in VE is limited. Interestingly, such passive conveyance is also attributed to higher levels of sickness (see chap. 30, this volume).

6. ROLE-PLAYING AND SITUATED LEARNING IN SHARED VIRTUAL WORLDS

Several of the projects already described were designed with explicit social dimensions. VRRV had students work together to design and build worlds, and NICE had groups of students sharing a CAVE system. In fact, NICE had two CAVE systems in use at once, with a network so that each user could see the other's avatar. However, the presence of specific characters inside the virtual world, with differentiated capabilities and assigned roles, was not central to the instructional design of those projects.

It can be argued that virtual worlds without specific, visible, differentiated characters (avatars, see chap. 15, this volume) and roles are of an essentially different nature than worlds built around avatars. There is a spectrum of abstraction in simulation-based learning. At the most abstract are simulations with no situational information, just the essence of the phenomenon at hand. Less abstract are simple simulations that are situated within a simulated world, but which are used, so to speak, "through a window." When an immersive system with free motion of viewpoint is used, the situation gets even more concrete, but the learner is still

free to behave in a godlike fashion. The *behavioral schema* is oriented toward objects, and there is nothing but the simulated world's own rules to constrain one's behavior.

As soon as human forms appear in the world and begin to plausibly interact with the user, behavioral schema shift and become oriented toward shared experience. This may be the least content friendly of all forms of simulation; social interaction can be a powerful distractor from reflective thought. But students can and do learn from shared experiences. They explain things to one another and observe the result of others' experiments (Johnson & Johnson, 1987).

With younger children, one possible distraction is that they may begin to compete rather than cooperate. Instructional designers sometimes optimistically assume that activities originally conceived of as cooperative tasks will naturally be treated that way by students, but students may see the simulation as a me-win/you-lose game. The social schema must be carefully constructed so that learners can take advantage of known ways of interacting. Roles such as leader/follower, teacher/student, or allies/adversaries are obvious possibilities. Both the projects to be described below have carefully designed roles for participants.

6.1 The Round Earth Project

Like the NICE Project, the Round Earth Project was carried out by the Electronic Visualization Laboratory at the University of Illinois at Chicago. The same CAVE equipment was used. However, in the Round Earth Project, the interaction of two students within a shared virtual world is essential to the instructional design. The work is described in Johnson, Moher, Ohlsson, & Gillingham (1999).

6.1.1 Purpose

The experimenters wanted to select a problem that met the following criteria: Learning goals must be important and hard, and VE must offer some plausible enhancement to the learning process. The concept of the earth as a sphere was selected because it is in standard elementary science curricula and is known to be hard for many children to grasp.

The actual purpose of the experiment was to investigate how VE could teach concepts that are inconsistent with a user's current mental model. It is necessary both to establish the new phenomenon (in this case, the experience that "down" points toward the center of a sphere rather than perpendicular to an infinite ground-plane) and to link this knowledge to one's prior mental model. Two theories of deep learning, "transformationist" and "displacement" approaches, were investigated.

6.1.2 Setup

One CAVE and one ImmersaDesk system were used. An ImmersaDesk is a single-projector system arranged like a large drawing table, in contrast with the CAVE's four viewing surfaces arranged as three walls and a floor. Stereo glasses are used by both participants, and a bidirectional audio link is provided.

Two treatments were provided: Astronaut World and Earth World. Astronaut world was intended to provide a clean break from the current flat-earth experience, with an astronaut-avatar walking around a tiny spherical asteroid while the other learner observed and directed his actions from a command module. To enhance collaboration, the task (picking up fuel cells) was designed so that the observer had knowledge of what was essential for the astronaut's success. The students alternated roles so that each experienced both the god's-eye view and the immersive view.

Earth World involves a satellite mission in Earth orbit. Thus the learners experience the transition between the "flat earth" as seen before launch and the spherical planet with a curved horizon.

6.1.3 Experiments

In three successive pilot studies, a total of 17 pairs of children were used. The children were predominantly African-American third graders from a Chicago school in which 93% of students' families are below the poverty line. An initial pilot study led to improvements in the user interface and controls. Students were introduced to the system and then spent 10 minutes on each task twice: for instance, mission controller, astronaut, mission controller, astronaut. The children were usually actively talking to one another. They focused on the task of finding and collecting fuel cells and did not pay much attention to the issues of up and down, gravity, and so forth. A group debriefing in front of the ImmersaDesk occurred after the interactive session.

Pre- and posttests were initially done using 2-D pictures and open-ended questions. When these showed little learning, a Play-Doh 3-D model was used with interview-style questions. It quickly became apparent that little conceptual learning was taking place. For the third pilot study, the approach was modified to focus more attention on the concepts. Only Asteroid World was used. The introductory activity was extended so that the students were given a guided tour around the asteroid. Students' hands-on time was decreased from 40 to 20 minutes. The group ImmersaDesk debriefing was replaced by individual guided inquiry with a physical globe and model of the asteroid.

6.1.4 Experimenter's Conclusions

Some clear instances of learning occurred, but there was no large and consistent effect. The use of young children from a challenged population and away from their schools imposed severe logistical strains. The experimenters plan to refine the virtual world and experimental approach and analysis.

6.1.5 Analysis

The experiment was designed to use the interaction between two children as the focus of learning. The concept of the round earth would presumably fall into Gagne's category of "factual knowledge." The observer was expected to notice and remark on the fact that the explorer was "upside-down." In the experiments, however, the observer was usually so focused on the task of helping the explorer to navigate that abstract concept formation seldom occurred.

Experimenters were surprised by how difficult it was to convey abstract information to children from deprived backgrounds, and (like the Virtual Gorilla Exhibit project) found themselves adding traditional teaching methods such as tangible 3-D models to their experiment.

6.2 ExploreNet

Not all virtual worlds are three-dimensional. Since 1994, Charles Hughes and Michael Moshell at the University of Central Florida have been exploring the educational utility of shared virtual worlds by using a relatively simple 2-D cartoonlike system called ExploreNet, which was inspired by the Habitat role-playing system (Morningstar & Farmer, 1991). Moshell and Hughes have conducted a series of experiments in various learning contexts, and developed an instructional model built around role-playing and improvisational drama.

6.2.1 Setup

ExploreNet is a Windows application, running on ordinary PCs with Internet connectivity. A group of two to eight computers are set up with identical software. One of the computers is

designated as a server, but also remains available for student use as a workstation. The users select a shared world and then choose the avatars or characters they will control during the simulation. One station can control one or several characters by taking turns.

Characters move by walking or flying to the location where a mouse-cursor is clicked. If the user clicks on a character or a “prop” (a noncharacter object) in the scene, a menu displays the actions that object can exhibit. If the user types the words appear over the head of the avatar currently controlled by that user on all workstations currently viewing the scene.

The principal expected advantage of ExploreNet’s 2-D user interface over 3-D virtual worlds was its ease of world construction and use. ExploreNet’s limited repertoire of simple behaviors allowed students to concentrate on the tasks at hand. However, there were a number of user interface problems that emerged as studies continued. Scenes are static and “hot spots” at the edge of scenes are used to move between scenes. When a character steps on a hot spot it disappears from the scene and finds itself in another scene. This proved quite confusing for many users. Ultimately it was found necessary to provide “mentor characters,” which control student characters’ ability to leave the scene of an intended action. Similar problems arose in dealing with the control of props, particularly when several props were close together.

6.2.2 Experiments

Three worlds were built and tested between 1994 and 1997. Zora’s World was based on stories in the autobiography of Zora Neale Hurston, an African-American writer from Eatonville, Florida, and tested in Eatonville’s Hungerford Elementary School. Dinosaur World was built in cooperation with students at Maitland Middle School and tested there. AutoLand was built to specifications provided by third grade teachers in the U.S. Department of Defense Dependents’ Schools in Germany and tested there. These experiments are described in Moshell (1996) and Hughes (1996, 1997).

The key questions being investigated in these worlds were:

- How should the roles played by different students be differentiated?
- How many students can profitably interact within a simulation?
- How can “free play” and a story line, with educational goals, be reconciled?
- How can the learning experience be managed?

6.2.2.1 Zora’s World. In the first experiment, two *mentor characters*, an owl and a dog, were provided. Other students controlled auxiliary characters (i.e., chickens and a cat). The students controlling the mentor and auxiliary characters were referred to as *cast members*. In addition, two pairs of *guest characters* were provided. The objective of the guests was to get eggs from the barn, build a fire in the back yard, and cook the eggs. But the chickens did not want to give up their eggs. Solving this problem required cooperative behavior between two guests. The mentor characters were trained to give hints as needed without giving away the entire story at once.

The cast members knew how the story was supposed to come out; they were responsible for the experience of the guests, much as uniformed staffs are responsible for the experience of guests in a theme park. Thus the entire experience involved eight students, four guests and four cast members. Usually, six computers were used, with two guests and two cast members sharing computers.

Like the Round Earth Project, Zora’s World focused its experiments on underprivileged children. However, the experiments were conducted in the children’s own school; in fact, they were situated in the classroom alongside the rest of the class. The six computers were set up with their screens facing the wall, so only the eight participating students could see what

was going on. The other 16 children in the class knew that their turns would come; they were supposed to work on other projects in small groups while the current crew explored Zora's World.

Various age pairings were tried, with fourth-, fifth-, and sixth-grade children playing the roles of cast members and guests. It was found that sixth-grade students acting as cast members had the best chance of retaining control of the learning situation and achieving desired outcomes. Younger children would lose track of the fact that they were supposed to be managing others' learning experience and would play the game themselves. However, in general the younger children acting as guests successfully completed the game as often as the older ones.

All students viewed the game as a competitive one, though it had been designed as a cooperative experience. Students would hoard resources (firewood for instance) and bring the game to a standstill until a mentor character could convince them to share.

6.2.2.2 *DinoLand*. In this world, four individual guests represented different dinosaur species, two herbivores, a carnivore, and an egg-eating species. The only cast member played a managerial role in charge of invoking a day-night cycle. Every night represented a new generation of dinosaurs in which those species that successfully laid and defended their eggs in the previous round became stronger.

The students were extremely motivated by the competitive aspects of predator-prey relationships. One carnivore-player discovered that he could collect all the plants and starve the herbivores into submission. The use of four rather than eight characters proved to declutter the screen and keep interactions focused.

6.2.2.3 *AutoLand*. AutoLand was designed as a collaborative constructionist activity in which four guests had to find raw materials, assemble them, and create the components of an automobile. Unlike the previous two worlds, this lesson was created on the basis of a textbook chapter (specified by third grade teachers) and was provided to the teachers along with worksheets and paper maps. Because participating students were third graders and could not type, they were allowed to interact verbally (by talking to the students on adjacent computers). Instead of on-screen mentors, each student had a "shoulder buddy" who had previously been through the experience. A teacher served this role for the first group.

According to the teachers, Autoland was very successful as a supplementary classroom activity. In testing by 50 children in two classrooms, over 90% of the four-person teams succeeded in constructing the automobile within the allotted 40-minute period. A formal external evaluation was provided for, but due to transatlantic logistical difficulties was not completed.

6.2.3 Experimenter's Conclusions

The succession of experiments led the project away from the use of in-world cast members and toward a close correlation with subject matter that was of interest to teachers. The provision of external reading materials and in-class activities provided necessary *a priori* knowledge (e.g., of where in the United States one might find iron ore, coal, etc.) so that the virtual experience could serve to transform abstract concepts like north and south into real experiences.

6.2.4 Analysis

The ExploreNet experiments were intended to teach "attitudes" (cooperation) and "cognitive strategies" in Gagne's terms, or "interpersonal and intrapsychic" skills, in Gardner's terms. In AutoLand there were also goals related to factual information (where cars come from).

Lessons were learned about techniques for using one group of students (cast members) to guide the experience of other students, and about how to build materials that teachers would willingly use.

7. THE FUTURE OF VE TECHNOLOGY IN EDUCATION

From the six projects analyzed in this chapter, some common themes emerge. The most striking of them is that no project achieved significant, measurable learning in its first attempt at using VE technology, and most had not achieved clear results even after several experimental revisions. Among many possible reasons, the most plausible seem to be:

- System complexity and novelty consumed most of the students' and experimenters' attention.
- Evaluations that measure factual knowledge in traditional ways may not be very sensitive to the kinds of procedural knowledge and cognitive strategies that might develop in VE.
- The process of instructional design for virtual worlds is very immature. Tools for constructing 3-D geometric models require specialized technical knowledge and are generally difficult to use.

The explosive growth of video game technology means that the technical and cost barriers to high-performance 3-D computer graphics are disappearing. Interactive software will become easier to build, though it is difficult to predict how fast or far this trend will go. It seems likely that many more experiments will be conducted in the use of interactive simulation for learning. The authors hope that the lessons learned from the pioneering projects reported in this chapter can make the way easier for those who follow.

1. INTRODUCTION

Recent research suggests that virtual environments (VEs) may offer significant benefits to all types of education, especially in light of the types of learning supported by VE compared with other computing technologies (see chap. 45, this volume, for a review). However, evaluation studies have highlighted usability issues (see chap. 34, this volume) unique to virtual learning environments (VLEs), which traditional human–computer interaction (HCI) guidelines do not cover. Moreover, much of the HCI research to date has focused on mainstream applications and does not provide guidance on how to build interfaces for users with special educational needs (SEN), which is an important early market for VLEs. What is required is a structured approach to the design, development, and evaluation of VLEs, with close liaison with representative users and professionals at all stages of development to ensure adequate design of VEs to support learning. In this chapter the initial steps toward a user-centered model of VLE development and evaluation is described.

1.1 Computers in Education

The growth in the number of new technologies applied to education has produced many varied applications within the classroom. One of the most controversial of these has undoubtedly been the idea of introducing the microcomputer as a “teaching machine,” first seen in schools in the 1950s (Fry, 1963). In most early examples, education via computer followed the behaviorist school of thought. Using teaching machines, responses were conditioned by providing a list of words or arithmetical products to which the student was required to respond, the correct answer being revealed after each attempt (Fry, 1963; Richmond, 1965). Skinner was an advocate of these machines and felt that many of the ideas developed in his study of animal learning could be applied to the task of improving instruction (Hilgard,

Atkinson, & Atkinson, 1979). At the same time the use of drill and practice programs was thought to be the best teaching structure to use for children with learning disabilities to acquire new skills (Mittler, 1979). Consistent computer feedback was also used for profoundly disabled children to learn cause and effect (Rostron & Sewell, 1984). This type of instruction did not significantly impact mainstream education, but the belief that computer-aided-learning (CAL) was an effective idea continued. The features of CAL seen to be of most benefit were: that it provides *active participation*, where the learner is actively interacting with curriculum materials; that *feedback* is provided immediately so that an error can be corrected and an incorrect belief or response is not reinforced; and there is *individualization of instruction*, where different learners can move ahead at their own pace (Hilgard et al., 1979).

The “LOGO” programming language for children was designed in accordance with Piaget’s ideas that children should construct their knowledge in building blocks: “One might say the computer is being used to program the child. In my vision, the child programs the computer” (Papert, 1993, p. 5). He believes that in allowing the child to explore and follow his own path of inquisition, the child learns in a less formal and more natural way, paralleling the way in which basic functions such as walking, talking, and eating are learned. Papert was one of the early contributors to applying computer technology in education, and many regard him as revolutionary, although today computers are much more powerful than those used in his early work, and the number of educational computer programs available has increased dramatically.

The majority of educational computer programs created recently have been multimedia programs that combine text, graphics, sounds, and film. A major criticism of these types of programs is that they mimic resources already existing in schools, such as books. “Most multimedia programs fail because they add video and graphics to page turning programs” (Schank, 1994, p. 69). What appears to be lacking in these computer education applications is that they do not provide anything of significant value that is additional to current educational resources.

The outlook is somewhat different in special needs education, where a number of research projects have found that attributes of computers can support learning in a way in which traditional teaching methods do not. Bridge stated: “The educational potential of the micro-computer appears to be immense, and nowhere more so than in the field of Special Needs Education” (1987, p. 3). He attributed this to a change in role of the teacher from educator to advisor. A more active and exploratory learning style (Clariana, 1997) combined with students’ control over their own pace of learning may motivate students.

1.2 Learning in Virtual Environments

Virtual environments allow the user to actively participate in experiences of infinite possibilities. A VE may allow the participant to see representations of scenarios familiar to them or objects that they may not be able to view in the real world. Any situation may be represented as a three-dimensional (3-D) environment, and the user may take on any role or perspective within the environment. The potential for learning may therefore be great, as specific skills may be practiced and observed from different viewpoints and information to be learned may be presented in meaningful and concrete ways.

While early educational computing allowed users to practice repetitive tasks (Solomon, 1986), VEs offer a different kind of arena for learning. They allow a greater degree of self-paced and determined exploration, as well as practice of naturalistic tasks in realistic settings (Brown, Cobb, & Eastgate, 1995; Brown, Standen, & Cobb, 1998; Cobb, Brown, Eastgate, & Wilson, 1993). Virtual environments provide facility for experiential learning by allowing the

student to explore the VE at their own pace and interact with the VE in real time (Bricken, 1991; Dede, 1995; Winn, 1993).

For example, Bednar, Cunningham, Duffy, and Perry (1992) provide five main points, which outline the features of constructivist learning environments. These include: contextualizing learning; learner as an individual; authentic tasks; situating cognition, and nonprespecification of content.

Constructivism has been discussed as a learning theory on which to build an instructional technology for a number of years (Duffy & Jonassen, 1992; Papert, 1988; Perkins, 1996) and is the single most reported education theory supporting development of VEs for education (see review by Youngblut, 1998). However, in practice, the theory has only been applied loosely in the construction of a number of educational VEs (Dede, 1996; Roussos et al., 1999; Winn, 1993; see chap. 45, this volume).

A study by the authors (Neale, Brown, Cobb, & Wilson, 1999) describes a structured evaluation of VLEs to investigate to what extent these learning environments met constructivist principles (using principles developed from Jonassen, 1994). It was found that the applications supported moderate rather than extreme forms of constructivism. Different learning environments supported distinct learning principles in varying ways. This was mainly due to differences in the objectives of the VLEs. VLEs that aimed to promote communication skills were found to support collaboration and social negotiation, but contained more abstract visual content and did not represent the natural complexity of the real world accurately. Conversely, VEs that aimed to teach real world life skills represented the natural complexity of the real world more accurately and presented more authentic tasks.

Virtual environments have a number of characteristics which may promote certain behaviors that enhance special needs education, such as self-directed activity, motivation, and naturalistic learning (Neale et al., 1999). These features of VEs lend themselves to supporting learning according to a constructivist perspective.

In all of the VLEs herein investigated, it seemed necessary to include some form of behaviorist/objective learning. In the cases explored, teachers and students with a learning disability collaborated “shoulder to shoulder” using the virtual environment. Teachers always provided some directive or instructional role, this meant that students were more likely to take in important points of focus and understand the meaning of their actions.

1.2.1 Uses of VE in Mainstream Education

Most of the VLEs that have been created for mainstream education have made use of specific characteristics that the technology provides. Virtual environments allow representation of things that would not normally be visible to the naked eye, for example, molecules in a compound (Byrne & Furness, 1994), inner workings of a machine (Wilson, D'Cruz, Cobb, & Eastgate, 1996), or electricity flow in a house (Middleton, 1992). The technology provides facility for taking on different perspectives within the virtual environment. In the case of the above examples, as well as taking a global view of each scenario, you might “be” an atom in the molecule, a part being manufactured, or an electron flowing through the wire. Virtual environments allow participants to explore dangerous situations safely. Health and safety issues have meant that some activities, such as science experiments involving dangerous chemicals, cannot be carried out in schools. Virtual environments allow these experiments to be recreated so that the “hands-on” element is put back into the lesson (Crosier, Cobb, & Wilson, 1999). Also, limited access to industrial plants could be overcome by creating virtual factories (Copeland, 1998; Goldsmith, 1999). Due to their 3-D nature of presentation, VEs also have great potential for demonstrating complex abstract concepts, for example, representing a magnetic field (Dede, Salzman, & Bowen-Loftin 1996).

1.2.2 Uses of VE in Special Needs Education (SEN)

The potential for the use of VE technologies in special needs education has been talked about for a number of years (Middleton, 1992; Powers & Darrow, 1994). Virtual environments have subsequently been developed for users with physical disabilities and vision and hearing impairments.

Inman, Loge, and Leavens (1997) have used a head-mounted display (HMD) to train the use of electric wheelchairs for children with physical disabilities. A similar project is being carried out using desktop VEs for the education of severely disabled children, using a VE as a safe, enjoyable, scaffolded wheelchair training environment (Desbonnet, Cox, & Rahman, 1998). Virtual environments have been used to teach spatial skills to physically disabled children, and evaluation studies have found generalization of such skills to real physical environments (Stanton, Foreman, & Wilson, 1998).

The use of VE for blind users is being explored by a number of research groups (Jansson, 1998). For such applications, the VE interface must first be adapted to allow the user to receive and interact with 3-D information by using haptic, kinesthetic, and tactile devices (Colwell, Petrie, Kornbrot, Hardwick, & Furner, 1998; see chaps. 5 and 6, this volume). Studies have looked at the potential uses of VEs for education, training, Web browsing, and as navigational assistive devices. Lumbrieras and Sanchez (1998) have developed 3-D acoustic interactive Hyperstories that are intended to develop the cognitive skills of blind children. Berka and Slavik (1998) suggest the use of such devices for navigation training in VE, or the extension of this device so that the user can navigate in real time in a real, unknown environment.

The use of VE applications for the rehabilitation of cognitive processes and functional abilities in clinical neuropsychology has included studies of developmental and learning disabled clinical populations (see chaps. 46 and 51, this volume). Rizzo, Wiederhold, and Buckwalter (1998) detail research in this area and review a numbers of studies where VEs have been used to promote learning for a disabled population. Despite growing numbers of VE applications within special needs and mainstream education, there is still little evidence of research concerning the profitable use of VEs with users with developmental and learning disabilities (Darrow, 1995; Youngblut, 1998). The few studies include the use of VEs for training autistic children safe street crossing (Strickland, 1996) and the communication and experiential VEs developed by the Virtual Reality Applications Research Team (VIRART) at the University of Nottingham (detailed in section 4).

There are many more possible applications that could be developed and used for successful learning. Preliminary studies have indicated a number of benefits from their use by clinical populations. This may be due to a combination of many factors, but one issue may be the resources required when attempting to develop virtual learning environments (VLEs) for such user groups.

2. DEVELOPMENT OF VIRTUAL LEARNING ENVIRONMENTS

There are three general phases of VLE development: specification of the application and its content, programming, and evaluation. Although these phases are distinct and progressive in themselves, development of the final product requires a good deal of iteration (see Fig. 46.1). A user-centered approach taken in the specification and design of VLEs will result in more useful and appropriate applications.

2.1 User-centered VLE Specification

In this section, involvement of user groups in early conceptualization stages of VE design is emphasized. At each stage, representatives of users and professionals should be involved to

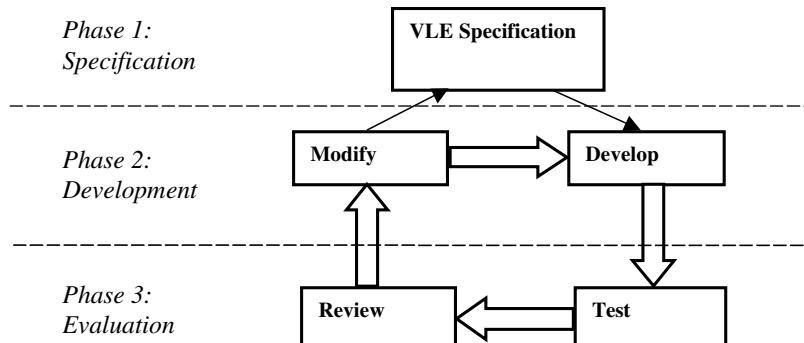

FIG. 46.1. Stages of VLE design and evaluation.

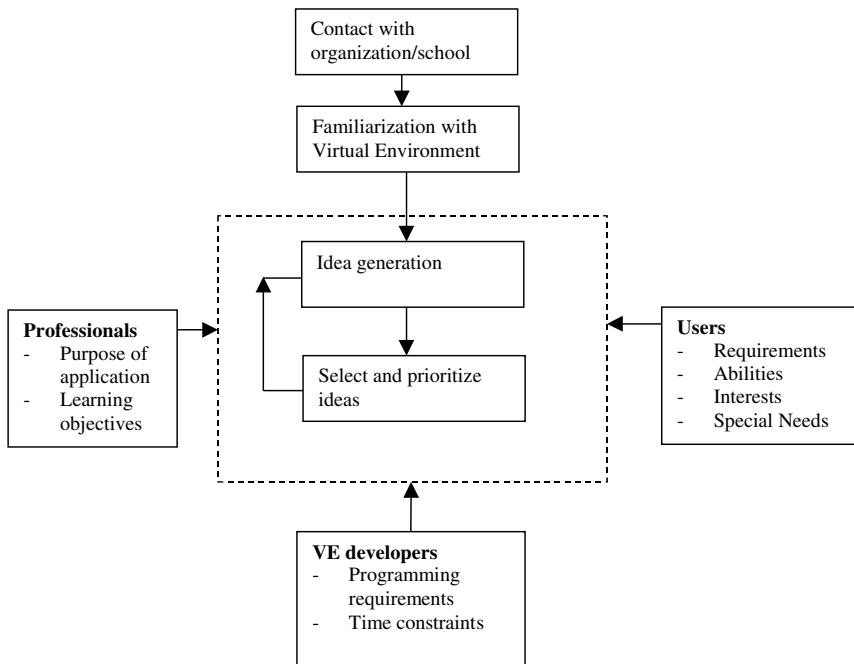

FIG. 46.2. User-centered VLE specification.

ensure that concepts are relevant and interfaces are accessible. Figure 46.2 shows how users and professionals can influence VLE development.

2.1.1 Initial Contact with Schools/Organizations

When designing educational VE applications, the first step is to make contact with the schools or organizations that may use the VLE. Initial contact may arise through several routes:

1. Cold contact with schools to recruit interest in a project
2. User representatives approaching developers asking them to meet a specific need
3. General interest from potential users after seeing a demonstration or publicity

It is important that VLEs are developed with a clear view of the value of VE as an aid for learning. The user-centered design approach involves teachers and professionals in the first initiation of the VE design. They will determine the purpose of the VLE, as an additional teaching aid to support existing methods or as a specific program aimed at providing learning in a unique way. In addition, they inform VE developers of the practicalities of computer-based teaching within their organization (e.g., resources available, staff interest and motivation to use the program, acceptability, etc.).

2.1.2 VE Familiarization

After initial contact, the next step is to familiarize teaching professionals or care workers with VE technology and features of virtual environments. It is important to give a realistic view of VEs in accordance with the users' needs and level of available resources. Demonstration of previous applications can be used to highlight features of VEs as follows (Crosier, 1997):

1. Representation of Objects and Environments. VEs can be used to model all types of objects or environments. These may be representations of things that actually exist in the real world, or they may be replicas of things that either do not exist or cannot ordinarily be seen. It is possible to model an entire city, a single building, or just a single room, such as a school classroom. The example in Fig. 46.3 shows part of a virtual city, and Fig. 46.4 shows the inside of a school (Brown, Kerr, & Eynon, 1997; Kerr, 1995).

2. Different views of the environment. In VEs the user can take different perspectives; in many cases these are linked with movement constraints. For example, when driving a car around a virtual city, if the user moves the joystick left, the steering wheel will turn counter-clockwise and the car will turn to the left (see Fig. 46.5). In Fig. 46.6 the user takes on the characteristics of a skier (Brown, Kerr, & Wilson, 1997; Brown, Stewart, & Mallet, 1997). In this case a constraint is applied that prevents the virtual object (which contains the user viewpoint) from moving backward, as this would be impossible on a real ski slope. It is not always the case, however, that movement is restricted in this way. It may be that the user should be able to interact with an environment in ways they would not be able to in the real world, for example, "flying" above the ground or walking through walls. This has been highlighted in special needs education where wheelchair-confined students can "walk" through walls.

FIG. 46.3. A virtual city.

FIG. 46.4. Inside a school.

FIG. 46.5. Virtual driving.

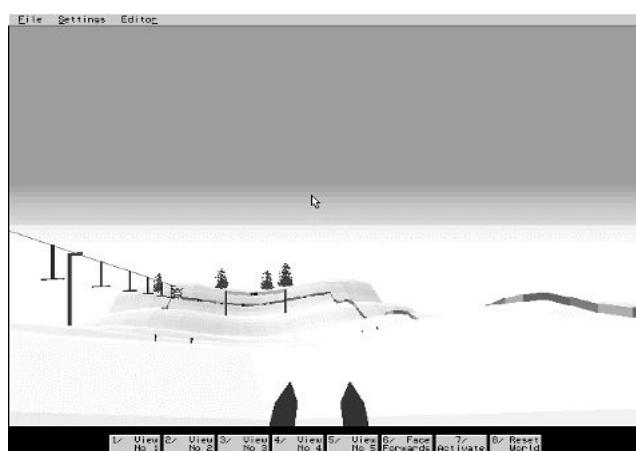

FIG. 46.6. Virtual skiing.

3. Real-time interaction. An important attribute of VEs is the fact that they allow real-time interaction between the user and environment. In a virtual training environment, the user can respond to a ringing telephone by clicking on the receiver with the mouse to pick up the phone (Fig. 46.7). This is also an example of how an environment can be created to elicit certain actions from the user. The kitchen environment in Fig. 46.8 includes a number of different objects with which a user can interact. The taps can be switched on, tea and coffee can be prepared, and the oven can be operated.

4. Split-screen interfaces. Virtual environments are completely versatile and so can be designed to suit application, task, or user specifications. An example is to split the screen or overlay menus that provide additional functions in a similar way to multimedia interfaces. Figure 46.9 shows an interface layout where a virtual hand signer and Makaton communication symbol is permanently displayed on the left side of the screen. The user can move around the VE on the right side of the screen to explore and interact with the objects represented by the Makaton symbol to gain an understanding of their meaning and function (Brown et al., 1995). Another example is where written instructions provided in text, icons, or picons (i.e., picture icons) are displayed around the outside of the screen (Cobb & Brown, 1997). Further

FIG. 46.7. Answer the telephone.

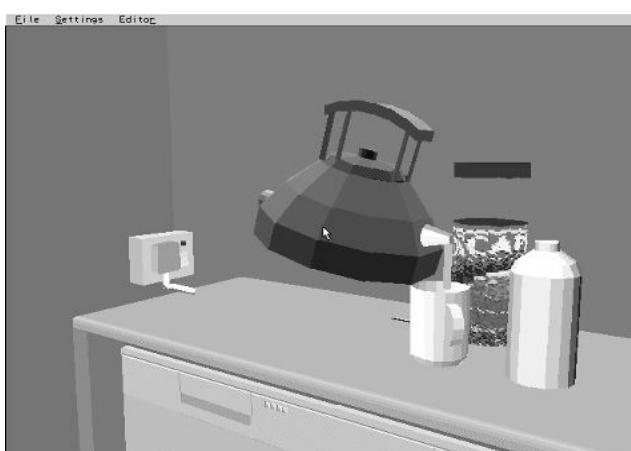

FIG. 46.8. Cooking in a virtual kitchen.

FIG. 46.9. Learning Makaton symbols and sign.

FIG. 46.10. Health and safety at work.

information can be gained by clicking on the forms on the left, which when selected are viewed in full screen and can be read (Fig. 46.10).

5. Reality and “superreality.” One of the potential advantages of VEs is that they allow behaviors not normally possible in real life. Figure 46.11 shows how a laser has been represented (Brown, Micropoulos, & Kerr, 1996). The user can navigate with a mouse or joystick to observe the laser from different perspectives and can actually look inside the laser beam where the wavelengths of the light are represented. Figure 46.12 shows a representation of a factory that demonstrates how an entire production run can be simulated. Various aspects of the run can be altered and the consequences observed. For example, quantities of product can be altered or machines can be moved. It is also possible to see the internal workings of the machines to gain an understanding of how the process works. This VE was created as a training environment to demonstrate specific features of VE to representatives from the U.K. manufacturing industry (Cobb, D'Cruz, & Wilson, 1995). This led some companies to develop their own virtual environments (Wilson et al., 1996).

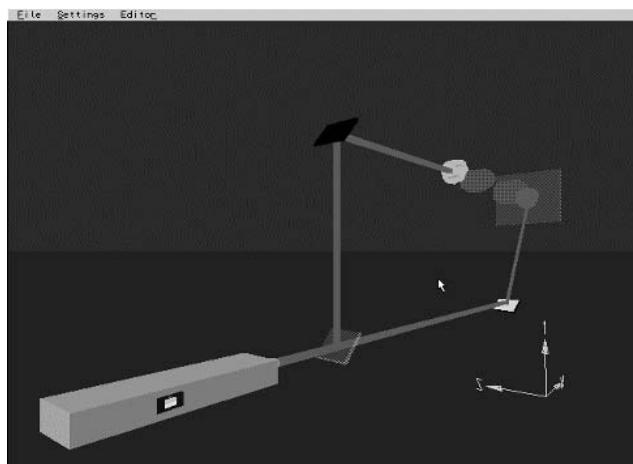

FIG. 46.11. Laser physics.

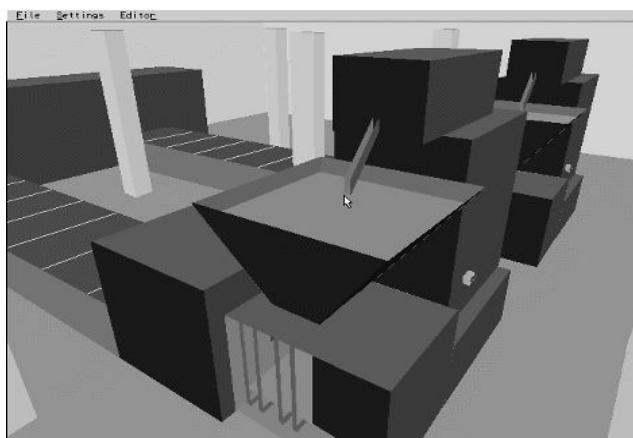

FIG. 46.12. Virtual factory.

During this familiarization phase, it is important that teachers and/or care workers are given the opportunity to explore exemplar VEs and become accustomed to participating in them. With a realistic understanding of what a VE is and the current capabilities and potentials of VLEs, both developers and potential users can work together to develop ideas for future educational VE applications. This ensures that ideas for VEs are relevant and useful to educational organizations, as well as being feasible (i.e., within the constraints of current VE technology).

2.1.3 Application Idea Generation

Once teachers and support workers have been made aware of VE technology and its capabilities, they are in a better position to be able to comment on how it might be useful to them. A brainstorming session can be held to generate ideas for specific applications of interest. Teachers and support workers will have responsibility for using the technology on a day-to-day basis and its integration within existing teaching methods. It can also be useful to involve users at this stage, where permissible. Users can provide insights into areas that they are interested in learning about, issues they want to more fully understand, and where current

teaching methods are inadequate. In this way the VLE produced should be derived from an authentic learning need expressed by the users themselves or the professionals responsible for teaching these skills and issues (Crosier & Wilson, 1998).

2.1.4 How to Select and Prioritize Ideas

The early stages of idea generation frequently end up with more possible VEs than can practically be developed. Prioritization of these ideas should involve a number of professional teachers or care workers, who will have a sense of what learning or development objectives are most important for the target user group. In the case of mainstream education, decisions may be governed by curriculum restrictions.

Technical and practical information also needs to be provided by researchers and VE developers, regarding what ideas are feasible in terms of time and technology capabilities. Virtual environment scenarios should be developed which maximize VE capabilities, so consideration needs to be given to other technologies or methods which may be equally useful in teaching the subject area so as not to “reinvent the wheel.”

Involvement of relevant groups of professionals at this stage of VE development is critical; it gives them insight into *why* the VE is being developed and provides them an opportunity to contribute information that could render the VE more relevant to their students or clients. Just as important, their involvement in early stages of development means that host or client organizations will be much more understanding and helpful when their time and cooperation are needed in the later stages of VE development. Since VLEs must not be one-off initiatives but should be embedded into schools and other institution’s general operations, early two-way dialogue with organizations will clear the path for ongoing success.

2.1.5 Involvement of End Users

It is axiomatic for human factors professionals that involvement of end users results in better developments and development processes. These procedures originate from participatory design of the workplace (Noro & Imada, 1991; Wilson, 1995; Wilson & Haines, 1997). The involvement of end users in the design process gives information as to how the end product will actually be used and puts it in a real-world context. When there is a distinct user population, with characteristics far removed from the designers of the product, there may be an increased need for user involvement in the development process. The field of HCI has recently adopted these design philosophies, and in the 1990s the design of technology for children has become more prominent (Druin, Stewart, Proft, Bederson, & Hollan, 1997; Druin, 1999; Druin & Solomon, 1995; Scaife et al. 1997). The involvement of older students in the design of educational technology may not be as essential in terms of the development of an “easy to use interface” as it is for other user groups such as young children. However, the way in which the technology is used, including the environment in which it is used and how the program is used (e.g., by one student, by the student and teacher together, by a group of students) may have an impact on how it should be designed. For example, in a school setting, sessions with the computer are often held in a designated “computer lab.” The students may have weekly 1-hour sessions within which they may use the computer. The software designed should take account of this and have enough content to keep the students occupied for the entire session.

The contribution of people with a disability to the research process has considerable importance as they have differing demands on the final product. Minkes, Townsley, Weston, and Williams (1995, p. 97) argued that involvement of people with learning difficulties resulted in: “research which more clearly benefits the people whom it is supposed to help.” Edwards and Hancock (1995, p. 365) also promote the involvement of disabled users in HCI research: “It is vital to involve potential users in the design process so that their needs (and not the

able-bodied designer's perception of their needs) can be addressed." The benefits of involving representative users in research and product development has been echoed in the Virtual Life Skills Project (Brown, Neale, Cobb, & Reynolds, 1999), also presented in this chapter as a case example (see section 4). Its production focused on users' needs and gave people with a learning disability the opportunity to develop and test a product, which they will use with professionals as part of their development. This resulted in a VLE that is both useful and usable and also improved confidence and skills of the individuals involved in the project (Meakin et al., 1998).

2.2 Building a Virtual Learning Environment

There is no single correct approach to building a virtual environment. In practice, the approach taken depends on what the VE is intended for, how well formalized the idea is, how specific users are in their requirements, and the experience and programming style of the individual VE programmers involved. What is most important is that the communication channel between user (or user champion) and programmer works well. In some cases this may not be a direct one-to-one communication channel but involve several links between different people such as teachers, support workers, researchers, and programming managers.

Development of VEs for education is an iterative process. Wilson and Eastgate (see chap. 17, this volume) detail a general framework for the development of virtual environments. Initial brainstorming with teachers or support workers provides the context for the learning environment, specific learning objectives, and an outline of the layout and visual representation of learning scenarios. During these discussions sketch-style storyboards are drawn up, which are then presented to VE programmers, who examine them and make recommendations back to the review or steering group about what they think is feasible within the time scale allocated. This may require the review group to prioritize features of the VE or to identify particular learning objectives that should be the main focus of the VLE. In our experience, we have found that initial user requirements are often based on what they already know about VE capabilities; having seen familiarization demonstrations, users will ask for similar scenarios.

Therefore, it is useful at this stage to have a discussion between programmers and the review group, at which the programmer suggests alternative ways to achieve required effects or ways to reduce programming effort, but does not tell users what their objectives are. It is important that user objectives for a new VLE are not derived from what they have already seen, but that they are guided into stating their actual requirements. The level of programmer involvement in initial contact with users and professionals will affect their level of understanding of user needs. There is often a different level of communication required between the programmer and user, for example, more detailed questions about the design of a layout or a task within a VLE. If VE developers are involved from the start of the process then they will have a greater understanding of the messages that the VLE should put across and how this should be done.

The design of any computer program may be directed by the use of relevant guidelines. There are a number of HCI principles and rules, which may be used to guide interface design. A number of high-level and widely applicable principles can be useful to VLE developers. General principles that should be followed by VLE designers include: know the user population; reduce cognitive load; engineer for errors; and maintain consistency and clarity (Preece, 1994). An in-depth knowledge of the user population is essential to follow all of the other principles. For example, the level of cognitive load that is appropriate will be dependent on the user (children, adult with special needs, teachers, etc.).

Many design rules developed within general HCI are not relevant to VE design because of the different features and objectives of VEs as compared to graphical user interfaces (GUIs) or more traditional computer interfaces. For example, a user of a VE can navigate in 3-D space (see chap. 24, this volume) and interact in a more "naturalistic" way with representative of their

real-world counterparts (see chap. 13, this volume). These advanced navigational and interaction techniques require new directions in usability engineering (see chap. 34, this volume). Kaur, Sutcliffe, and Maiden (1998) have found that conventional interface guidelines are only partially applicable for designers of virtual environments. Designing for user populations who do not conform to general user assumptions compounds this situation.

There are a number of general guidelines and observations about VE design, a few of which concern representation of objects (Slater & Usoh, 1995), qualities of a virtual human (Thalmann & Thalmann, 1994), and communicating depth (Pimentel & Teixeira, 1993). A number of techniques for the design of user interactions have emerged such as support for guiding the user (Wilson et al., 1995) and support for object alignment (Buck, Grebner, & Katterfeldt, 1996). However, little experimental work or evaluation has been done, and there are few comparisons or established standards (Kaur et al., 1999).

There have been few studies into HCI for disabled users. Among these, Edwards (1995) reports on the work of Scadden and Vanderheiden (1988) and how they have considered the design of computers and operating systems for people with a range of disabilities. The populations covered included users with physical disabilities, visual and hearing impairments, and people sensitive to seizures. They recommended a series of steps for reducing cognitive barriers to computer use by such populations:

- Simplify language in task instructions
- Provide online help
- Make displays simple

Cress and Goltz (1989) compiled a more detailed list of design guidelines for improving computer accessibility for persons with cognitive disabilities. This list uses data from rehabilitation and educational literature and is intended to guide the design of computer hardware and software. The recommendations focus on input/interface control, presentation format, and information content and prompts.

The appropriateness of such guidelines for the development of VEs is not always clear. Perhaps, as the user is presented with a more interactive and realistic medium than the traditional computer interfaces for which these guidelines were derived, the VE interface will become more intuitive and easier to understand. Example guidelines include the recommendation for the visual and audio complexity of the output display to be minimized, as well as inclusion of online memory aids and help screens. During the development of VLEs for special needs education, developers have aimed to make VEs as naturalistic as possible, partially eliminating the need for online help. The display should allow the user to recognize the situation and to gain appropriate educational knowledge from the VE; however, this will not always result in a “simple” display.

3. EVALUATION OF VIRTUAL LEARNING ENVIRONMENTS

This section discusses the evaluation of VLEs, how this is being done and attempts to identify how it differs from evaluation of other learning technologies. The evaluation of VLEs may focus on two main issues. First, the design of the VLE itself may be evaluated: Does it contain relevant information and tasks for the intended user groups, and is it usable? Second, do users learn anything from using the VLE? A number of frameworks exist for the evaluation of learning technologies, such as Jones, Scanlon and Blake (1998) and Oliver (1997), and these may provide a useful basis upon which to base evaluation studies of VLEs.

In a number of cases VLEs have been compared with traditional methods of teaching and learning. The aim of technology development has frequently been to produce a program for a

medium, which some hope will be better for teaching and learning than traditional methods. However, it is very difficult for evaluators to prove that something is better. Jones et al. (1998) report that the educational experience often changes when educational technologies are used, meaning that it is impossible to make direct comparisons with traditional methods as something different, not better or faster, is learned. This different experience may be even more pronounced when comparing VLEs with traditional teaching methods or computing systems. Interacting with a VLE allows the user to experience situations, visualize in 3-D, and interact in a more natural and realistic manner. Comparative studies have shown on a number of occasions that VLEs will provide a very different learning environment and features of both VLEs and traditional teaching methods should be combined in order to reap the benefits from both types of systems. For example, a comparative study carried out on CDS (Conceptual Design Space) by Georgia Institute of Technology, reported in Youngblut (1998), found that there were different strengths to the use of VEs and traditional CAD systems for an architectural design task. One of the main findings was that qualities of VE should be combined with traditional methods to exploit the strengths of both. These apparent differences between VLEs and traditional learning systems make it clear that it is important in evaluating VLEs to concentrate on the experience of using the VLE in order to understand its unique impact on learning.

Evaluations of VLEs have, to date, been limited by the size and focus of the research projects within which they have been based, and by the maturity of VE technology. The review of educational uses of VEs by Youngblut (1998) includes descriptions of the types of evaluations that were carried out on VLEs up until 1997. The majority of evaluation studies was informal and employed only one iteration of evaluation. Many early studies focused on the usability of VEs, asking basic questions such as can the VE be used by students and which input devices are preferable? Many of the studies report attitudinal data to find out if the students enjoy using VEs to learn.

A number of VLEs have been more extensively evaluated using multiple strands of evaluation, an approach that has been advocated for such an immature technology (Rose, 1995). Roussos et al. (1999) describe the NICE project, where multiple measures of performance were taken in order to examine usability, orientation, attitudes, cognitive skill, pedagogical learning, and collaborative behavior. The ScienceSpace VE has been subject to a number of successive evaluations, looking at, among other aspects, students' interactions with the VE, expert ratings, and knowledge assessments. The findings have informed the VLE development process and are reported in detail in Moshell and Hughes (see chap. 45, this volume).

Evaluations of VLEs for users with special needs have not been as widely reported as those in mainstream education, and this may be because there are fewer VE developments in this area. This is also a very difficult area to evaluate. A disabled subject population, which may find it more difficult to use the VLE, may compound the usual difficulties of evaluation. There will therefore be more usability issues, and user feedback about the VE may be more difficult to obtain. Strickland (1996) examined the use of VE for education of children with autism. This took the form of an informal observation of two young children's use of a virtual environment. Neither child could communicate well enough to describe their thoughts, and so their actions were interpreted as indicating different responses to the virtual environment. VIRART have conducted a succession of evaluation studies of VLE use with learning disabled users. Early informal studies looked at whether students with learning disabilities could access VLEs and how they could be used in support of standard teaching methods (Brown et al., 1995; Cromby, Standen & Brown, 1996). Further studies had a more formal and focused aim, such as Crosier (1996), who compared input devices for use with VEs, and Standen, Cromby, and Brown (1998), where transfer of skills from the VLE to the real world was assessed and compared with students that had no VE training. A more structured evaluation approach was adopted by Neale et al. (1999), who examined in detail the process of students interactions with VLE.

This study was based mainly on collection of observational data, as interpretation of subject's feedback was limited (i.e., participants were all young children, aged between 7 and 11, with severe learning disabilities).

Formative evaluation and iterative development of VLEs should ensure a more useable and useful product. In this section, a series of questions are presented, which researchers will face when deciding how to evaluate a VLE. The actual evaluation strategy used will be dependent on the answers to each of these questions; due to the interdependent nature of the questions, this may be a highly iterative process.

3.1 What to Evaluate?

The first issue evaluators of VLEs will have to ask themselves will be what do they want to evaluate. One way to determine this is to look at the rationale behind the development of the technology. The evaluator should find out what the VLE is intended to "teach," in which settings, and with which populations. These issues should have been decided in the early stages of VLE development, with the involvement of representative users and teaching/training professionals (as detailed in section 2).

The application of traditional methods for measuring knowledge acquisition has not found clear learning effects in a number of cases. Moshell and Hughes (see chap. 45, this volume) have reported that this "weak learning effect" may be due to a brief period of use of the technology, difficulty of use, and different types of learning (process and strategies rather than facts). Therefore, in deciding what to examine, the researcher may use a pilot study. By examining what happens when the VLE is used, important factors, not taken into account during the design of scenarios to support learning, may be highlighted. For example, the study may focus on usability and attitudes. If the VE is neither usable nor enjoyable it will not be used, and so the educational aims will not be achieved. There may even be a broader range of effects from the use of educational technology (Draper, Brown, Henderson, McAteer, 1996).

3.2 When to Evaluate?

A VE may be evaluated a number of times throughout its development cycle. Earlier in the cycle, evaluation may take the form of informal reviews, initially with research colleagues and later more formal meetings with educational professionals and representative end users. Pilot studies early on in the development cycle may be used to highlight the elements important to assess in the project and identify and develop useful methods to do so. These will be applied in more detailed summative evaluations that may take place further into the development cycle (see chap. 34, this volume).

3.3 Where to Evaluate?

The two basic settings for evaluation are the laboratory and the field. All the usual advantages and disadvantages of each are relevant, with the added need to consider the effects of either bringing young children or people with special needs into the laboratory or else of the researchers entering their environment. In the laboratory it is possible to control extraneous factors and to manipulate independent variables to allow stringent experimental designs to be followed. This can also be a criticism of this setting, as it is suggested that results often cannot be transferred to the real-world setting or that all the real variables of interest are those that cannot be manipulated in any valid sense. Moreover, for some individuals, the unfamiliarity of the research laboratory can represent a potentially hostile environment in itself, and this could negatively affect their attitudes and learning.

Access to classrooms or working environments for field evaluations may be limited, but can give good ecological feedback for VLE design. The types of evaluation methods used in-situ need to be carefully considered. For example, audio recording may not be successful where there are high levels of background noise. School and college classrooms often provide a challenging space in which to work, as the researcher has to fit in with class timetables as well as contending with other classroom activities and noise. However, field work gives an insight into how the application will eventually be used and may be most useful in making sure the VLE will be practical and usable.

3.4 Who to Evaluate?

Deciding who participates in the evaluation study will depend on when the evaluation takes place and the scale of the study, as well as upon what is to be measured. For example, teachers would identify whether educational objectives are satisfactorily represented in the VLE, pupils can provide usability data, and both might provide attitudes towards the VLE. The particular evaluation participants may vary at different stages of the evaluation cycle; different population samples may be used in parallel to look at different aspects of the same VLE.

3.4.1 *Development Team As Evaluators*

The initial review of the VLE will be executed by the technology development team. This is commonly an informal run-through of the VLE, when bugs are checked for, the running order is verified, and consistency is examined.

3.4.2 *Representative Users As Evaluators*

There may be difficulties in involving representative users for a number of reasons, for instance:

- Access may be limited due to busy school timetables or resistance from teachers, care workers, authorities etc.
- Insufficient communication skill among the user populations limits subjective feedback.

In spite of these difficulties, there are a great number of benefits to involving representative user populations in many stages of evaluation. Some research projects have tried to minimize the difficulties faced from working with a disabled population by testing VEs with participants not representative of the intended user population. This is often used as a first step in the evaluation process (Jansson, 1998; Jones, Scanlon, & Blake, 1998). It is often both quicker and easier to get colleagues and university students to test the virtual environment. However, the depth and validity of information that may be gathered when representative users are involved in the evaluation process will help to contribute to a more accessible, appropriate, and useful VLE.

3.4.3 *Educational Professionals*

It may be advantageous to involve educational professionals in the evaluation phase. They have an intimate knowledge of the learning objectives that should be represented in the VLE, are likely to use the VLE themselves, and will be responsible for determining how and when the VLE will be used in-situ. Educational and learning disabilities professionals can respond to interviews and questionnaires, providing a great deal of detailed information in a short space of time.

3.5 How to Evaluate?

Once decisions have been made regarding the when, where, who, and what, appropriate evaluation methods must be chosen. A number of different methods may be applied to complement each other and obtain relevant information. As few guidelines exist for the development of VEs, evaluation methods tend to be based on those which have been applied extensively in HCI, education, and social science research (Dane, 1990; Oppenheim, 1992; Preece, 1994; Robson, 1993). We have begun to apply some of these methods and modify them so that they meet more specific VE evaluation needs. Deciding which methods to employ will be dependent on the educational objectives of the VLE, the intended use and user populations, and the time available for evaluation. Time is often at a premium when the evaluation stage of VE development is left until last.

Qualitative data, collected from observation studies, interviews, and questionnaires, can be illuminating, as they are used to describe and interpret what is going on. This information may be particularly useful in the examination of a recently developed VLE, as there may be little previous knowledge as to how the VLE will be used. The majority of evaluation frameworks for educational technologies and VLEs advocate a combination of methods that complement each other (Oliver, 1997). By using different methods, multidimensional aspects of VLE use may be investigated (Roussos et al., 1999).

The current immaturity of VEs in general and VLEs in particular has impacted on the types of evaluations that have been carried out. The VLE evaluations described by Moshell and Hughes (see chap. 45, this volume) reinforce this view, as the most useful results found came from informal observed phenomena, not formal evaluations. However, the field may move further toward that of educational technology evaluation, where formal comparative studies are carried out in order to show that the technology is educationally effective, which is essential if it is to be widely adopted in an educational setting.

4. CASE EXAMPLE: THE VIRTUAL LIFE SKILLS PROJECT

Following an early series of VLEs developed for special needs (Brown et al., 1995; Cobb et al., 1993) funding was obtained from the U.K. National Lottery Charities Board to build a virtual city. This aimed to support experiential learning environments within which adults and older children could practice a range of life skills in preparation for independent living (Brown et al., 1999). Three modules were constructed: a house (Fig. 46.13), supermarket (Fig. 46.14),

FIG. 46.13. A virtual house.

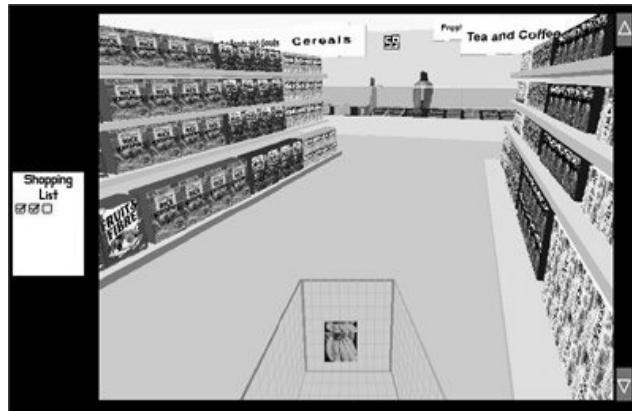

FIG. 46.14. A virtual supermarket.

FIG. 46.15. Ordering at a bar in a virtual cafe.

and cafe (Fig. 46.15), which were linked together via a bus transport system (Fig. 46.16). A variety of learning scenarios were placed into each module (26 in total), including: choosing appropriate clothing for the weather conditions; using the bathroom (highlighting issues of privacy); dealing with emergencies (e.g., fire); creating an icon-based shopping list; finding items in the supermarket; paying for goods at the checkout; choosing the right bus; crossing the road safely; putting food away in the kitchen; preparation of a simple meal (including safety issues in the kitchen and use of appliances); and ordering in the cafe.

Content and presentation of these learning scenarios were determined in consultation with a user group comprised of children and adults with learning disabilities who met regularly to brainstorm ideas and feedback on design ideas. This user group was involved with development all throughout the project, culminating in them presenting their own research paper, describing their involvement in the project, at a European academic conference (Meakin et al., 1998).

The involvement of a number of different community groups, including special needs schools and colleges, as well as adults in supported housing, meant that the project involved users from many areas ensuring the final product would have as wide an audience as possible. The user group and steering group also included members from different disciplines. This allowed people from different backgrounds, ages, and abilities to be involved in production, development, and evaluation, thereby having a real influence on the product.

4.1 The User Group

Fifteen representative users from the community groups previously mentioned worked together with a facilitator to provide effective advocacy to form the user group. Members of this group

FIG. 46.16. Catching a bus.

were selected to ensure a balance of age, gender, disability, and cultural heritage. The group met every month to brainstorm ideas about what components they thought should be included in a virtual city and what tasks they would like to practice in each part of the virtual environment. The group initially identified 38 modules they wanted to be included, ranging from a cinema and a pub, to a railway station and a health center. The user group decided which of these were important to them and what they wanted to be able to do in each module.

The first drafts of the VE storyboards were drawn at these meetings. The group's ideas were represented by cartoon-style storyboards, which were used to promote discussion about a topic or object using an easy to understand visual design aid.

4.2 The Steering Group

A project steering group, was comprised of professionals who work with learning disabled clients or students. They worked for a number of organizations, including those from which the users were drawn. Their main role was to identify specific user requirements and learning objectives appropriate to the skills to be developed. Initial meetings highlighted differences of communication, terms, and focus of interest between the disciplines. This forced the groups to bring consistency to their way of working and use effectively their diverse range of knowledge and experience.

4.3 User-centered Design

The ideas generated at user group meetings, represented by storyboards, were taken to the Steering Group. Their role was to identify how suitable learning objectives associated with the scenarios defined by the user group could be conveyed in a virtual environment. A final storyboard, detailing layout, structure, learning objectives, and dialogue was then drawn up for each component.

During the construction phase, members of the user group and steering group regularly reviewed developments to ensure that they were being built within the original vision of the storyboards. When completed, a program of testing was carried out to assess the suitability of these VLEs for learning of independent living skills by the user group. Evaluations were carried out by users and professionals using a variety of measures; including performance of tasks under experimental conditions, observations of usability, questionnaires, and informal interviews. The results produced recommendations for design changes to each of the VLEs.

4.4 Evaluation of the Virtual City

Evaluation of the project assessed usability and access of the VEs themselves, as well as skill learning and transfer to the real world. Fourteen participants completed a 7-week experimental program comprising observation of skills in the real environment (supermarket, cafe, or bus), 5 weeks use of the VE, and another visit to the real environment. Results from this and other projects show that despite support worker expectations of usability problems, users with learning disabilities are able to access and use virtual environments, and often take control over navigation and interaction decisions (Neale et al., 1999). High levels of enjoyment and motivation were expressed by users and some evidence of transfer of training was recorded, although it was not expected that high levels of skill learning would be acquired in such a short training period (Cobb, Neale, & Reynolds, 1998).

A contribution to the success of these projects has undoubtedly been the user-centered design approach. This ensures that issues of access and usability are taken into account during development and also that presentation of information is given in an interesting and appropriate manner. An added bonus to the project was that some individuals from the user group expressed personal gain from being involved in a research project (e.g., decision making, discussion, and presentation skills). Meakin et al. (1998), written by the user group, describes the user group's involvement in the Virtual Life Skills project. It is uncommon in the wider scientific community for users to be an integral part of the design process, but in this case, user group involvement ensured the relevance and accessibility of the end product. What proved important was that the users developed a sense of ownership of the project and that their needs and interests were represented in the design of the virtual city.

5. CONCLUSIONS

This chapter has discussed the importance of user involvement at all stages of design, development, and evaluation of virtual learning environments. As a culmination of a series of VLE development projects in which professionals from mainstream and special needs education worked with VE developers at VIRART (Brown et al., 1995; Cobb et al., 1993; Crosier et al., 1999; Neale et al., 1999), the Virtual Life Skills project, presented as a case example in section 4, provided the opportunity for a broad range of professionals and users within the community to collaborate in VLE development (Brown, Kerr, & Bayon, 1998; Brown et al., 1999; Cobb, Neale, & Reynolds, 1998; Meakin et al., 1998). An initial User-Centered Design Model, based mainly upon this particular project, is shown in Fig. 46.17 and summarized here.

It can be seen that there are a number of iterative loops within the process. At the outset of the project, the interests of end users and the professionals who will apply the VLE are gathered (via the user group and steering group). These two groups work together to define the objectives and content for the VLE. During this process storyboards are drawn up, and the user group and steering group work with VE developers adapting the storyboards until they provide a specification, which is both technically feasible and meets the requirements of the user group and Steering Group.

Once the VLE specification has been agreed, VE developers start the creation of VE modules. It is important that there is facility for regular review of VLE development to ensure that developers have interpreted storyboards appropriately. It is recommended that review meetings be held at least once every month, but the more frequently project members can review VLE development the better. It is often the case that, when members of the user group and Steering Group actually see their ideas put into effect in VLE development, they change and/or add to their original requirements. This may be because the VLE is not developing as they had

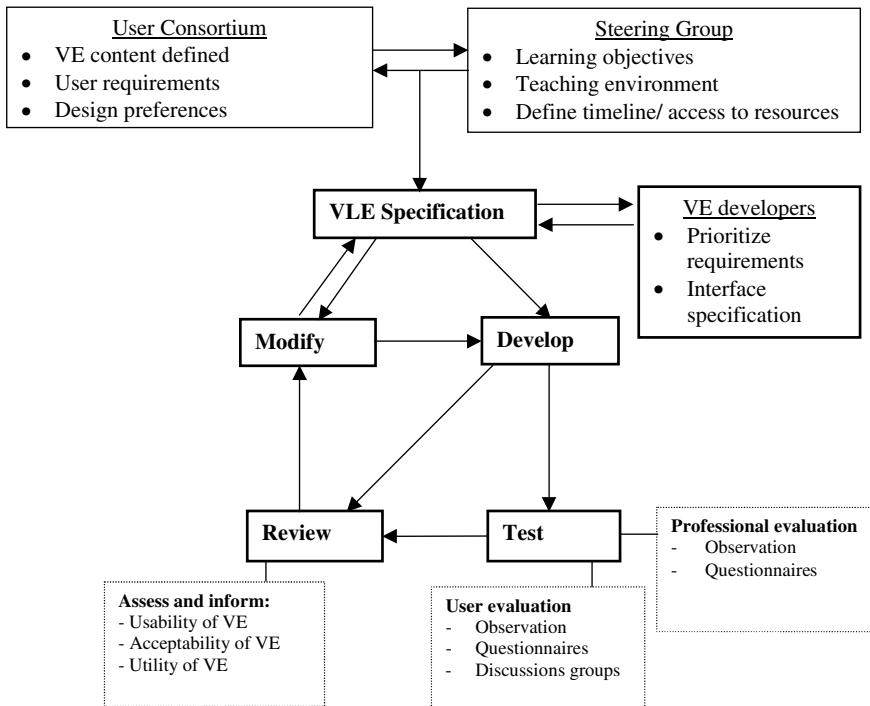

FIG. 46.17. User-centered design and evaluation model.

envisioned, or because they get new ideas as they see what can be done. They may also become more confident in expressing their views as they become more familiar with VE technology. This phase of VLE development can therefore be extremely creative, and it is worthwhile taking time to complete this phase fully.

There is an iterative cycle between VE building, review of VLE development by representatives of the user group and steering group, and modifications made to VLE modules, with reference back to VLE specification, and back into continued development of the VLE. This forum allows what may be the first opportunity for project members to discuss specific features of VLE design. Decisions made at this stage can have a huge impact on usability and acceptance of the final VLE. This chapter has indicated that existing HCI design guidelines are limited in their application for VLE design. Involving users and professionals in regular informal review and evaluation sessions can help to highlight and resolve potential barriers to usability.

When VLE development is complete, formal evaluations can take place. These evaluations feed into VLE review, which can then be used to provide recommendations for additional design modifications. Early evaluation studies provide feedback on general usability and acceptance of the VLE. If this takes place during project development, the user group and steering group will be able to comment on the results and may be able to offer suggestions for design modifications. It is not advisable to leave all of the formal evaluations until the end of the project, as there may be insufficient time and resources to make any necessary amendments.

Evaluation studies may include a number of measures in order to capture information from a number of sources to address questions such as usability, enjoyment, and educational effectiveness. It is important to take context into account, as this may greatly impact upon how

the technology is used. For example, the number of users sharing a computer and length of time users have to explore in a classroom situation, as compared with home study, will affect the effectiveness of the final design.

In the case example presented for special needs education, user involvement led to many benefits over and above those provided by the VLE itself. Users expressed positive outcomes relating to increased self-esteem, confidence, and motivation as a result of participating in a research development project (Brown et al., 1999). Moreover, it was clear that users valued the fact that researchers had bothered to ask them what they wanted (Meakin et al., 1998).

The model/framework presented in this chapter has allowed us to develop useful and usable VLEs. However, it will be constantly updated as we refine and improve our ways of developing VLE systems. For example, we plan to design and evaluate new VLEs with increased numbers of user groups from different organizations, cultures, and countries. This may require additional iterations with the model to update or refine for different user groups.

One ongoing project that has adopted a similar framework of development aims to develop VEs to support social skills learning for adults and adolescents with Autistic Spectrum Disorders—the AS Interactive project (Parsons et al., 2000). In the development of the first VE prototype groups of autism training practitioners, teachers, and end users have been involved in design, through workshops, reviews and observation studies. The model has been adapted to meet the specific needs of this project, this has included the development of design criteria derived from expert literature reviews as well as refining evaluation methods so that they are appropriate for autistic users. The framework was also adopted in a three-year research project to develop a virtual environment for teaching radioactivity at secondary school level. The resulting VE, Virtual RadLab, was developed with the co-operation of thirty teachers from sixteen schools in Nottingham, UK. Teachers were closely involved in the development process, making initial decisions about the most suitable use of virtual reality for support of secondary science teaching—radioactivity—and advising the research team on design and content of the Virtual RadLab (Crosier, Cobb & Wilson, 1999). As well as the highly iterative design process, Virtual RadLab also underwent a series of school-based evaluation studies (Crosier, Cobb & Wilson, in press; Crosier, Cobb & Wilson, 2000). As a result of the research, funding was obtained to produce and distribute 3,000 copies of Virtual RadLab to schools across England. This has allowed teachers and students across the country to experience VEs first hand, and also to recommend areas of application for VEs in the future.

Only with careful design, development, and evaluation of software can an understanding of the impact of well-designed, appropriate, and useful VLEs in the general field of education be gained. Content, its representation in the VE, which takes into account qualities of VE technology and intended users, need to be considered in the development of VLE systems. In this chapter, a framework for carrying out such a development process is introduced. Only when evaluations have shown that the content covered is both appropriate, well presented, and the VLE is usable can the true value of VLEs as a learning tool be comprehended.

6. ACKNOWLEDGMENTS

The authors would like to thank all of the users and professionals who have worked with us in the development of virtual learning environments. These include infant, primary and secondary schools in Nottinghamshire, Nottingham Social Services, Mencap, and further education centres supporting special needs. Particular thanks go to David Brown, who initiated the Virtual Life Skills project. Also to David Stewart of the Shepherd School in Nottingham, and Hugh Reynolds of Metropolitan Housing Trust, Nottingham, who have provided us with access and insight into the needs of users within the community. The Virtual Life Skills project was funded

by the U.K. National Lottery Charities Board. The work of Joanna Crosier is funded by a Ph.D. studentship from the EPSRC.

1. INTRODUCTION

The benefits of virtual environments (VEs) to health care can be summarized in a single word: revolutionary. The “Information Age” has yet to arrive for medicine, and the infrastructure put in place by other disciplines and industries can be used to leapfrog into the next generation of health care. The most pervasive aspect of VE will be the core technology of interactive three-dimensional (3-D) visualization (see chap. 53, this volume). Those aspects of VE that are relative technologies, such as whether the experience is immersive, augmented (see through), or whether the display is an head-mounted display (HMD), 3-D video monitor, or room-size Cave Automatic Virtual Environment (CAVE), or whether the experience is on a local computer or distributed over the Internet, are analogous to peripherals that can be used to customize the VE application to best suit the health care provider or patient. While there are many different ways to classify the medical applications, one that incorporates the essentials for the practice of medicine provides an excellent framework. The key components are diagnosis, therapy, education and training, and the medical record. However, it is essential that the implementation of these applications is totally integrated and that the full spectrum of health care is incorporated. One method to accomplish these two goals is through the 3-D representation of the patient as a virtual person “medical avatar” (Satava, 1998, p. 29) or Holographic Medical Electronic Representation or

* The information contained herein reflects the opinion of the authors and in no manner represents the official opinion of the Department of the Navy or Department of Defense.

holomer™. The greater the amount of data used to recreate the “information equivalent” of the person, the higher the fidelity of the representation and the more accurate and useful for patient care.

The origin of digitally representing a person derives from two sources: Negroponte’s (1995) concept of “bits instead of atoms,” whereby an object in the real world (atoms) can be represented in the information world by a computer image (bits), and Ackerman’s (1998) program from the National Library of Medicine, the Visible Human, which is an actual person who was scanned in three modalities (computed tomography, magnetic resonance imaging, and phototomography) to provide a full 3-D-information-equivalent computer image (Spitzer & Whitlock, 1992). As more and more of the medical technologies become information-based, it will be possible to represent a patient with higher fidelity to a point that the image may become a surrogate for the patient—the holomer. The practice of medicine can take advantage of the power of the science of modeling and simulation and optimize the patient care by first performing on the surrogate until the best solution is achieved, then providing personalized quality care. The initial accomplishments will be at the macro level for the whole body, organ, and tissue systems; then further levels of glandular structure, molecular, biochemical, and genetic information can be added. With each increase in information, the validity of the model will improve and hence the quality of patient care and value of the model. In order to illustrate the power of this approach, the following scenario is offered as a reference framework of how the total spectrum of care can be completely integrated. For the purpose of identification, this framework is called the Doorway to the Future, and may require 20, 50, or even 100 years to achieve (Satava, 1998, p. 30). It is not possible to ever complete such a project, because modeling the human organism can always have more information derived for greater fidelity.

As a patient visits a physician, they will pass through a doorway in which numerous sensors and imagers are embedded, such as CT or MRI scan, ultrasound, and other technologies. Until this is accomplished, previsit scans will be accumulated. When the person sits at a desk, noninvasive vital signs and biochemical data will be acquired, just as pulse oximetry is used today to acquire heart rate, oxygen saturation, and other values. All information and images will be collected in a database, and then between the physician and patient a holographic image of the person (holomer) will be displayed, just as Dimensional Media Associates suspended holographic image (Chinnock, 1995; Fig. 47.1). This will be the medical record, a visual database with all of the information contained within the image. It is simultaneously the

FIG. 47.1 Suspended holographic image of a mandible. Courtesy of Alan Sullivan, Dimensional Media Associates, New York, NY.

interface—an intuitive method of query. After the patient provides the history of illness and physical exam, the physician can interact with the image (similar to visual databases today) to obtain information. If the person complains of right upper quadrant pain, the image can be made transparent and the liver directly queried for relevant laboratory data such as liver enzymes, alkaline phosphatase, or bilirubin, as demonstrated by Engineering Animation, Inc. (Sellberg & Kerr, 1998). If there are any abnormalities noted, the physician can use the image for diagnosis by performing a virtual endoscopic procedure to look for abnormalities. There are numerous physicians performing the clinical comparison of conventional video endoscopy to virtual endoscopy (see below, virtual endoscopy). If an abnormality is found, the physician can use the image for patient education to show and explain the patient's problem—the image is now a patient education tool. If the abnormality will require a complicated operative procedure, the image can be used for preoperative planning, as done by Taylor, Hughes, and Zarins (1998), or imported into a surgical simulator, like Levy (1996), and used to optimize the surgical procedure for that specific patient. At the time of surgery, the image can be imported into the procedure using data fusion with a video image of real-time surgery, providing assistance with intraoperative stereotactic navigation, as performed at the Brigham Women's Hospital by Jolesz and Shtern (1992). Finally, when the patient returns for follow-up weeks after the procedure, a complete scan is once again performed, the database will perform data fusion and digital subtraction like E. Grimson (personal communication, 1997), with the difference being automatic outcomes analysis. The power of this scenario is that it provides a framework for the technologies that encompasses the full spectrum of health care, and integrates the information equivalent of the patient into a single record continuous across time. It can be updated as needed and made available to the patient on a personal credit card sized record, like the military's personal information card, or perhaps contained on a secure webserver on the Internet and available for global consultation through telemedicine.

The VE technologies and applications that support this framework can be discussed within the context of the provision of medical care, mainly for diagnosis, therapy, and education and training. However, there is overlap in many of these areas, for education and training is increasingly being embedded into the actual devices that are being used for diagnosis and therapy. An example is ultrasound (Fig. 47.2), where the real-time image from a procedure is replaced by an archived image of an actual patient, and the student scans a mannequin as an ultrasound simulator with the same equipment and in precisely the same manner as an actual patient (Meller, 1997). It is imperative to understand that the utilization of VEs is in its infancy, and the following applications are just the beginning of a new direction. Many are in the laboratory investigation, beta prototype, or clinical investigation stage; few have been inserted into routine clinical practice. The furthest developed of the applications are undergoing rigorous and stringent testing and evaluation for technical and clinical efficacy, for Food and Drug Administration (FDA) approval and cost-effectiveness. It is unclear which will succeed in this arduous process for full-time clinical practice.

2. DIAGNOSIS

Diagnosis using virtual endoscopy is one of the areas that will achieve clinical efficacy in the earliest time frame. The National Institutes of Health and the National Cancer Institute have targeted virtual colonoscopy as the pilot study to compare standard video colonoscopy to virtual colonoscopy for colon polyps and cancer screening. Should this prove effective, virtual endoscopies of any of the other organ systems will follow. There are over two million standard video colonoscopic procedures performed each year, and over 75% are "normal," the majority due to screening for cancer. A virtual endoscopic procedure is performed by using a

FIG. 47.2 UltraSim, the ultrasound simulator, displays patient-derived ultrasound anatomy and pathology on a monitor in response to motions of an actual transducer, precisely mimicking an ultrasound examination. Courtesy of Garrick Herrmann, MediSim, Inc., Ft. Lauderdale, FL.

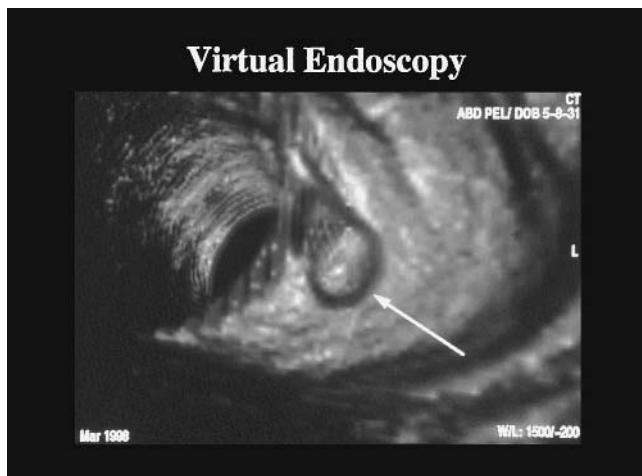

FIG. 47.3 Virtual colonoscopy. Courtesy of Dr. James Brink, M.D., Yale University School of Medicine, New Haven, CT.

standard CT scan or MRI scan, reconstructing the organ of interest into a 3-D model, and then performing a fly through of the lumen (Fig. 47.3). Typical examples of effected organs include the colon, stomach, esophagus, tracheo-bronchial tree (bronchoscopy), sinus, bladder, ureter and kidneys (cystoscopy), pancreas, or biliary tree. There are numerous advantages to such a diagnostic tool as compared to inserting actual instruments (endoscopes) into the body. First, all endoscopic procedures are invasive, and thus the patient must be sedated

and during the procedure they are subject to complications (small though they are) such as perforation, bleeding, and others. The cost for a typical colonoscopy is significant, for it must include a dedicated suite, personnel, specialized equipment, consumable materials, medications, and administrative staff. A virtual colonoscopy is constructed from a helical CT scan of the abdomen, is completely noninvasive, and thus without known complications. The actual cost is less than one third of video colonoscopy because it is performed in the same place and manner as all imaging modalities, utilizes the same staff, and has no consumable materials. The advantages of the video colonoscopy is that a therapeutic procedure can be performed if an abnormality is found, whereas any abnormality on a virtual colonoscopy must be referred for true colonoscopy for the therapy, such as polypectomy or biopsy of suspected cancer. Virtual colonoscopy has the advantage of being able to view the colon from any angle inside the lumen (small polyps can be hidden behind folds or twists in the colon during actual colonoscopy), or being able to fly "outside" of the lumen to see if a tumor has spread to the surrounding tissues or lymph nodes. In addition, the virtual image can be manipulated, actually opening up the tubular structure and lying it flat like a terrain map, to look for abnormalities (Meller, 1997). The wall thickness can be measured for early flat cancers, not usually detectable by standard colonoscopy (S. Napel, personal communication, 1999).

The limitations to virtual colonoscopy at this time are significant and will need substantial research to reach their full potential. These limitations include accurate color and texture mapping of the tissues (Hohne and Bernstein, 1986). A preliminary step has been taken by John Kerr of Engineering Animation, Inc. (Sellberg & Kerr, 1998), in which a color look-up table has been created using the visible human data set, comparing Hounsfield units of the CT scan to color values from the phototomographs. The preliminary images, using a liver model, are promising but are not accurate enough to be useful for clinical diagnosis. Just as the early attempts to convert black-and-white cinema films into colored films have progressed to excellent representations today, advances need to be initiated to create accurate color and texture for endoscopic images. Another limitation is removal of all the stool within the colon to prevent false diagnoses of abnormalities. Solutions under investigation include more effective purgatives or drinking a fluid that will tag the stool, allowing it to be digitally subtracted during the virtual reconstruction. Finally, the level of resolution of the image today is at 0.3 mm for the helical CT scanners. This is usually adequate for gross lesions, though full 3-D reconstruction does not give this accuracy. For lesions greater than 3 mm in size there is a 75% detection rate, and those greater than 5 mm have a 95% detection rate (Beaulieu et al., 1998). This is becoming comparable to detection rates of standard colonoscopy. As imaging modalities improve, so will resolution and detection rate. Perhaps next generation systems will acquire multiple modality images (CT, MRI, ultrasound, etc.), and then using data fusion, provide more information than can be obtained with a single image. The extraordinary challenges of automatic segmentation, registration, accurate tissue identification, and data fusion provide nearly unlimited research opportunities, which can provide both early and long-term benefits for clinical application to patient care.

Another diagnostic application is that of preoperative planning using the virtual image of patient specific data. There are numerous areas that have had initial investigation, especially in the neurosurgical, orthopedic, maxillo-facial, plastic surgery, and vascular arenas. Stereotactic neurosurgery has been clinically implemented for over a decade, and central to its success has been accurate localization of abnormalities in the brain through 3-D reconstructions from CT and MRI scans. Using fiducial markers on the skull or by placement into a frame that provides stereotactic reference, neurosurgeons have full 3-D models of the brain to precisely plan both the exact position, as well as safe pathway to removal or ablation of deep-seated brain lesions (Fig. 47.4). The current generation systems are using bony landmarks of the skull as frameless fiducial references for the preoperative model, and then updating the image with real-time open MRI scanning as the stereotactic neurosurgical procedure is being performed (Beaulieu et al.,

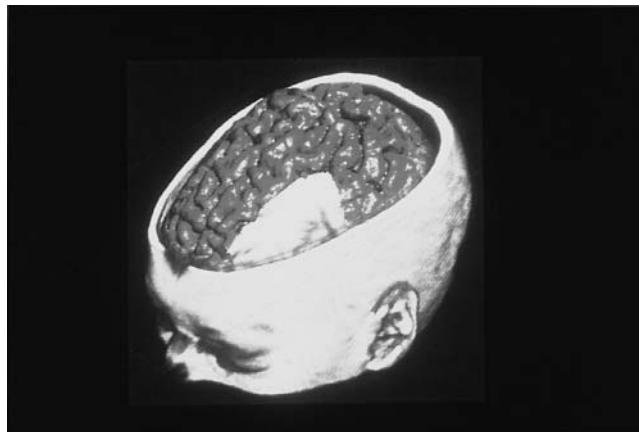

FIG. 47.4 Three dimensional representation of a patient with a brain lesion. Courtesy of Dr. James Duncan, Yale University School of Medicine, New Haven, CT.

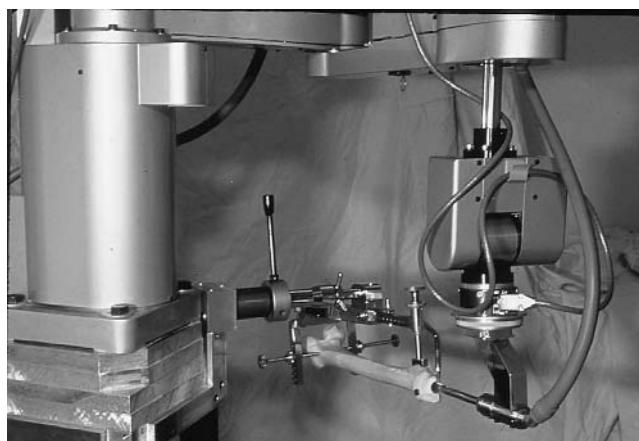

FIG. 47.5 RoboDoc, precision surgical robot for hip replacement surgery. Courtesy of Dr. William Barger, M.D., University of California, Davis.

1998; Jolesz, 1997). In orthopedic surgery, the areas of hip and knee replacement are maturing as clinical tools. One of the earliest robotic surgical devices, RoboDoc for hip replacement (Fig. 47.5), uses a computer program called OrthoDoc to preplan the procedure (Paul, 1992). Taking orthogonal views of the patient's hip as well as manufacturer supplied models of the prosthesis, an accurate preoperative match can be obtained. The coordinates of the placement for the prosthesis are fed into a robotically controlled system to bore out the center of the bone to mount the prosthesis. Normally, a surgeon using handheld surgical instruments can create a cavity into which the prosthesis fits with approximately 75% of the surface contact to the bone. Using RoboDoc, the cavity can be precision crafted so the prosthesis has 96% surface contact, providing a better fitting and longer lasting replacement. Similarly, Anthony DiGioia of Shadyside Hospital in Pittsburgh is doing preoperative planning for replacements using HipNav (DiGioia, Jaramaz, & Colgan, 1998). For maxillo-facial reconstruction of congenital or traumatic abnormalities, Altobelli et al. (1993) of Brigham and Women's Hospital and

recently Montgomery, Stephanides, Schendel, and Ross (1998) of Stanford University have been using 3-D images from CT scans. The face is a symmetrical structure, so abnormalities on one side of the face or skull have a mirror image portion of the face that is normal. By comparing the normal side of the face to the defect, an accurate reposition or replacement for the malformation can be planned. In the area of defect, the mirror-image model can be exported to a computer-assisted design and computer-assisted manufacturing (CAD/CAM) system, which can precisely manufacture an appropriate prosthesis for implantation and reconstruction. The new generation systems are able to use 3-D stereolithography to automatically construct a 3-D prosthesis directly from the CAD/CAM information (Bill et al., 1995). Drs. Pieper and Rosen of Dartmouth University (Pieper, Laub & Rosen, 1995) have developed a preoperative planning tool for plastic surgery reconstruction of skin lesions on the face. Using finite element modeling of the layers of the skin, portions of the skin can be removed, and then the results of reapproximating the skin edges using different techniques can be visualized for optimizing cosmetic appearance. Liver surgery is a very complicated and demanding procedure because of the multiple different pathways for arteries, veins, the portal system, and biliary tree. Marescaux et al. (1998) of the Telesurgical Institute of Strasbourg, France, is using patient-specific CT scans of the liver to preoperative plan these complicated procedures (Fig. 47.6). In vascular surgery, Taylor and Zarin of Stanford University (Taylor et al., 1998) have approached the difficult problem of choosing the best vascular grafting for complicated vascular lesions of the aorta and lower extremities. From digital MRI angiography, 3-D representation of the vascular tree, patient specific lesion, and fluid dynamics (flow) can be modeled. With this specific anatomy, as well as characteristics of the vascular graft prosthesis, numerous different possibilities for bypassing specific vascular obstructions can be tried, with each model predicting the probable flow to the lower extremities. The accuracy of these predictive models will soon be validated using animal and clinical trials.

The power of preoperative planning is analogous to testing and evaluation through computer simulation in many industrial sectors, from aerodynamics and ergonomics in the aerospace and automobile industries to building structure and interior appearance in the architecture and design fields. The ability to try numerous different possibilities, optimize the procedure for the

FIG. 47.6 Liver surgery simulation demonstrates any of the various hepatic anatomies, as well as patient-specific pathology. Courtesy of Dr. Jacques Marescaux, Telesurgical Institute, Strasbourg, France.

best choice, and then apply that choice to the patient will significantly increase the quality of health care. The question remains as to whether it is cost-effective and who will pay for the added expense of the preoperative planning. Without these computer assisted planning tools, the cost of "planning" an operative procedure is included as the physician's fee, the payment for a surgical procedure includes the surgeon's experience in choosing the best option based on personal experience. It is uncertain if third-party payers for health care will be willing to pay extra for very expensive tests (CT-generated 3-D representations) and planning procedures unless cost savings or long-term improved outcomes from the preplanning of the surgery can be demonstrated.

3. THERAPY

In the area of therapy, virtual environments usually include computer-assisted surgery, image guided surgery, and telesurgery, because the interface through which the procedure is being performed includes an image of the patient rather than directly viewing the patient's anatomy. The display is often simply a monitor; however, head-mounted displays or overlay screens have also been used (see chap. 3, this volume). In computer-assisted surgery, the purpose is to obtain preoperative planning information that is entered into a computer program, and during the procedure the surgeon is assisted by a robotic device to perform a part of the procedure beyond human physical limitations. An example is RoboDoc mentioned above, with 96% accuracy in prosthesis placement. Telesurgery, or more accurately dexterity enhanced surgery, uses a video monitor with stereoscopic real-time video image to enhance the precision and dexterity of the surgeon through direct telemanipulation. Under these circumstances, the surgeon's full attention is on the virtual image of the patient image, and remote manipulators carry out precisely the hand motions of the surgical task. The system is in the same operating room next to the patient for the purpose of improving the performance of the surgeon (dexterity enhanced surgery); however, the procedure could just as easily be at a distant place (telesurgery, see chap. 48, this volume). The systems are comprised of a remote manipulator system with surgical instruments that are mounted (and can be interchanged) on the end of a pair of robotic arms. The instruments are placed inside the body in the proper position by the surgeon, who then sits at a surgical workstation next to the patient and uses input devices (modified handles from surgical instruments) to directly control the end effectors. The systems include force feedback for haptic response, 3-D vision on the monitor for depth perception, scaling of hand motion to increase dexterity, and filtering of tremor (at the 8–14 Hz frequency) to increase precision. Research is being conducted to include motion tracking so the system can pace the motion of the beating heart and therefore perform surgery on a beating heart without needing to place the patient on an heart-lung machine while performing the procedure. There have been no remote telesurgery procedures performed on patients; however, two systems have performed the procedures in the same room as the patient. In 1997, Himpens and Cardiere in Brussels, Belgium (Himpens, Leman, & Cardiere, 1998), used the Intuitive Surgical, Inc., system to perform the first telesurgery gall bladder operation on a patient. They also performed a number of other procedures, such as Nissen fundoplication and arterio-venous fistula construction. In 1998, Carpentier, Loulmet, Aupecle, Berrebi, and Relland (1999) of Paris, France, began performing heart operations using this system and has successfully performed over 150 of the procedures. A second system by Computer Motion, Inc., called Zeus is similar to the above system, but focuses more on performing microsurgical procedures (Fig. 47.7). In 1998, Margossian et al. (1998) performed the first procedure in the United States with a reanastomosis of a fallopian tube using the Zeus system. Both systems are currently undergoing controlled clinical trials on selected patient populations.

FIG. 47.7 The telesurgery system Zues, which scales hand motion and removes tremor. Courtesy of Yulun Wang, Computer Motion, Inc., Goleta, CA.

Psychiatry and rehabilitation are areas where immersive VEs have had important clinical applications (see chaps. 49–51, this volume). Lamson (1994) of Kaiser Permanente has been using VE for what he calls “virtual therapy” in patients with various forms of phobia. By recreating representations of the Golden Gate Bridge or an elevator, people with fear of heights can be deconditioned by repeatedly being exposed in small increments to the virtual threatening environment and allowed to conquer their fears without physical danger to themselves. After 1 year there is a 85% success, and some of the patients who regress are easily given further virtual therapy and they respond very well. A similar system has been developed at Georgia Technical Institute by Hodges et al. (1995), creating a variety of different environments to test acrophobia and other phobias. An interesting success has been achieved with a patient with arachnophobia (fear of spiders) by Rothbaum et al. (1995) at the University of Washington. In rehabilitation, Greenleaf and Tovar (1994) have provided a virtual world for wheelchair patients to travel through. By giving the patient ample opportunity to practice without harm to themselves, they can then begin using a wheelchair in a real environment.

An interesting project by D. Zeltzer (personal communication, 1999) is beginning called the Empathy Network. In this project, the concept is to provide the patient’s family and loved ones an opportunity to experience the disability that the patient is suffering, such as memory lapses or visual disturbances secondary to minimal brain injury or stroke. A commercial project entitled In My Steps has been successful in creating the fatigue that a cancer patient suffers while under chemotherapy (Moran, 1998). The family member dons an HMD and sits on a stepping machine. The scenario is in the patient’s home (Fig. 47.8), where the patient must prepare a small breakfast while waiting for delivery of important prescriptions. The person must pedal (walk) to the kitchen and put on a tea kettle and toast. By the time they have “walked” to the kitchen and put the kettle on the stove, they are fatigued (from the heavy pedaling). The door bell then rings. Even though they are pedaling hard, their walking progress is extremely slow, and by the time they open the door they see the prescription delivery truck departing without leaving their medications. At that moment the tea kettle begins whistling, so they must pedal back to the kitchen, and just as they reach the kettle the toast begins to burn. By this time the person is totally exhausted from the pedaling. There is no empiric data from this project; however, the subjective reports have had uniformly high ratings for imparting the sense of fatigue and frustration that their loved ones must be suffering.

FIG. 47.9 Tendon Transplant simulator with superposition of model of leg that is actually being seen on the head-mounted displays. Courtesy of Dr. Joseph Rosen, Dartmouth Medical Center, Hanover, NH.

4. EDUCATION AND TRAINING

Education and training is the largest early application (see chaps. 43–46, this volume). In the beginning of the 1990s, Delp and Rosen (Delp & Zajac, 1992) created one of the first VE applications in medicine—a tendon transplant simulator (Fig. 47.9). Using an HMD and DataGlove as the interface, they created a mechanical and anatomic model of the skeleton of the lower limbs that used red lines to represent muscles and tendons. The limbs had mechanical properties and kinematics of the legs, which could be animated to simulate walking. By moving the insertion point of a muscle's tendon to a different point (to plan for a tendon transplant operation to correct a patient with a gait disorder), the model was then animated and

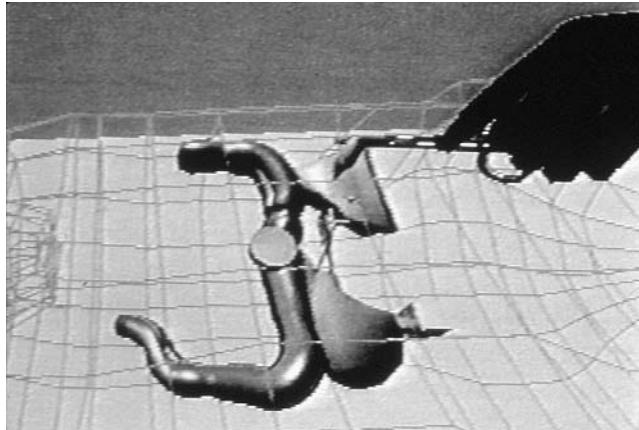

FIG. 47.10 Cholecystectomy simulator based on graphic drawings of upper abdominal organs. Courtesy of author.

FIG. 47.11 Higher resolution graphic representation of the abdomen with morphing. Courtesy of Gregory Merrill, HT Medical, Inc., Rockville, MD.

the gait observed to predict what the result of the tendon transplant might be. In 1991, Satava and Lanier (Satava, 1993) made the first abdominal simulator (Fig. 47.10), created of simple graphic representations of the liver, stomach, colon, pancreas, gall bladder, and biliary tree. Once again, with an HMD and DataGlove, it was possible to fly around the organs and pick up and move them. A few simple surgical instruments were included, allowing for a very abstract representation of the surgical procedure of removing a gallbladder. By 1993, Merrill of High-Techsplanations had added increased graphic realism and introduced morphing to demonstrate changing of tissues in response to interaction (Merrill et al., 1995). While appearing much more realistic, the deformations were based on approximations rather than measurement of properties of actual tissues (Fig. 47.11). At about the same time Sinclair et al. (1995) developed a very practical ophthalmology simulator, demonstrating that a sophisticated operative procedure such as removal of a cataract could be realistically reproduced (Fig. 47.12). The landmark was 1994, with Ackerman's (1998) program from the National Library of Medicine and the release of the Visible Human Project (performed by Drs. Spitzer and Whitlock [1992]). For the first time visual representation was based on actual anatomic data from a person rather than graphic

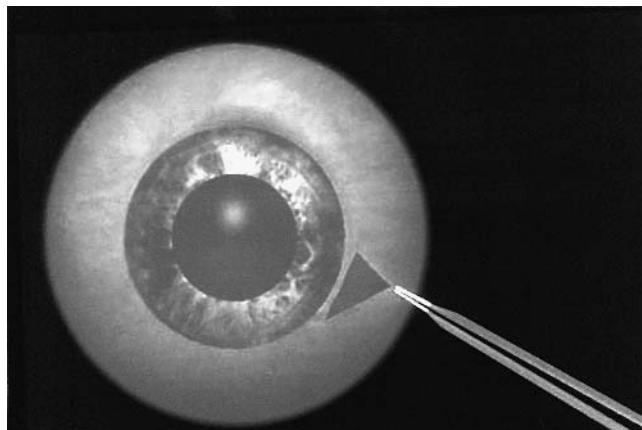

FIG. 47.12 Eye surgery simulation of removal of a cataract. Courtesy of Drs. Sinclair and Peifer, Georgia Technology Institute, Atlanta.

FIG. 47.13 Anatomically precise reconstructed knee from the Visible Human Project. Courtesy of Dr. Victor Spitzer, M.D., University of Colorado Medical Center, Denver.

approximations of organs and tissues (Fig. 47.13). However, the database is massive—over 150 megabytes—so at the present time it is not possible to render the entire representation in real time interactive simulation. But the Visible Human does provide a standard reference for interoperability of different simulations.

The next step was with Delp's (1998) Limb Trauma Simulator for the military Combat Casualty Care training program. Taking the upper thigh from the Visible Human and adding

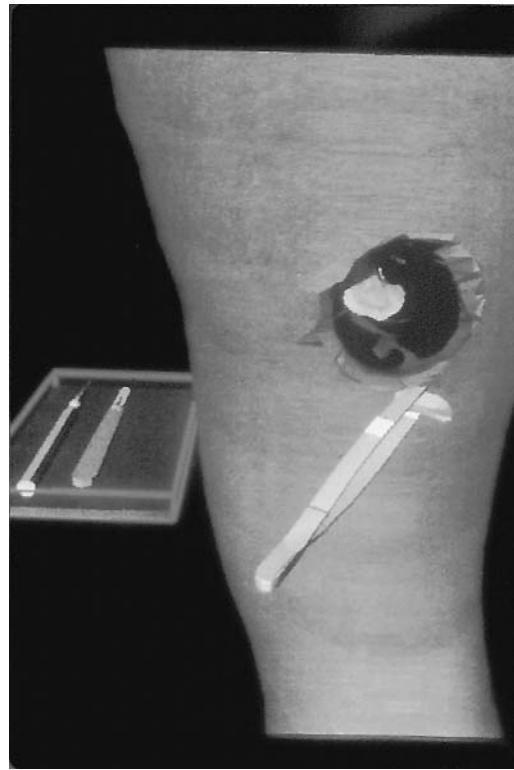

FIG. 47.14 The Limb Trauma Simulator with gunshot wound to the thigh. Courtesy of Dr. Scott Delp, Ph.D., Musculographics, Inc., Chicago, IL.

to it the properties of muscle, ballistic damage, shrapnel, bleeding, and other parameters of wounding, a simulation of a gunshot wound to the thigh was created (Fig. 47.14). The purpose was to provide an alternative to wounding animals for training in combat casualty care. The simulator provides both visual representation of the wound as well as interactive control of bleeding, debridement, and hemostasis using input devices with force feedback for haptic control. However, by the time all of the interactive properties and haptic interface (see chaps. 5 and 6, this volume) have been added, the visual fidelity of the image is reduced to a relative low-resolution representation rather than photorealistic.

As computer power increases, virtual representation will eventually have both visual fidelity, with physical-based properties derived from scientifically measured tissue and real-time interactivity at a minimum of 30 frames per second with a latency of image generation of less than 50 milliseconds. The Limb Trauma Simulator is currently under evaluation at the U.S. Army medical training laboratory of the Uniformed Services University of Health Sciences (USUHS) by Kaufmann, Rhee, and Burris (1999). In 1996, Levy collaborated with Engineering Animation, Inc., to create a hysteroscopy simulator (Levy, 1996). This system not only integrated visual and haptic input, but the image was derived from patient-specific data (Fig. 47.15). Before performing a hysteroscopic procedure on a patient, Dr. Levy imported the image from the patient's CT scan and was able to practice numerous different procedures to optimize the surgery for that specific patient. By making the task to be performed rather simple and developing the software for a personal computer platform, Merrill et al. (1995) of HT Medical created a photorealistic simulation of a central venous catheter insertion (Fig. 47.16), demonstrating that it is possible to produce a commercial system that is both realistic and cost-effective. Using training methodologies for terrain following and target acquisition

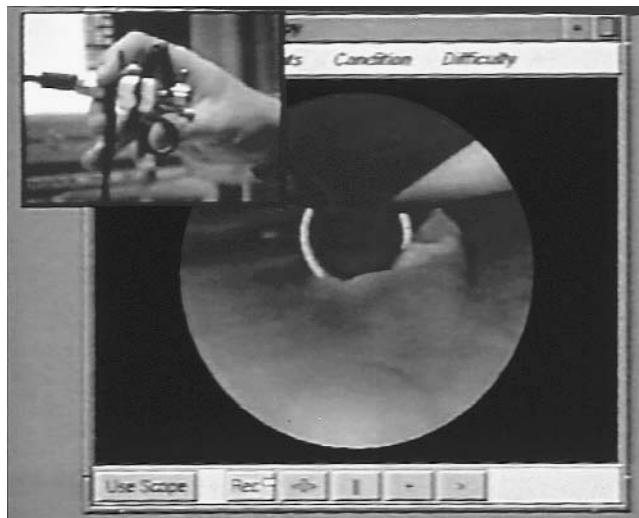

FIG. 47.15 The Hysteroscopy Simulator demonstrates patient-specific imagery for practice on an individual patient's pathologic anatomy. Courtesy of Dr. Jeffrey Levy, Engineering Animation, Inc., Ames IA.

FIG. 47.16 The IV insertion simulator demonstrating high visual fidelity and haptic input on an inexpensive personal computer-based platform. Courtesy of Gregory Merrill, HT Medical, Rockville, MD.

developed by the military, Edmond, Wiet, and Bolger (1998) of the University of Washington have introduced the graphics overlay as an aid to instructing a student on the correct path for a surgical procedure. A sinus surgery simulation reconstructs the nasal cavity (Fig. 47.17) with all its irregular protrusions (turbines), and a series of circles is used as the "cross hairs" for the student to follow in order to navigate through the nasal passages to a designated pathology (target). This is very similar to the navigation system used by fighter pilots to follow terrain and identify targets of interest.

By 1998, Raibert and Playter of Boston Dynamics, Inc., constructed the Anastomosis Simulator (Raibert, Playter, & Krummel, 1998). In addition to increasing visual fidelity and tissue

FIG. 47.17 Sinus endoscopy simulator provides internal anatomy of the nasal sinuses with overlay of circles that are path planning aids to endoscopic navigation for a surgical procedure. Courtesy of Dr. Charles Edmond, University of Washington, Seattle.

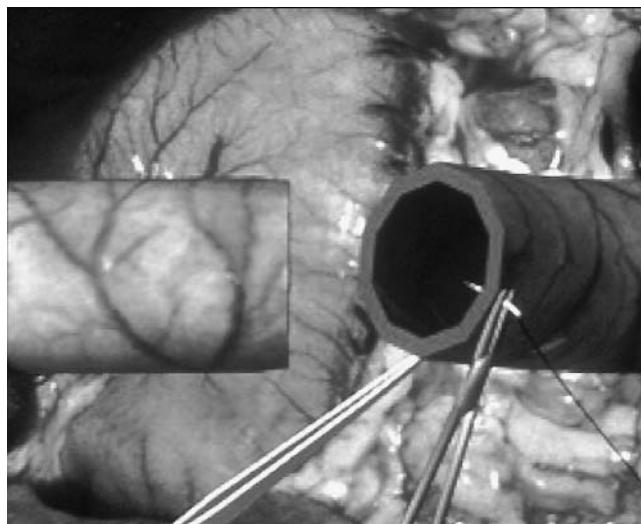

FIG. 47.18 The Anastomosis Simulator incorporates real-time tracking of hand motions by the graph in the upper left corner to give continuous feedback to the student on level of performance. Courtesy of Dr. Marc Raibert, Boston Dynamics, Inc., Boston, MA.

interaction with haptic input, this system incorporates a testing and evaluation component (Fig. 47.18). The input devices (Phantom Haptic Input Device), which track the precise motion, position, pressure, and timing in order to provide accurate force feedback, also output the information to a graphic display that tracks in real time the student's performance in regard to accuracy, position, pressure, and time to completion. At the end of the practice session, a scorecard of the student's performance is tabulated and printed out. This can be used both for real-time feedback for training, as well as evaluation for certification. The next steps are to provide a curriculum that will support the simulation technology and to develop metrics for evaluation of performance and outcomes analysis. By working with the American Board of Orthopedic Surgeons, Raibert has developed a first-generation arthroscopy simulator (Fig. 47.19),

FIG. 47.19 Knee Arthroscopy simulator with mannequin leg and high-fidelity internal knee anatomy. Courtesy Dr. Marc Raibert, Boston Dynamics, Inc., Boston, MA.

thus involving those authorities who are involved in determining the efficacy of simulation for testing and certification.

There are a number of projects that focus at medical-student-level education. Imielinska at Columbia University (Imielinska, Laino-Pepper, & Thuman, 1998) of the Vesalius project is providing a combination of CD-ROM and Web-based VEs for pelvic and skull anatomy. Heinrichs of Stanford University (Heinrichs & Dev, 1999) is leading a team to understand pelvic and gynecologic anatomy through VE system training. Hoffman of University of California, San Diego (Hoffmann & Murray, 1999), has a curriculum based on a virtual representation of the organ systems called the Virtual Reality Multi-Media System, or VirtualizeR. The module for the biliary tree is complete, with a full 3-D hepato-biliary system (liver, gallbladder, and bile ducts) and interactive links to all relevant information. For example, while highlighting the gallbladder, the student can access normal and abnormal anatomy, typical patient history and physical exam, histology, pathology, radiologic images, surgical procedures, and a full range of other information, as well as the capability to fly through or practice procedures on the anatomic representations. The image is both the educational content and the interface to the information.

5. CHALLENGES

There remain a number of challenges and barriers to implementing VEs more extensively in medical applications. In all areas, there is the issue of cost and maturity of the systems. Most of the applications are still simplistic, requiring a substantial amount of "suspension of disbelief." The equipment is still rudimentary, from HMD to CAVE (see chaps. 3 and 11, this volume) to haptic input device (see chaps. 5–6, this volume). Nearly every system requires a dedicated

staff or at least a computer technician to keep the system running smoothly. The majority of applications do not have a large number of patients or students for which it is applicable. The following looks at individual areas and identifies specific challenges.

In order to create image-based medical records (*holomer™*), there is the challenge of acquiring enough data noninvasively and automatically inserting it into a database. There is neither a consensus database, nor are the literally hundreds of databases interoperable. In terms of displaying the information as an image, there are the challenges of automatic segmentation of the CT, MRI, and ultrasound images, reconstruction of 3-D structures, accurate registration of images, and then data fusion of not only image data, but embedding the physiologic, biologic, and other data to the appropriate source. If the intent is to have an Internet-based record, there have been a number of simplistic Web-based medical records (all of which are incompatible with any other database), however, there is no method to automatically download specific data.

There are a number of overarching problems that are nontechnical but which have definite possible solutions. One of the largest challenges is coming to an agreement on a standard computerized database (computerized medical record), which can easily and transparently accept all forms of medical information (images, text, data signals, equations, etc.) for automatic archiving. It must have a powerful retrieval engine to function as an intuitive interface for access to information. The next challenge is to agree on a standard method of displaying the information, which is independent of the display device. One suggested possibility is the visual medical record in the form of a *holomer™* (see chap. 15, this volume), which can be viewed on a standard monitor, as a hologram, with an HMD, in a CAVE, or with any other display device. For universal access to archived data, there appears to be consensus that a Web-based medical record can provide a unifying platform; however, as in all Internet applications, there are the issues of data accuracy, security, and privacy.

In creating 3-D images for diagnostic purposes, such as virtual endoscopy, the most important and technically difficult barrier is real-time automatic segmentation of organ systems and tissues. The issue of accurate color and texture to be derived from the acquired images has only been proposed in preliminary demonstration. There is no consensus on the best method of displaying the image. In order to aid radiologists in interpretation, automatic recognition and interpretation by decision support systems needs to be developed. To be able to have a robust diagnostic tool that rivals that of current radiologic standards, imaging technologies need to improve the resolution of the image significantly, possibly as much as an order of magnitude.

In the therapeutic implementation of telesurgical and dexterity enhancing systems, there remains the issues of latency when attempting to implement at a distance; there must be a lag time of less than 50 milliseconds for the entire system (see chap. 48, this volume). For increasing precision and dexterity, improvement is needed in the degrees of freedom of systems, accuracy of tracking of position (at least 1 mm accuracy, and for some procedures such as neurosurgery, 0.1 mm accuracy), see chap. 8, this volume), and appropriate scaling of haptics (see chaps. 5 and 6, this volume). In current computer-assisted and robotic systems, although the interface is dramatically better than current laparoscopic systems, they are far from ideal. Some unresolved system specific issues include automatic initialization and registration of the system before beginning the operative procedure, acceptable hand–eye axis, most appropriate display (HMD, monitor, binocular optical system, etc.), a tool changing system, and method of control for subsystems (voice activated, menu driven, etc.).

For education and training applications, there are the same technical issues listed above for image generation in 3-D visualization in diagnosis (automatic segmentation, registration, etc.), as well as the interface issues. In addition, the biggest challenges are those of content—of developing an appropriate curriculum that can take advantage of the technology. Of all the applications, education requires that the system be intuitive and easy to use, especially to be usable by students without long periods required simply to learn the system in order to begin

studying (see chap. 34, this volume). Content must be developed in order to have metrics that are able to measure technical skills and performance in such a way as to give meaningful outcomes analysis. To date, none of these metrics have been developed, and until they are derived through consensus and evidence-based testing, implementation of training systems will not be accepted by residency training programs or certification bodies.

Nontechnical challenges to the implementation of VEs are those that prevent development of the application in spite of technical feasibility. In implementation of such a diverse set of applications, which must be interoperable (such as simulators which can be used on student workstations or be integrated into telepresence surgery systems), the most important factor is standardization. To date none of the various systems are interoperable. An attempt has been made to approach such integration by requiring the 3-D visualization projects to be compatible with the Visible Human data set. This does not guarantee standardization; however, it provides a common reference from which to start. As systems become more complex, the questions of safety and liability apply, as well as certification to use the systems (see chap. 27, this volume). Not only are mechanical systems under stringent evaluation from the medical device division of the FDA, but also the computer programs that handle data or control the mechanical devices.

Once a device or software program is approved for use, a major challenge is getting third-party payers to reimburse for the cost of procedures (e.g., virtual endoscopy) or paying extra for a procedure because more advanced equipment is used, as in image-guided or computer-assisted surgery. Health care insurance companies or managed care organizations delay implementation of a procedure until it can be shown to reduce costs. The current mantra for new technology, whatever the type, is cost-benefit ratio; yet conducting the long-term clinical trials with clearly definable outcomes analysis causes a prolonged delay in payment for a service. On the other hand, a number of new technologies will not be accepted by physicians or patients because of unfamiliarity, conventional prejudice, or outright ignorance of the benefits. There is a natural skepticism against anything new and an almost inborn resistance to change. It required almost a new generation of radiologists to accept the new digital images instead of film-based radiology; it is uncertain if it will require decades to accept 3-D visualization and virtual endoscopy. Finally, there are a number of applications that raise serious bioethical and moral issues (see chap. 33, this volume). Should a psychiatrist subject a patient to a threatening VE that could possibly cause irreversible damage when the capabilities of the state of the art is unknown? Is it permissible for a surgeon to operate on a patient (using telesurgery) if the surgeon has not met the patient (in a distant city) or is not physically present in the operating room should something go wrong—are we developing a “tele-itinerant surgeon”? Thus, there are many nontechnical hurdles that can impede acceptance of what is otherwise an excellent technical solution to a difficult problem.

6. CONCLUSION

This overview has presented numerous specific VE applications that are emerging in the medical field; however, the majority are in the laboratory or clinical investigation stage. It will take significant effort to move these technologies into commercial success and therefore routine clinical use. As in many other fields, standardization and interoperability are some of the major issues whose solution will dramatically increase the implementation of the technology. Of all the technical challenges, auto-segmentation, registration, and data fusion are the most difficult, but these have the possibility for producing the greatest amount and most rapid acceptance of VEs as a clinically useful tool. Although there needs to be orders of magnitude increase in computer power for near realistic visual fidelity, the complexity of the human being is such that there will always be the need for further fidelity, whether on the macroscopic, microscopic, or

molecular level. Yet the final determinant is the end user; therefore all VEs in use today need to become much more user friendly (see chap. 34, this volume). They must be turnkey solutions that are extremely robust and fault tolerant and that require nearly no technical support or continual maintenance.

The VE applications above provide a framework of what is possible today and give rise to speculation as to what would be possible by extending the capabilities described. The implications of a 3-D computer-generated representation of a specific person (a “digital me”) or holomerTM that can act as a surrogate for optimizing (and possibly predicting) individual patient care is extraordinary. Virtual environments are the tools and methodology to create such an interactive information representation, a step in the direction of representing the complexity of human and biologic systems in a manner more clearly understandable and that eventually will be usable and practical for each person. The more devices developed that can acquire information about a person (whether handheld imagers or noninvasive biosensors continuously worn in our clothing or embedded in the body), the richer the holomer and the more accurate the results from modeling and simulation, preoperative planning, or intraoperative assistance. Not only is this relevant to patient care for medical conditions, but at all levels, including school age. Imagine the power of each child having a holomer that “grows up” with them, which they carry on a credit card device and use in class. By inserting their holomer into a virtual environment, they can learn health and nutrition by observing the consequences to their holomer. For example, by implementing the “smoking” module, the child’s holomer could grow a cancer, get bronchitis and emphysema, and decrease its ability—as a prediction of what would happen with long-term smoking. These types of “what if” scenarios can also be used to engage people into complex intellectual dilemmas, such as bioethical and medical ethical issues of cloning, research on embryos, and alternative forms of therapy. Theoretically, if a “generic” or standardized holomer could be created, the early phases of clinical trials (on drugs or devices) or virtual “crash dummies” could replace some of the extremely expensive and high-risk testing and evaluation occurring today. Other more practical components of VE, such as customizing individual prostheses (or in the not too distant future, creating the model for the instructions to “grow” replacement organs through tissue engineering) will result from an extension of the emerging field of medical stereolithography. The applications in psychiatry or virtual therapy (see chaps. 50 and 51, this volume) are to treat disease; perhaps with insight, a VE in the home can be created to ameliorate other disorders before they erupt. By implementing VE for shared experiences, there are a number of pragmatic research goals that can soon be achieved to enrich, through high-bandwidth communications of Internet 2, a much higher sense of presence with tele-immersion for telemedicine consultations. The ease of use within these VEs needs to make the interactivity more transparent, perhaps by increasing the use of voice commands (see chap. 4, this volume) and other intuitive interfaces (see chap. 13, this volume).

It is apparent that there are numerous other directions in diagnosis, therapy, and education and training that could be speculated, and the above are listed as examples of technically feasible projects as next steps in the evolutionary process. Yet the medical discipline is unique, in that final result will impact on a living, breathing human being. The challenge will be to focus upon those applications that can make a quality-of-life difference for each and every patient.

1. INTRODUCTION

Teleoperation is the technology of robotic remote control. Teleoperation systems synergistically combine humans and machines, and this man–machine link is what differentiates these systems from their predecessors. Teleoperators are used in place of robots when the latter are unable to overcome, by themselves, either the evolutionary situation of performing a task or its dexterity demands.

The first teleoperation systems were built after the Second World War for needs in nuclear activities. These early systems used a master–slave concept with two symmetrical arms. The master arm is handled by the operator; while the slave replicates the operator's motions at the location where the task being performed. In the earliest systems, master and slave were mechanically connected. Later systems were electrically powered, affording the possibility of any distance between master and slave. In the 1980s, computers were introduced as control systems opening the way to computer-aided teleoperation (CAT). Contemporary CAT utilization has been deeply modified by the emergence of virtual environment (VE) technology.

In early systems, the absence of sophisticated electronics and computers obliged a symmetrical mechanical device to correctly transfer motions from the operator to the slave device. Nevertheless, a great aid to manipulation came from the integration of force feedback, allowing

the operator to “feel” what he or she manipulated remotely. The introduction of computers led to further enhancements in the design of master and slave devices. Whereas the slave kept its mechanical structure, the master could be reduced in size, as well as transformed into a joystick with force feedback, or into a set of different mini-systems that were easy for the operator to move. However, these new master interfaces, although better adapted to the human, did not resolve the general difficulty of correctly performing remote tasks. Remote operations require visual access to the activities being conducted in the slave environment. Classic cameras, even stereoscopic ones, did not succeed in adequately informing the operator. The operator thus often became disoriented (see chap. 24, this volume), lost sight of his subject of interest, and became afflicted with motion sickness–like symptoms (see chap. 30, this volume) after several minutes of work. Virtual environments, with their ability to provide partial or total immersion (see chap. 40, this volume), promise to seriously improve this situation. The great interest in VE-enhanced teleoperation is based on expected improvement in teleoperation efficiency, from gains in both ergonomics (see chap. 41, this volume) and user friendliness (see chap. 34, this volume), as well as an information feedback point of view.

2. PROBLEMATIC TOPICS

Teleoperation has matured both technological and from a conceptual point of view. Yet, there are still many problems that have yet to achieve a satisfactory or convincing solution. These problems are summarized below:

- **The unreachable ideal transparency.** After stability (i.e., in terms of a control theory point of view, stability means that a system will remain close to its original motion trajectory if slightly perturbed away from it), one of the most important teleoperator characteristics is transparency, which is a kind of action/sensing fidelity measurement index (see Laurence in IEEE TRA, 1993). Although a trade-off between stability and transparency has been found, such solutions have largely been derived from a pure control theory point of view. It is an established fact that ideal transparency can never be achieved by conventional bilateral control unless it is redefined by other criteria or conceived differently. This limitation comes mainly from (1) the operator action and the feedback being conveyed through the master–slave chain before reaching the target task and the operator channels, respectively, and (2) this chain including dynamics which cannot be neglected or compensated for without compromises in stability or operator safety. Challenging bilateral coupling seems to be one way to deal with this problem.

- **Time delay in control of remote systems.** Communication time delay between master and slave constitutes one of the most crucial problems in teleoperation. Indeed, time delay affects not only transparency, because the operator actions and feedback are delayed, but also stability. In conventional control solutions (those not using VE techniques), constant and variable time delays have been solved by Anderson and Spong (1988) by means of a strategy resulting in a clever “damping” design via low-level control. This method has been more elegantly formulated by Niemeyer and Slotine (1991) and astutely adapted, recently, for the case of nonstationary time delay. Kosuge (1996) and Oboe and Fiorini (1998) also proposed solutions to deal with variable time delay. Nevertheless, it is utopia to try to keep force feedback from the remote environment when delays are of the order of seconds (IEEE TRA, 1993).

- **Taking into account human factors.** Industrial robotics is sometimes opposed to teleoperation solutions from a flexibility viewpoint. Yet teleoperation flexibility is in many ways

dependent on operator adaptation to the teleoperation system. Indeed, to perform a task the operator must be trained and specialized. How to quantify human factors is also a well-known old problem, which still has no satisfactory qualitative and quantitative evaluation methodology, yet means of assessing VE usability are under development (see chap. 34, this volume).

- **Slave autonomous behavior and man-machine shared control.** Many tentative solutions concerning man-machine cooperation, that is to say, shared control architectures and semi-autonomous teleoperators, have been proposed. The problems of autonomy sharing, modeling, and quantification are narrowly linked to the degree of robot autonomy and to the level of operator intervention, which can range from full manual to symbolic (supervisory) control (Sheridan, 1992). Although some issues do exist, this point is important and raises an unanswered question about the relation between man's intervention methods and robot autonomy level.

- **Reliability and safety.** Use of high-powered master-slave devices is unquestionably as dangerous as today's industrial robots. In addition, since the operator works very often in the vicinity of powered axes, dangers in addressing system integrity, losses of functionality, and device or sensor degradations exist (Struges, 1996). Powered manipulation arms are inherently slow devices; no quick or jerky motion should be attempted in using them. Unlike computers, the manipulator arms, if used improperly, have the physical capability of destroying themselves and their environments.

3. VIRTUAL ENVIRONMENT-BASED TELEOPERATION

The manifold appropriate solutions that VE offers, in order to refine solutions to the inter-related specific teleoperation problems, make it difficult to infer a standard way VE could assist teleoperation. This difficulty paradoxically constitutes the strength and cleverness of VE techniques. Therefore, the remainder of this chapter concentrates on the state of the art in VE-based teleoperation, including examples of the capabilities of some teleoperator systems and current challenges in VE-assisted teleoperation schemes. Topics covered include: coping with time delay; enhancing computer aided teleoperation; improving bilateral and shared control; human-centered architectures; enhancing sensory feedback to the human operator; and improving operator safety with human factors issues.

3.1 Coping With Time Delay

Predictive graphic displays offer a solution to dealing with time delay inducing instability in bilateral force reflection teleoperation. Predictive graphic display development was pioneered by the efforts and results of the Massachusetts Institute for Technology's Man-Machine Laboratory. Noyes and Sheridan (1984; see Sheridan's review in IEEE TRA, 1993) developed a predictive display where the manipulator was displayed as a stick graphic figure overlaid on the delayed video image of the manipulator. Experimental results have proven the efficiency of the proposed strategy. Bejczy et al. (1990, quoted in Kim, 1996), improved the stick figure with a high-fidelity graphic predictive display they called the phantom robot. Two graphic models (wire frame and solid) accurately depicting the actual slave robot can be overlaid on the delayed video feedback. The operator chooses, according to the context, one of the two graphic robot representations (wireframe or solid) to act as a predictor. Since the graphic representation of the actual slave robot is faithfully reproduced, accurate virtual to video superimposition on a common display window was made feasible thanks to a VE calibration method thoroughly discussed in Kim (1996).

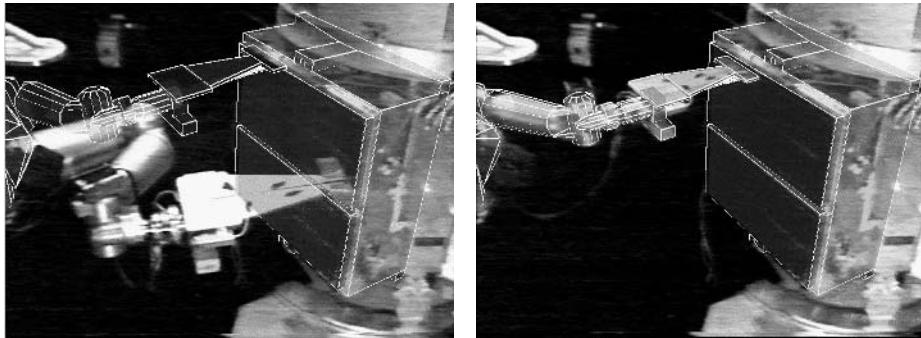

FIG. 48.1. Predictive display by means of augmented reality techniques for space teleoperation. Courtesy of Kim (1996), Jet Propulsion Laboratory, NASA.

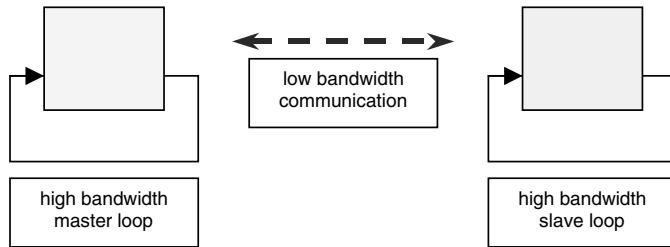

FIG. 48.2. A high-level view of teleprogramming (adapted from Funda et al., 1992).

Figure 48.1 shows a teleoperation instance in a space operation simulation case. The predictive “phantom robot” reacts in real time and smoothly to the operator commands. When subsequent predicted actions are considered satisfactory, trajectory commands are sent to the actual robot. This method, although enhancing operator performance, still uses a move-and-wait strategy in which moving concerns the virtual robot and waiting concerns actual and virtual robot matching. It must be noted that force display is obviously prohibited because only the model of the robot is available. To maintain force feedback, however, Kotoku proposed using a VE representation of the entire remote location and its components (including the slave robot) as a predictive display (Kotoku, 1992). In this case, the system consists of: the master force feedback arm; the VE, including a virtual robot actually coupled to the master arm, the actual slave robot and its environment; and communication media linking the VE to the actual robot controller. The virtual robot is operated within the VE in a similar manner as if the virtual robot were real. Indeed force feedback is artificial, generated from the VE computer simulation, and flows from estimated interaction forces between the virtual robot and the virtual environment. Since object geometric modeling is based on a polyhedral representation, the artificial force feedback algorithm is based on polyhedron interpenetration calculations, including collision detection and other well-known features used in computer graphics simulation (Anderson, 1994). In fact, this system splits the bilateral loop into two local loops, the master bilateral loop coupling the operator to an estimated remote environment (VE) and the slave loop managing actual robot interaction with its real environment provided that the interrelated (i.e., embedded local autonomy, necessary degrees of freedom, and suitable sensors instrumentation) are convenient.

In the above cited predictors, distant robot control is achieved according to the online predictive planned trajectory. An alternative clever way to perform teleoperation in the presence of considerable time delay is teleprogramming. As shown in Fig. 48.2, the principle of teleprogramming is nearly similar to VE predictive teleoperation. Indeed no bilateral coupling is

achieved between the master arm and slave robot. The master site is set up with a VE coupled with the master arm. This fact allows high-bandwidth virtual robot operation with immediate visual and haptic feedback. The slave arm is also a high-bandwidth closed loop between the remote robot and its environment and concerns the classical sensory feedback needed for the controller.

Compared with the predictive display method, teleprogramming is peculiarly different. Indeed, on the one hand, robot instructions are symbolic and somehow flexible rather than low level and accurate. Subsequently this requires some robot autonomy. It also makes teleoperation nicely continuous (i.e., not move-and-wait). On the other hand, feedback from the remote location to the master site matters to the execution status. In addition to providing real-time interaction, the virtual representation software continuously monitors the slave robot and any object in its grasp for collision detection or contacts with the virtual environment. Subsequent macro-commands are generated by an integrated software, based on a priori task knowledge and a predefined command language. To prevent execution errors, due to virtual model uncertainties, guarded commands (motion, force, etc.) are generated, rather than absolute or static commands. This teleprogramming architecture, together with experimental results, are thoroughly described in Funda, Lindsay, and Paul (1992).

Another variance of predictive display and teleprogramming was developed at the German Aerospace Center (DLR). The Hirzinger team conducted the first actual space experiments on a space robot technology called ROTEX, which flew with the space-shuttle COLUMBIA from April 26 to May 6, 1993 (see Hirzinger et al. in IEEE TRA, 1993). Among the four operational modes of the ROTEX are teleoperation from ground using a predictive display and tele-sensor-programming. Both operational modes are based on a virtual simulation of the ROTEX with its remote space laboratory features (see Fig. 48.3). The predictive display contains a model of the up and down communication link delay, as well as a model of the actual states of the real robot and its environment features, more peculiarly moving objects. Measured object poses are compared with estimates as issued by an extended Kalman filter. This filter predicts, and graphically displays, the situation that will occur after the up-link delay has elapsed and allows the performed action loop to be closed by operator control, via shared control, or purely in an autonomous mode. This kind of prediction has been made possible due to a nearly perfect world model together with knowledge of the dynamics of objects under zero gravity. The tele-sensor-programming operational mode is a kind of teleprogramming but differs in that it is nearly teaching-by-showing, as applied to robot offline programming. In the proposed tele-sensor-programming, complex tasks are split up into elemental moves for which a certain constraint-frame and simulated sensor type configuration holds. This provides the actual remote robot with simulated sensory data that refer to relative positions between its

FIG. 48.3. The DLR MARCO system: Overview of the telesensor-programming interface (*left*); the ROTEX experiment VE setup; and the gripper sensors simulation (*right*). Courtesy of Hirzinger, DLR.

sensorized gripper and the environment. This compensates for any kind of inaccuracies in the absolute positions of robot and real world. These operational modes were successfully tested for multiple space laboratory tasks, including grasping of floating objects and assembly tasks.

The DLR is conducting ongoing research toward a unified concept for a flexible and highly interactive programming teleoperation station. The actual system, called MARCO, is designed as a 2-in-2 layer concept representing a hierarchical control structure ranging from the planning to executive layer. User layers are comprised of the task and operation modules, whereas the robotic expert layers module concerns elementary operations, actuators commands, and sensor phase. In the frame of a DLR–NASDA (Japanese Aerospace Agency) joint program, called German ETS-VII Experiment (for GETEX), the above modular task-directed programming scheme (MARCO) was successfully involved (April 1999) in the recent unmanned teleoperation of NASDA's ETS-VII free-floating space robot (ETS-VII, 1999).

Other ETS-VII teleoperation experiments have been conducted from the ground (ETS-VII, 1999). The purpose of the ETS-VII mission is to examine the ability of canonical tasks to support and confirm future space investigations such as building and operation of the international space station, inspection and repair of orbiting satellites, and planetary exploration. Teleoperation tasks include: an onboard satellite antenna assembling experiment, truss structure teleoperation, servicing, orbital unit replacement, add-on tools exchange, free floating target satellite capture, and visual inspection. ETS-VII ground robot control systems use operator aids based on VE techniques to assist telemanipulation. These include: predictive computer graphics, shared control capabilities, imaginary guide planes (a kind of a core-shaped virtual wall) to guide the robot arm motion to a desired position and to inhibit undesirable motions, various force controllers (for local compensation of geometric discrepancies), visualization and verification of motion commands using a motion simulator, multimodal interfaces, a visual aid system for direct teleoperation using a predictive force method, and teleoperation through virtual force reflection (including potential force fields, virtual force as physical constraints, adaptive virtual force by probing environment, etc., ETS-VII, 1999).

Figure 48.4 shows screen snapshots related to the ETS-VII teleoperation experiments. In conclusion, predictive displays and teleprogramming seem to be an attractive solution to deal with time-delayed teleoperation. Many other recent advanced teleoperation applications, such as mobile robots (an earlier application domain of teleprogramming initiated by a joint effort of the Laboratoire d'Automatique et d'Analyse des Systèmes—LAAS at Toulouse, France, and the GRASP Laboratory at the University of Pennsylvania; see also the mobile robot teleoperation section in this chapter), subsea robots, and even flying robots also use teleprogramming and graphic predictive displays. In terms of pure control theory, predictive displays and teleprogramming could likely be seen as an implementation, in the frame of teleoperation, of the well-known Smith predictor controller, proposed in 1957.

3.2 Enhancing Computer-aided Teleoperation

Computer-aided teleoperation (known also under the name of tele-assistance) can benefit from the high standards of excellence set for the modern human–machine interfaces associated with VE technology. Resourceful developments and solutions of VE-aided teleoperation that have potential for enhancing CAT include: virtual fixtures, active guides, and graphical programming metaphors.

One of the applications of VE techniques in CAT is directed toward fitting abstract perceptual information within the human–machine interface. The work proposed by Rosenberg (1992) explores the design and implementation of computer generated entities known as “virtual fixtures.” Virtual fixtures are defined by Rosenberg (1992, p. 4) as: “abstract sensory information overlaid on top of the reflected sensory feedback from the workspace which is completely independent of all sensory information from the workspace.” Although they

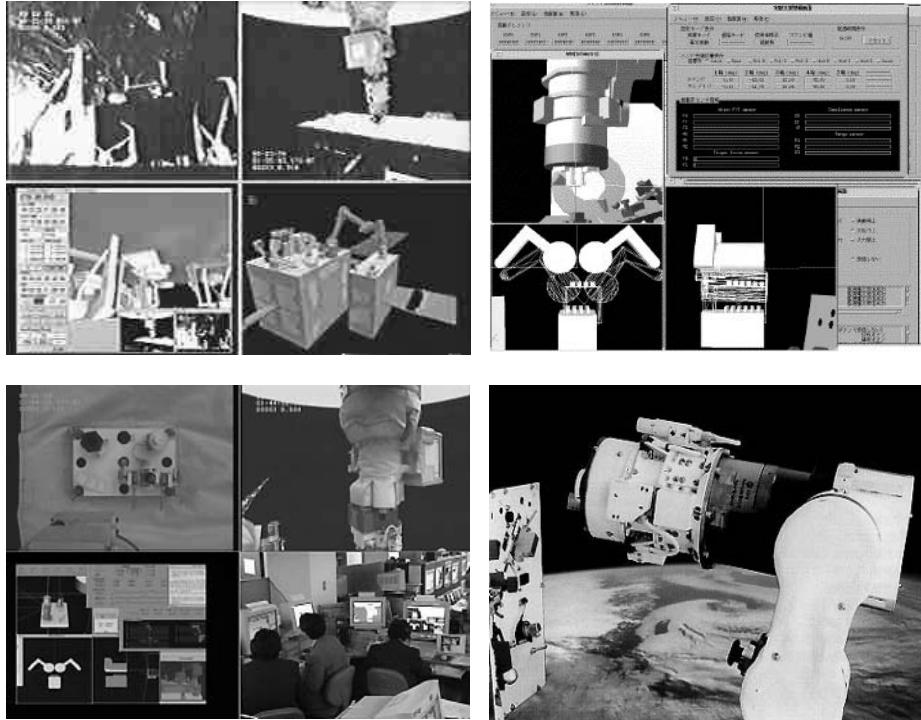

FIG. 48.4. The ETS-VII unmanned space teleoperation experiment. Clockwise: target satellite handling experiment; displayed CG image of simulation (predictive simulation system); an image from an onboard TV camera; and the whole setup. Courtesy of NASDA, <http://oss1.tksc.nasda.go.jp/ets-7>.

functionally embody fixtures in the real world, there are many benefits inherent to virtual fixtures, as compared to real physical ones, because they are computer generated. Indeed, virtual fixtures can be extended to include other modalities, such as visual (see chap. 3, this volume), auditory (see chap. 4, this volume), and even tactile (see chaps. 5 and 6, this volume) sensations used alone or in cross-modal combination (see chap. 21, this volume). Rosenberg highlights these advantages by an instance consisting of plotting a straight line. Obviously, the use of a ruler enhances human operator performance in plotting a straight line as compared to when no ruler is used. This may be seen as what has been proposed earlier in the frame of CAT, namely the possibility to freeze some of the robot degrees of freedom while constraining the operator to control the slave robot in the remaining ones. Virtual fixture are different, since they offer a more powerful and more flexible tool, which does not act on the slave robot directly. Indeed, more attention is given to operator assistance rather than the robot, through artificial sensory feedback overlaid on top of the sensory feedback from a remote teleoperation work site, which serves as a perceptual aid for task performance. How to make virtual percepts using perceptual rather than physical parameters is the main issue being investigated in using virtual fixtures. How does it work? Simply, as the operator interacts with virtual fixtures (via haptic or other defined modalities), appropriate reactive sensations are computed and fed back locally to the operator's perceptual channels. According to Rosenberg, abstraction can be used to operate on virtual fixtures, thereby enhancing interactivity (see section 3.5). Rosenberg has demonstrated that performance could be enhanced by 70% in telerobotic tasks that use virtual fixtures. Thus, virtual fixtures might be used to reduce operator load, facilitate supervisory control, ease the control of complex tasks, and even to "compensate" for performance degradations due to time delay.

Sayers (1999) used virtual fixtures to automatically generate low-level robot commands appropriate to the tasks to be performed. Although Sayers' team gave an implementation within a teleprogramming context, the developed strategies can be used in an augmented reality context as well. In their experiment, synthetic fixtures present the operator with task dependent and context sensitive visual and force cues. No attempt was made to provide realistic force feedback. Instead, the intention was to supply the operator with force and visual cues that can best aid task performance.

In Fig. 48.5, screen snapshots show an instance highlighting the use of virtual fixtures in a VE teleprogramming application. In the upper row of Fig. 48.5, a single-point fixture (represented as a cross) is used to help the operator bring the end point of the robot held tool to a point in space. When the telerobot tool is operated near the desired location, the virtual cross fixture is activated and pulls the robot held tool toward the cross-fixture location. In this case, the virtual fixture has not been defined to completely constrain operator (thus robot) motion. The system anticipates the operator's next desired action. In the same instance, another fixture allowing the robot to achieve circular motions is activated just after the operator decides to leave the cross fixture location. In the lower row of Fig. 48.5, a set of fixtures were defined to aid the operator in achieving flat face-to-face contacts. Each time the operator moves near the surface, the appropriate face-to-face virtual fixture is activated.

Kheddar (1997), attempted to give a unified formalism to the virtual fixtures metaphor and named it "active virtual guide" in the frame of a hidden robot teleoperator (see section 3.4). Under this metaphor, virtual fixtures are classified in three categories:

1. *Pure operator assistance*: This group includes the well known graphic metaphors used in CAT (e.g., sensory substitutions, etc.), in which virtual guides are not directly linked to robot control. Their role is mainly focused on assisting the operator to intuitively perform desired tasks.
2. *Pure remote robot control assistance*: This group includes virtual mechanism concepts, or any other virtual metaphor, induced in the low-level control necessary for strict execution of a real task by the actual robot.
3. *Operator and robot shared assistance*: This group includes those fixtures that are dedicated at the same time to operator and robot assistance in terms of robot autonomy sharing. Actual task completion results are issued from a combination of the virtual task designed by the operator and an autonomous module linked to robotic tasks. Hence, this category is split into three subclasses: autonomous function; semi-autonomous function; and collaborative function.

Virtual guides lead then to a unified structure composed of the following items:

- *Attachment*: A particular spot associated to the virtual guide. The virtual guide can either be statically attached (to any frame within the VE, object, robot controller part, etc.) or dynamically attached, appearing on a specific event (collision detection between objects or robot interaction with its environment, etc.) in a specific spot.
- *Effect zone*: A virtual guide may be associated with an effect area (volume, surface, part of the robot reach space, etc.), which may play the role of an action zone or an attractive/repulsive field within which the virtual guide acts.
- *Activation condition*: For each virtual guide an activation condition is allocated.
- *Function*: It defines the functionality, thus the reason for existence of the guide.
- *Inactivation condition*: While true, renders the guide ineffective by a set of specific actions. Any whole structured virtual guide may be completely removed, attached, or replaced offline or online (during teleoperation).

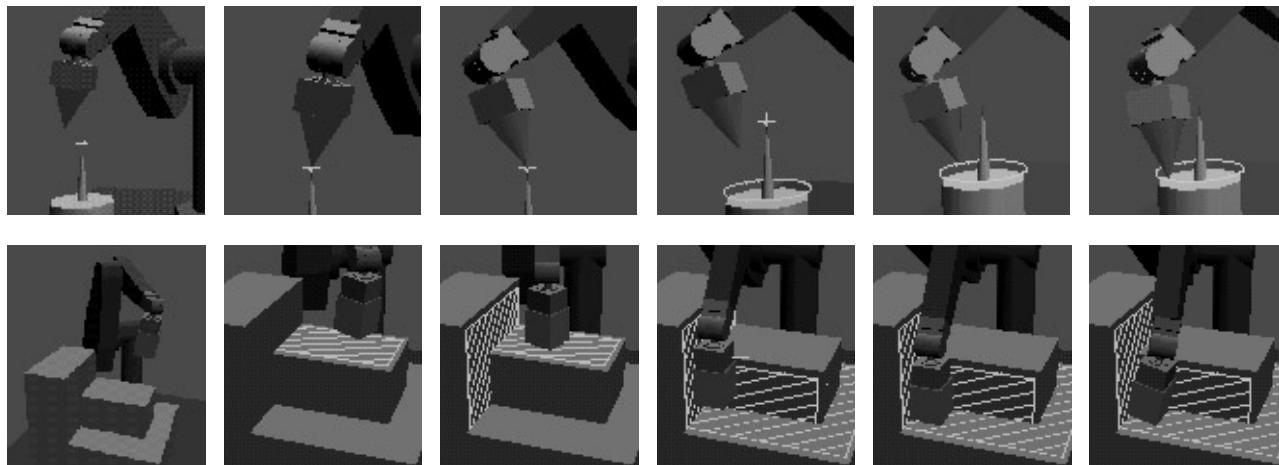

FIG. 48.5. The use of synthetic fixture in teleprogramming-based teleoperation. Courtesy of Sayers (1999), the GRASP Laboratory, University of Pennsylvania.

In Fig. 48.6, a teleoperated task consisting of grasping an object has been simulated with a cylindrical guide. The same geometry guide can serve as a collaborative (this case instance), semi-autonomous, or autonomous guide. In an autonomous style, the virtual object can be assumed grasped when one of the operator fingers touches the handle (unrealistic but easy operator grasp), which triggers an autonomous robotic grasp. In a semi-autonomous instance, the virtual object operator grasp is based upon physical realistic laws. When the virtual operator grasp is stable, the robot triggers an autonomous grasp. In a collaborative mode, operator grasping is realistic, the guide effect being used just to align the robot axis according to the object handle frame, thus freezing the guide robot gripper orientation to that of the handle and leaving the robot controlled according to the operator translational hand movement.

Graphic programming by means of VE technique is one of the most attractive paradigms used in advanced teleoperation architectures. On the one hand, graphic programming may be seen as one of the potential solutions to the well-known operator—telerobot shared control and autonomy problem. On the other hand, it might be seen as the ultimate way to fulfill both user friendly and human factors performance with high ergonomic characteristics. Some instances are presented below to give a better idea of how graphic programming can carry out the above cited points.

Figure 48.7 represents the task line and motion guide paradigm, which is an original form of teleoperation proposed by Backes et al. (1998). Motion guides consist of fashioning paths intuitively, in the robot virtual environment. Then, the actual telerobot is constrained to follow these paths when this is possible. Subsequent continuous commands sent to the actual telerobot are only one dimensional: forward, back, or halt along the motion guide. Motion guides are graphically represented by paths (curves and lines), and the motion direction is specified using arrow icons. Specification and modification of motion guides is achieved interactively offline or online (during teleoperation). Task line is a metaphor to design subtasks attached to motion guides, which is represented in the VE by icons. A task line is a collection of command sequences that are executed when the telerobot reaches the task line location. Among the general commands found in a task line, reactive sequences can be included to be performed upon specific events related by means of internal or external robot sensory capabilities (see Fig. 48.7).

At the Sandia National Laboratories, graphical programming tools based on three-dimensional (3-D) graphics models (called Sancho, see Fig. 48.8) are being developed to be used as an intuitive operator interface to program and control complex robotics systems, including teleoperation for nuclear waste cleanup (Small & McDonald, 1997). Sancho uses a general set of tools to implement task and operational behavior and works in four major steps:

1. The tasks are defined, by the user, by means of menus and graphical picks in the simulation interface (define/select step). In this step, a 3-D world model is used to simplify task definition; indeed, direct object selection is a primary method for defining task work location and to control task execution. At this stage, task definitions are based essentially on two paradigms: (a) operation-based, by which robot tasks are subsequently derived from a set of individual sequence executions that consist of the task to be accomplished, and (b) task-based, less flexible than the first and in which case the task results from a set of predefined useful goals (predefined subtasks).
2. The system plans and tests the adopted solutions under operator monitoring and supervision (plan/simulate step).
3. If the adopted plans are considered satisfactory by the operator, a network based robot program of the approved planning is sent to the robot controller (approve/download step).
4. Finally, the Sancho system monitors the robot and updates the simulator's environment with the data fed back from the actual robot environment (see Fig. 48.8).

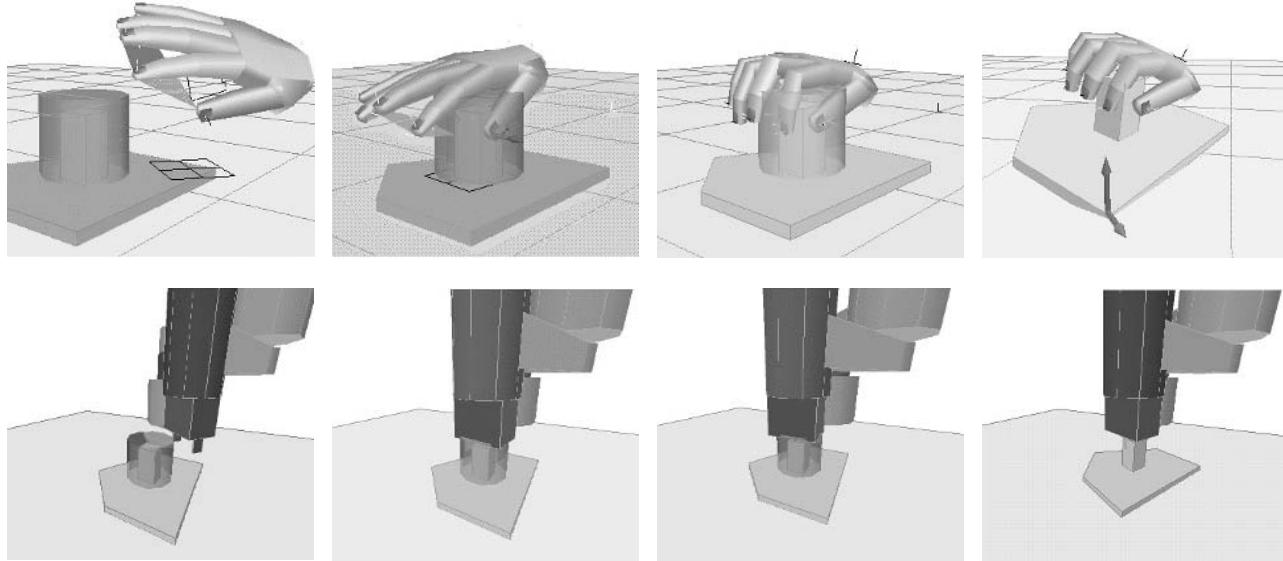

FIG. 48.6. The use of a collaborative active virtual guides in a grasping assist task for both the operator (*upper row*) and the slave robot (*lower row*) in the frame of the hidden robot concept-based teleoperation (Kheddar, 1997).

Another graphic programming system case, called TAO 2000, was developed by the French Nuclear Center (see Fig. 48.9). TAO's graphic programming interface foundation is a hierarchical mission decomposition (i.e., a functional objective decomposition) into a set of processes or methods. A process finds an expression in a set of operations (abstract functions); each operation is then decomposed into a set of tasks (i.e., generic functions); and each task is described by a set of actions (i.e., physical functions), which are easily mapped into telerobot executions (physical forms). The whole process constitutes an exploitable generic skill database. For a given mission (for instance, gate inspection), the operator selects a set of processes from a predefined skill database (e.g., an unscrewing process) to achieve each stage of the mission (the unscrewing step) and maps it onto the concerned object (one of the gate screws). The mapping (map unscrewing skill to the pointed gate screw) constitutes an operation that will be executed by the telerobot agent. The operation consists of a set of field containing selected symbolic tools, such as: positioning area, an active virtual guide, recovery procedure, calibrating procedure, and agent behavior mode (autonomous, semiautonomous, or full manual teleoperation, Fournier, Gravez, Foncuberta, & Volle, 1997).

The TAO 2000 system is equipped with the PYRAMIDE 3D modeling system. As shown in Fig. 48.9, only the functional objects (i.e., those involved in the specific mission—gate inspection) are rendered to unburden operator mission preparation.

3.3 Improving Bilateral and Shared Control

Using a virtual intermediary world between the master and slave robot offers additional paths in control architecture design. All the same, the human operator can gain assistance from low-level control. Virtual environment techniques contribute subtly to low level control, as well as provide a potential way to efficiently carry out shared control. From the remote robot control point of view, the great advantage of reflex control is the absence of high-level reasoning before an action takes place. It is a direct link between information and action without passing

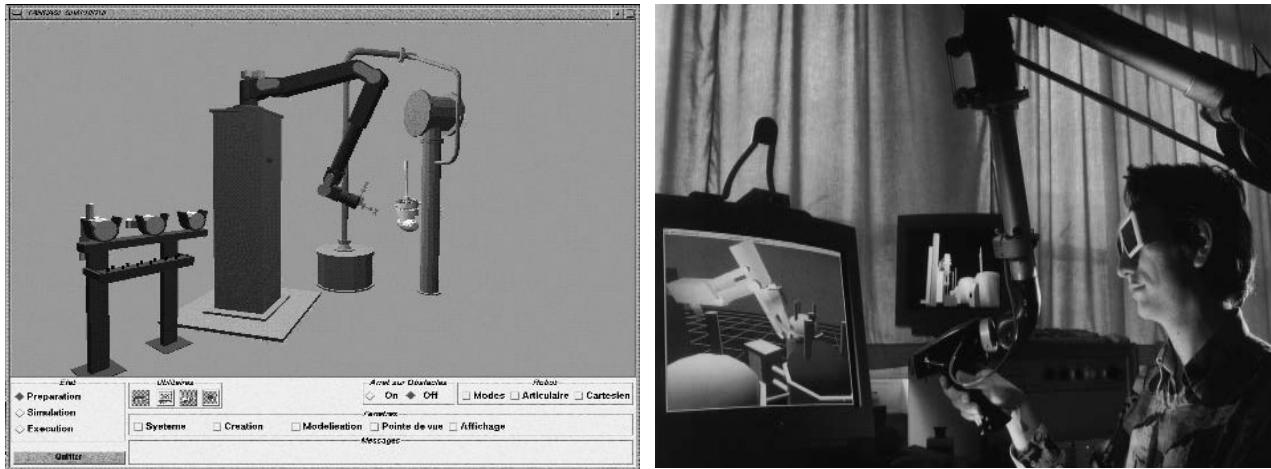

FIG. 48.9. TAO 2000: A VE-based graphical programming for nuclear maintenance (gate inspection mission case, (*left*); the whole system with the MA23 master force feedback arm (*right*). Courtesy of Gravez and Fournier, Advanced Teleoperation Service, CEA, France.

through a decision-making stage. Reflex behaviors are necessary to take advantage of robot capabilities and to make robot control easier for the operator. Moreover, when time delays prohibit bilateral coupling between the master and slave, reflex behavior becomes an intrinsic property to allow robot autonomy. Nevertheless, because decision is built into the information sensed, this inclusion of information is only possible if the environment is well defined. Therefore it is necessary to know beforehand, by some other means, the characteristics of the environment components involved in the teleoperation tasks. This unsolved problem relates to sensing and analysis of data. The use of VE may significantly improve this situation. Although the environment is unstructured it is, generally, not totally unknown. Thus, applying VE to this problem means that two categories of virtual objects may be created. The first category refers to the minimal meddling of what is known about the environment. An example is that of a robot pushing against a surface of unknown hardness. If the robot is guided under force control and the surface is actually very soft, then the system becomes unstable. Even if the surface is very hard this may also lead to instability. Traditionally, this is solved by adding a mechanical compliance at the end of the robot arm that absorbs energy. But if, instead, real environment hardness K_e is replaced by a virtual hardness K_v , which is much larger than K_e and is given a priori, then the robot, which applies a force F_c on the surface, becomes stable. Hence, an unknown characteristic of the real environment can be replaced by a known virtual characteristic, which assures a good interaction with the contacted surface (Fraise, Pierrot, & Dauchez, 1993). The same principle could probably be extended to most characteristics of unstructured environments.

The second category of virtual objects is the previously presented virtual fixtures or active virtual guides. While the concept has been previously applied in computer assisted teleoperation, it can be extended to enhance robot autonomy and to improve operator assistance through low-level control. As stated, the principle consists of introducing geometrical artifacts along which the robot is constrained to move. This has been expressed through the virtual mechanisms principle.

Kosuge et al. (1995) proposed an alternative control algorithm for telerobotic systems. For a given task, a task-oriented passive virtual tool is designed so that its dynamic behavior matches that of an ideal actual tool to be used as an interface between the remote robot and the object involved by the given task. Indeed, both robot maneuverability and stability are improved, while indirectly making bilateral control easier for the operator. As part of the TAO 2000 teleoperator project (see section 3.2 and Fig. 48.9), Joly and Andriot (1995) derived bilateral control laws from a simulated virtual ideal mechanism. Compared to Kosuge's, et al. (1995) work, the virtual mechanisms suggested here are connected to both the master and slave arms via springs and dampers. Using this, it is possible to impose any motion constraint to the teleoperator, including nonlinear constraints (complex surfaces and shapes) involving coupling between translations and rotations. This idea is being applied to most haptic interface controllers (see chaps. 5 and 6, this volume) interacting with virtual environments.

The research previously cited shows that VE techniques are not limited to operator assistance, but could also serve as an intermediary in achieving remote tasks by replacing problems related to man–robot–environment interactions with man–robot–virtual mechanism–environment interactions.

3.4 Human-centered Architectures

The purpose of any teleoperator is not the perfection of a master design, or an adequate executing machine, or the control architecture, or even the present remote environment state. The purpose is rather a future environment state expressed through its transformation. Indeed,

only this transformation is of interest. On the other hand, almost any complex task to be remotely performed can be broken down into subtasks that can be expressed by a set of elementary moves for which a certain sensory-based state holds (i.e., a set of relations between the motion space and sensors space). An important remark can also be formulated to justify the design of human-centered telerobotic architectures; the way human operators perform tasks is in most cases not the most suited way for robots, and vice versa (Kheddar, 1997). This basic idea constitutes the foundation of various so-called human-centered architectures.

In the “hidden robot” telerobotic architecture proposed by Kheddar (1997), the goal of an ideal teleoperation system is defined by the possibility to build an intermediate world keeping only a functional copy of the real remote environment adapted to the desired task transformation. The part of the system devoted to the execution of the task must involve additional transformations implicating the intermediate world as a real one. Thus, the proposed teleoperation scheme leads to the design of two separate subsystems and the development of the link layer necessary for their connection. Therefore, to the operator, a representation of the real environment (with the possibility of changing objects location, shape, etc.) is made to suit his ergonomic requirements. Moreover, this representation handles what is necessary to be adapted to operator skill and dexterity, free from any constraint or transparency compromise inherent to bilateral (real or virtual) robot control. Following the above cited consideration, it is easy to see that in any intermediate functional representation the first object to be eliminated will be the “picture” of the remote system moving the real operational tool. There are at least three advantages of such an approach compared to the use of a classical VE based representation. First, the master station components (VE plus haptic device and sensory feedback) are adapted to direct task performance by the operator without any interference due to robot control. Second, the slave station is adapted to the task achievement by the robot without any direct interference due to the operator. Finally, bilateral data exchange is performed according to clever cross-modality-based task transformations.

At the Institute of Robotic Research (IRF), Germany, a clever VE system was developed for teleoperation. It allows for intuitive control of a multirobot system and several other automation devices with a standardized, easy-to-understand user interface. The general aim of the development was to create a universal frame for projective virtual reality, in which it is possible to “project” tasks, carried out by the user in the virtual world, into the real world with the help of robots or other automation components. In a projective virtual world the user can act as in the real world. Therefore, this kind of man-machine interface reaches the previously not achieved standard of intuitive operability, even for complex automation devices. The less the user has to know about the real automation device, the better the design of the man-machine interface.

In the projective virtual reality approach, with the help of robots changes made in the virtual world are “projected” in the real world. Thus, this approach builds a bridge between VE and robotic automation technology by providing techniques for the connection of these two fields (Freund & Rossmann, 1999), see Fig. 48.10).

One of the current human-centered architecture technologies is telepresence or telesymbiosis (Vertut & Coiffet, 1986). When coupled to other ways of reproducing natural human actions at remote places, telepresence provides users with the possibility of creating, with different degrees of realism, the notion of presence (see chap. 40, this volume). Telepresence has been defined by Sheridan (1992, p. 6), as a human-machine system in which the human operator receives “sufficient information about the teleoperator and the task environment, displayed in a sufficiently natural way, that the operator feels physically present at the remote site.” Very similar to immersion-based virtual environments (see chap. 40, this volume), telepresence strives to achieve an actual feeling of presence at a remote real location. The end goals of both telepresence and immersion-based VE are fundamentally the same—a human interface that

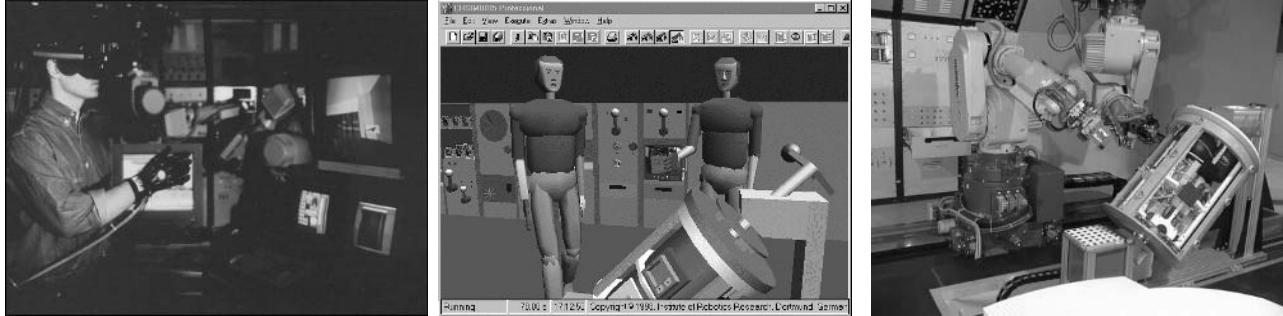

FIG. 48.10. Projective Virtual Reality concept for space and complex task telecontrol. From left to right: the operator interface (an immersion-based interfacing); the operator virtual projection into virtual avatars; and the actual robots mapping the virtual avatars actions into actual ones within the remote location. Courtesy of Freund and Rossmann, the Institute of Robotics Research, Dortmund, Germany.

allows a user to take advantage of natural human abilities when interacting with an environment other than one's direct surroundings. In the case of teleoperation in real environments, this is achieved by projecting the operator's skill and dexterity while reflecting sensory feedback so realistically that the operator feels present at the remote site. Indeed, telepresence borrows a lot from teleoperation technology because a remote physical device is needed to act on the remote environment while feeding back sensory information to the operator. The experience of being fully present at a real-world location remote from one's own physical location is obviously afforded by a high degree of transparency and realism. Someone experiencing transparent telepresence would therefore be able to behave, and receive stimuli, as though at the remote site. As for teleoperation, for any telepresence system there are three essential components: (1) the operator site technology; (2) the communication link; and (3) the remote site technology. Therefore, video (see chap. 3, this volume), audio (see chap. 4, this volume), and haptic (see chaps. 5 and 6, this volume) display systems, such as head-mounted displays (HMDs), auto-stereoscopic display screens, stereo headphones, and gloves or other devices equipped with touch feedback, may all be used by the operator. Control also needs to be exercised by the human operator and devices such as head and body tracking devices (see chap. 8, this volume), joysticks, master hands and arms in the form of gloves and exoskeleton structures, and other application specific controllers (see chaps. 11 and 13, this volume), are used. Contrary to teleoperation systems, telepresence VE techniques could be seen as being more concerned with interfacing technology and not interfacing strategy. If realistic and fully transparent feedback is the top consideration, illusion-based artifacts may be useless (see chap. 22, this volume).

In the RCAST laboratory at the University of Tokyo, Tachi's team is conducting studies on Tele-Existence, (Tachi, 1998). Tele-Existence is an advanced type of telepresence system that enables an operator to perform remote manipulation tasks dexterously with the feeling that he or she exists in the remote environment where the robot is working. He or she can "tele-exist" in the VE, which a computer generates, and be able to operate the real environment through the virtual space. One of the distinguishing characteristics of the system is the use of VE to allow operator self-projection. Two self-projection characteristics can be defined. The first one, defined by the authors, concerns the drawing of an operator's legs, body, arms, hands, and so on from which the operator feels as if he or she is self-projected onto the virtual human in the virtual environment. The operator "mapped" to the virtual robot can freely move around in the building, though the real robot can move only in restricted areas (see Fig. 48.11).

The second self-projection function that might be understood from using a VE tele-existence is the possibility to allow the operator, in an actual environment telepresence frame, to switch from a realistic representation to a virtual one so that he or she can plan strategy to exercise telepresence tasks thanks to a better understanding of the real environment from one's virtual representation. In this case the operator is split into two operators: the one who can explore ("what-if" strategies) the remote location without an actual, but rather a virtual, physical action ported on it (obviously a virtual representation is needed); and the one who can actually act on the real environment (a virtual representation is not necessarily needed in this case).

3.5 Enhancing Sensory Feedback to the Human Operator

Improving sensory feedback deals with using VE as a means to compensate for lack of sensory feedback from the remote site, that is to say, superimposing or combining artificial sensory feedback to the real one. With regards to the master site, in the presence of time delay, virtual environments were either used as an overlay to actual feedback (predictors case) or used as a

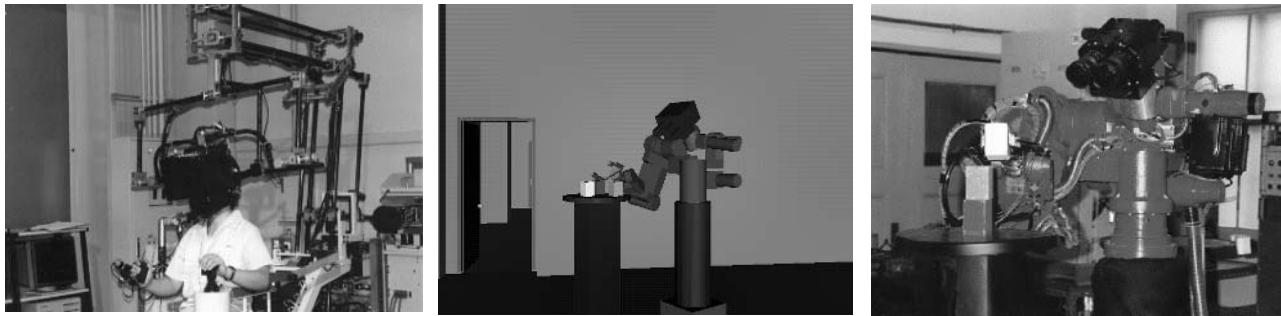

FIG. 48.11. TeleSAR (TELE-existence Slave Anthropomorphic Robot) system. From left to right; the master station, virtual environment tele-existence, and real environment tele-existence. Courtesy of Professor Tachi, RCAST, the University of Tokyo, Japan.

whole virtual intermediary to allow local feedback with respect to operator sensory bandwidths (for instance teleprogramming). Using VE as an overlay to real feedback is also known as augmented reality. Even in the absence of time delays, augmented reality may be helpful to improve corrupted sensory feedback information from the remote location. For instance, when vision feedback is defective (undersea boisterousness or cloudiness, smoky working area, or any poor-visibility environment) an augmented or VE display will not prevent the operator from driving the remote robot. The effectiveness of this kind of sensory feedback support has been proven in experiments by Oyama, Tsunemoto, Tachi, and Inoue (1993) and Mallem, Chavand, and Colle (1992). The virtual fixtures introduced by Rosenberg are also a powerful tool to improve sensory feedback. As stated previously, a virtual fixture is essentially a sensory overlay to actual feedback from the remote environment to increase operator performance. Moreover, fixtures can be invisible if the operator gains no benefits from visual cues, they can be viewed as a synthetic solid virtual object if rich visual cues are useful for the task, and can even be turned into a transparent glassy solid if visual cues are important and the operator does not want an occluded workspace. Virtual fixtures can be conceived as selective visual filters to block particular distraction, enhance contrast, provide depth cues, and even magnify a part of the workspace. Indeed, one could imagine the huge number of possible combinations that could be achieved by overlapping real sensory feedback in order to improve actual sensory feedback.

Sensory feedback enhancement can also stand out through different sensory substitutions (see chap. 21, this volume). For instance, the combination of visual fixtures, artificial sound, and tactile stimuli could substitute for a lack of actual sensory feedback from the remote robot location. In addition, using a whole virtual representation in the case of teleprogramming could be seen as a kind of sensory improvement because it maintains force feedback allowing more intuitive task achievement (even if this is within a VE). As far as a virtual representation is adopted, the number of sensory feedback modalities could be increased and combined in different ways thanks to various I/O interface technologies. For instance, the ROTEX experiment lacks force feedback, though a VE was used to perform space robot teleoperation. Instead, a SpaceBall was used for the virtual/real robot tele-sensor-programming and virtual interaction forces were monitored and substituted into visual cues to be displayed to the operator on a screen. Hence, force feedback is not always necessary if adequate substitution over the operator interface is conceived to tackle this shortcoming.

3.6 Improving Safety and Human Factors

In most teleoperator schemes using VE as an additional intermediary, operator safety could be addressed in two ways:

- The first is preventive and seems to imply the possibility to affix safety functionality integrated within the VE by means of computer programming.
- The second way deals with the possibility to fit the VE within human sensory capabilities so that teleoperation tasks could be achieved thanks to less risky, user-friendly, I/O devices derived from VE technology (3-D mouse, space balls, sensing gloves, desktop force feedback devices, etc.).

Obviously, both ways could be combined and additional features may be added to the remote site, namely by exploiting robot autonomy and enhancing its perceptual issues.

There might be various strategies to act on the VE by adding functions to improve operator safety (see chap. 41, this volume). One of them is straightforward: The operator would have

FIG. 48.12. Improving both visual sensory feedback and safety for the operator: The VE representation enhances visual cues and acts as a filter using an active collision avoidance algorithm developed for teleoperation purposes. Courtesy of Fournier, TAO 2000 Project, the French Nuclear Center.

the opportunity to simulate a teleoperation task before actually performing it. This is a kind of a “what-if” strategy. Another more transparent strategy is to prevent eventual collisions by means of clever active collision avoidance in the VE, as has been proposed for the before cited TAO 2000 system (see section 3.2 and Fig. 48.9). Extending this last principle to more general tasks, the VE can be fashioned to include functionally a kind of “intelligent” filter. The latter may guide or prevent situations that may compromise the operator’s safety (see Fig. 48.12).

In general, for direct bilateral master–slave coupling, the safety risk is the aggregate likelihood of master, slave, and communication media damage (or functionality loss). Since an intermediate VE is used: (1) the antagonistic well-known transparency-stability problem is subsequently shifted to a local man–VE transparency problem without compromising any of the slave stability; thus, (2) one can state that safety risk is reduced of master dysfunction or a VE crash. The first could be diminished by using more user-friendly interfaces (see chap. 34, this volume, as is the case for many teleoperator instances cited herein). Subsequently, additional mapping functions are added to derive telerobotic commands (as is the case of the hidden robot architecture). In this case, the VE must offer rich and astute sensory feedback modalities, however, potentially restricting experiential telepresence, because this could be counterproductive. Indeed, in a telerobotic system a certain detachment may be desirable to keep the operator from becoming totally immersed in a manual control phase such that he might resist returning to higher level monitoring (this prohibits the use of HMDs in many actual teleoperator systems). As far as a VE crash is concerned, this problem connects software engineering (i.e., one must foresee recovery procedures to restart teleoperation from the crash state) with debugging facilities (e.g., frequent VE state saving). While safety and sensory feedback improvement receives special attention (e.g., <http://www.ornl.gov/rpsd/humfac/base-frame.html>), no generic performance taxonomy exists for classical teleoperator evaluation (though a VE usability taxonomy does exist, see chap. 34, this Volume). Yet one can state that in essence VE-assisted teleoperation is a move toward user-friendly, more refined control, rich

multimodal feedback, but it is still difficult to give a qualitative and a quantitative measurement to these improvements. Concepts for teleoperation can be derived from human factor evaluation obtained from more general application results (Stanney, Mourant, & Kennedy, 1998).

4. VIRTUAL ENVIRONMENTS AS A POWERFUL TOOL FOR SPECIAL PURPOSE TELEOPERATORS

There are many special teleoperation applications among which VE plays a considerable role, either because without VE techniques, these applications would not be feasible, or because VE brings a considerable improvement and/or contribution.

4.1 Telesurgery

Improvement in the precision and reliability of robotic systems has won the trust of physicians and medical personnel. Indeed, applications of robotics in the medical field relate to surgery (see chap. 47, this volume), rehabilitation (see chaps. 49 and 50, this volume), general services including laboratory and prosthetics orthotics. Likewise, VE technology is a part of many medical applications. Because, on the one hand, an entire chapter is devoted to medical application of VE (see chap. 47, this volume), and, on the other hand, general medical robotics goes beyond the scope of this book, this section focuses on VE-based teleoperation aspects as applied to medicine and more specifically to telesurgery. Since the essence of surgery are precision and motion coordination of surgeons, it is not surprising that robotics—the technology of controlled motion—is investigated and widely used in operating wings. Because of the special safety needed, surgical robots are more “assistive” than “active.” This means that in terms of robot control, the surgeon may always be in the control loop.

In minimally invasive surgery (MIS; e.g., laparoscopy, thoracoscopy, arthroscopy), robots serve as telemanipulators used to guide micro-instruments. An operation is performed with instruments and viewing equipment inserted into the body through small incisions made by the surgeon, in contrast to open surgery, which uses large incisions. Like arthroscopes used in orthopedics, MIS requires endoscopes. Endoscopic surgery has many common points with teleoperation, because the surgical environment could be seen as “remote,” with sensing and manipulation projected via the endoscope and other long instruments. Nevertheless, endoscopes resemble mechanically coupled master–slave systems, i.e., action/feedback is directly mapped from the surgeon to the patient’s organs. The well-known limitations of master-slave systems are hampering surgeon’s abilities (Tendick, Jennings, Tharp, & Stark, 1993). In this mechanical “bilateral control” scheme, VE techniques enhance tactile sensory capabilities or augment visual feedback. Eventual use of robots as an intermediary for handling surgical tools is called telesurgery. Therefore, telesurgery is based on existing solutions from computerized teleoperation, and VE applications likely contribute in many ways to fulfill reduced dexterity, work space, and sensory input and feedback. Instances of actual telesurgery systems are cited in chap. 47 (this volume). Also, because tools are manipulated through medical robotic systems, the patient could actually be at a remote location from the surgeon. The other advantage gained from telesurgery is the use of a robot in a semi-autonomous mode. Indeed robots can move with a very low speed and can find less constrained paths thanks to their own haptic sensory or haptic sensory information (see Chaps. 5 and 6, this volume) fed back to the surgeon. This implies less healthy tissue damage for patients, resulting in shorter recovery time and reducing surgeon stress.

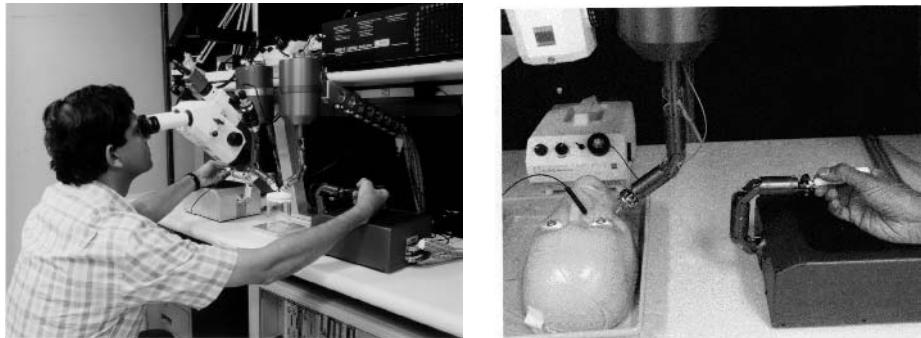

FIG. 48.13. Master-slave micro-telesurgery system. Courtesy of the RAMS Project at the Jet Propulsion Laboratory.

Teleoperation technology has also been investigated in the development of emerging microsurgery systems. An instance is the Robot Assistance Micro Surgery (RAMS) system, developed at JPL/NASA (see Fig. 48.13, Charles et al., 1997). The RAMS system is a 6 degrees-of-freedom master-slave telemanipulator with:

- (1) different control schemes including direct telemanipulation, which includes task-frame referenced haptic feedback and shared automated control of robot trajectories;
- (2) facilities such as physical scale of state-of-the-art microsurgical procedures; and
- (3) features to enhance manual positioning (e.g., procedures such as manual positioning and tracking in the face of myoclonic jerk and tremor that limit most surgeons' fine-motion skills).

Another example demonstrating the VE contribution in tele-microsurgery is the prototype system developed by Hunter et al. (1993), for eye surgery applications. This system includes two force reflecting interfaces (a shaft shapedlike microsurgical scalpel) to control the left and right limbs of the slave microsurgical robot. A stereo camera system is used to relay visual feedback, on a worn helmet, to the surgeon. The camera position is controlled through the surgeon's head movements, which lead to interactive changes of the camera point of view (see Fig. 48.14).

There are many applications where surgical assistance robots can be considered as VE/computer guided robots through picture processing and augmented reality. The latter technique contributes to surgeon's operation strategy improvement. Enhancement of surgical environments with image overlay has been proposed for online use in neurosurgery (stereotactic brain surgery), orthopedics (like hip replacement), microsurgery, obstetrics, plastic surgery, and other specialties. In these applications, the physician can view medical images or computer generated graphics overlaid on and registered with the patient. For example, in neurosurgery a rendering of a brain tumor can be displayed inside the patient's head during surgery, providing localization and guidance to a surgeon. Three-dimensional image overlay capabilities can be used in place of, or to complement, telerobotic systems.

There are also many investigations to use telepresence and/or teleoperation techniques allowing a surgeon to operate at a location remote from his real physical location. But because of ethical and safety reasons, even if telerobots were used clinically, human assistants at the remote site would certainly be needed.

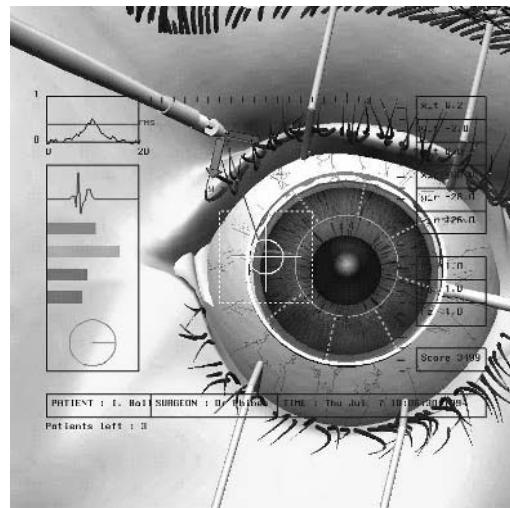

FIG. 48.14. Screen snapshot of a VE eye representation overlaid with additional information being used for online telesurgery as well as for training and simulation. Courtesy of Auckland University, New Zealand.

4.2 Teleoperation at Micro and Nano Scale

There is an important demand to reveal the nature of much smaller worlds. Micro and nano (abridged μn) system technology, including μn -robotics, is becoming a challenging area of research because of its potential applications. Interrelated applications concern: industry (μn : assembly, sensors, actuators, and mechanics, miniaturization); information technology (disk storage with high density, memory, semiconductor, and integrated circuits); biotechnology, biomedical, and genetic sciences (genes, biological particles and DNA manipulation; repairing or understanding mechanisms, cell handling, noninvasive eye and plastic surgery); and chemistry and materials (fabrication of μn structures and man-made materials, study of related quantum effect devices).

Consideration of μn -specific problems, in addition to task application, tools, and interconnection technologies specific requirements, lead obviously to many flexible μn manipulation concepts: purely manual teleoperation; automated; and robotics by means of flexible and co-operating μn -robots. Up-to-date, scanning tunneling microscopy (STM), scanning electron microscopy (SEM), and atomic force microscopy (AFM) seem to be the common tools for scanning and manipulating at the μn -scale. Each of the above microscopes has a range of applications linked to the remote environment nature and the kind of desired μn -tasks. Each has specific limitations while being used in an actual μn -manipulation. For instance, biological samples, such as cells, cannot be visualized using a SEM because their electrical properties can change during envisaged μn -manipulations.

Ideal performance requirements are such that a human operator manipulates in the normal-size world μn -parts and performs tasks (such as cutting, grasping, transportation, assembly, scratching, digging, and stretching), which have a direct similar mapping at the μn -world. Indeed, construction of the μn -manufacturing world is dependent on solutions adhering to the following constraints:

- The working environment must be perceivable by the operator and information in the processing scene must be transmitted accurately to the operator. As far as μn -tasks are concerned;

tools must be arranged in the observing area (colocality); bilateral magnification must be stable and fully transparent; and direct and natural perception is required with 3-D movements, dynamic images, sound, and haptics.

- The grasping, release, or assembly of μn -items in the μn -world need perspicacious procedures, which are completely different from those commonly used in the macro-world. Gripping with forceps may not be adequate in many cases. Indeed, vacuum-assisted gripping by electric power or fluid and release under vibration, the use of μn -forces and adhesion, the use of plunger mechanism, and other astute techniques are mostly used. Moreover, the success and performance of μn -grasping, release, or assembly functionality together with μn -manipulation are, in many cases, dependent on operator skill.
- The operational remote environment is actually a hostile environment to humans because μn -world components behavior is very complex to understand and to manipulate. Moreover, since humans operate based on macro world model physics, tasks cannot be easily executed by the operator. In the μn -world, mass and inertial forces are negligible and μn -interaction forces are non linear and resultant forces from van der Waals, capillary, electrostatic, pull-off, rubbing phenomena, and even radiation forces of light exceed the gravity.
- Task taxonomies might include operational sequences (e.g., positioning, assembling, grip, release, adjust, fix-in-place, push, pull, etc.) and processing steps (e.g., cutting, soldering, gluing, drilling, twisting, bending, etc.).

To link the macro world to the μn , an interface that can match the two physical worlds and compensate for human operator inaccuracy is indispensable.

From the vision feedback point of view, VE can bring a considerable contribution. Indeed, the field of view or scanning is in most cases restricted to a small area and the distance between μn -objects, and the lens or the probe is very small. Moreover, on the one hand, scanning (which is on the order of seconds to minutes in some cases) does not allow online imaging. On the other hand, since the same single probe is used for both functions, scanning and μn -manipulating, these cannot physically be achieved in parallel whatever the scanning speed. Finally μn -operation are executed, in general, within the field of view. For these reasons, a 3-D VE topology can be built and displayed to the user. A 3-D virtual μn -world can be a global view of the real μn -world or restricted to the actual working area, according to the operator needs. Static or intuitively manipulated multiple views are then allowed in real time. As well, remote features may be augmented with multiple contrasting colors to present data in a comprehensive and easily interpreted manner.

The lack of direct 3-D visual feedback from the μn -world on the one hand, and the fragility of the manipulated μn -objects on the other hand, make force feedback an essential — even unavoidable — component of the macro/ μn -world interface. Indeed it is primordial to understand well the condition of the probe during operation. An excessive force applied on a μn -object may lead to a non-negligible degree of probe or object deformation, destroy the μn -object, or make the μn -object flip away. As well-known, μn -interaction is not reproducible enough to automate μn -procedures. Hence teleoperation control mode seems to be attractive; however, the traditional bilateral control through master-slave coupling has to face many severe problems: understanding of μn -dynamics together with reliable modeling; the effect of various nonlinear forces is completely different from the macro world (attractive, repulsive, and adhesion forces, etc.); bilateral stable, transparent, robust scale mapping, and others. Thus, it is not always possible to adapt easily conventional bilateral methods, moreover, monitoring small forces of 1 μN to 1 nN range needs very accurate sensors. Thus, solutions using a VE-based intuitive interface, which hides the details of performing complex tasks using SPM in combination with 3-D topography, seem to be an attractive solution. As for assisted teleoperation at the macro world, the interface would include virtual tools or virtual effective probes (Finch et al., 1995)

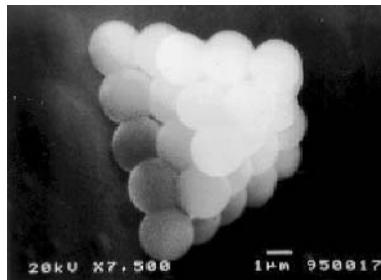

FIG. 48.15. Micro-Pyramid constructed with a μ -handling robot.

together with a 3-D representation used as a functional intermediary to map operator actions to the μn -world (rough to fine methodology) and vice versa. Then, the degree of abstraction of the commands would be determined by the capabilities of the control system. Hereafter, some developed prototype systems are mentioned.

At the University of Tokyo, Sato's team developed one of the most advanced μn -teleoperators (Sato, 1996). As a haptic interface, the system utilizes a touch sensor screen and specially designed, pencil-shaped master manipulator to enable sensitive bilateral μn -teleoperation thanks to its lightweight and small inertia during movements. A μ -handling result (see Fig. 48.15 at right, courtesy of Professor Sato, the University of Tokyo) is a Micro-Pyramid constructed with a μ -handling robot inside an SEM. This system is currently being enhanced by a more user-friendly interface based on bilateral behavior media for μn -teleoperation.

Other instances are from the Nanomanipulator research group at the University of North Carolina (Finch et al., 1995). Their system is using advanced VE techniques as an interface enhanced with virtual tools (grabbing, scaling, flying, etc.), virtual measuring fixtures (marked mesh, etc.), standard VCR functions (replay, save, etc.), and virtual modification tools. The main applications are concerned with biological studies and virus manipulations (see Fig. 48.16), the PHANToM is a force feedback desktop mechanism for VE applications, <http://www.sensible.com>).

At the same university, studies are being conducted in the frame of molecular docking. Indeed, today's computer-aided molecular design software (SibyllTM, MolMolTM, etc.) lacks user-friendly interfaces and algorithmic search of the configuration space is extremely costly. In return for advanced VE techniques and an "intelligence augmentation" man-machine system (see Fig. 48.17), chemists and drug designers would gain in efficiency and time (Ouh-young, Pique, Hughes, Srinivasan, & Brooks, 1988).

Another tele-nano-manipulation system is being developed in the Hashimoto laboratory at the University of Tokyo. This system is using an AFM for both scanning and manipulating at the nano scale. As a user-friendly interface, the tele-nano-manipulator is doted with a 1-degree-of-freedom haptic interface and a 3-D topology builder for nano manipulations (Sitti & Hashimoto, 1999). The controller is actually a bilateral mode based on impedance shaping to allow the operator to feel the forces from the nano world. Different control strategies utilizing the haptic interface have been tested, and results are thoroughly described in Sitti and Hashimoto (1999; see Fig. 48.18.)

4.3 Mobile Robots Teleoperation

Since long ago, mobile robotics had the connotation of autonomy and artificial intelligence, and was not concerned with teleoperation. Early mobile robots were designed with a "tele-operation" mode so a human operator could unilaterally control them during transportation,

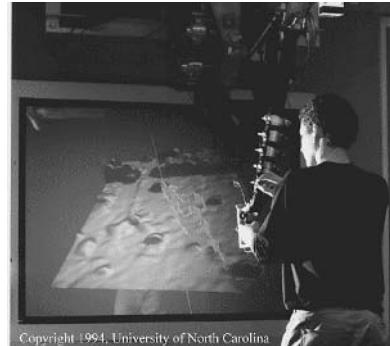

FIG. 48.16. Different n -manipulators configurations (*from left to right*): PHANToMT-based desktop configuration; a WorkBench together with the PHANToMT force feedback stylus; and the Argone robotic master arm (*right*). and setup phases. Difficulties in achieving completely autonomous behavior (see chap. 15 this volume) in terms of auto-decision and of a mobile robot unilateral teleoperation mode turns out not to be simple when the robots are conceived as a complex structure (subsea and flying robots), with specific locomotion (such as many legs) or propelling mechanisms, or when refined feedback using the operator haptic channel is attempted. Pioneering work in the latter was done by Clement, Fournier, Gravez, and Morillon (1988). Teleoperation mode can be considered as an intrinsic characteristic of advanced autonomous mobile robots. We emphasize this proposition with a simple example; the conceiver of the well-known Honda Humanoid robot reported: "...this robot is completely autonomous" and with insistence declared: "But, it can be teleoperated as well." We stress that this specificity tends to draw closer a classical teleoperation field researchers utterance: "...this robot is teleoperated, but, it can be autonomous as well." As far as mobile robot teleoperation is concerned, VE techniques can bring similar advantages as for classical robots. From the related literature, many VE-based mobile robot architectures have been proposed. Keywords that seem to be a standard in the way VE techniques are used include: off-line mission planning; highly interactive environment for abstract programming at various levels; simulation and prediction of complex missions with a virtual teleoperated vehicle; robot computer-assisted design; and training, safety, and user friendly control through augmented reality (superposition of virtual and real environments may reveal discrepancies or sensors defects, etc.).

In the work of Komoriya and Tani (1990), an actual robot together with a VE set around it constitute a simulation system considered to lie between the full computer simulation and the full actual system. This hybrid system provides an efficient testbed for developed control laws and planning algorithms, without any damage risks for the robot.

Another VE technique for teleoperation has been proposed by Kheddar (1997), which allows prediction and bilateral robot teleoperation control with multimodal feedback, including haptics. In this proposed scheme, operator commands will involve desired robot reorientation, speed, and acceleration, embedded tool(s) control, global inertia redistribution, and other factors. It has been suggested that pertinent parameters that the operator may feel include: stability margins, inertial forces, applied torque, joint limit margins, contact points and forces, related obstacles distance, and robot attitude. All these parameters are computed locally (i.e., based on the virtual model of the robot and its environment) and fed back to the operator locally thanks to a suitable sensory substitution. The appropriate sensory substitution is chosen to stimulate the operator sensory channel so that subsequent telerobotic actions are reflex generated. In this case, the VE constitutes a filter to intuitively control safely the robot since actual robot controls are sent only if some selected parameters fit within allowed margins. Nevertheless bilateral control is permitted only if the communication time delay between the master and robot is small enough (less than 1 sec). In the case of larger time delays, the VE is functionally used similarly to arm teleoperation (i.e., as a predictive or a teleprogramming interface). This is thoroughly explained in the following cases.

The exceptional instance highlighting the use of VE techniques in mobile robot teleoperation is indubitably the Mars Path Mission (a NASA Discovery exploring Mars planet). Indeed, a VE-technology-based supervision and control workstation was designed to remotely command the *Sojourner* rover, which landed on Mars by July 4th, 1997. A graphical user interface supplied numerous available rover commands (i.e., macro-operations with respective various parameters, such as Calibrate Heading with Sun, Capture Images, Drive, GoTo WayPoint, etc.). Offline, a 3-D terrain model is processed from both previous mission accumulated stereo images obtained from an embedded IMR camera (a stereoscopic imager) and the partial VE already constructed from previous missions. Hence, using a simple SpaceBall as an I/O device together with a stereo rendering of the virtual working environment and a virtual model of the Sojourner rover, the operator designs plans and actions to be achieved by means of a set of graphic programming metaphors. Subsequently, when the simulation results are considered to be satisfactory, a control code is generated and transmitted, by means of the Deep Space Network (up to 6 ~ 11 sec time delay, thus prohibiting manual teleoperation), to the actual Sojourner rover on Mars (see Fig. 48.19).

More enhanced interfaces and telerobotic technology are being developed for future unmanned exploration of the “Red Planet” to provide scientists with a telepresence interface for real-time interaction with, and interpretation of, the returned geophysical data (Backes, Kam, & Tharp, 1999).

In the frame of subsea robotics, Paul’s team at the GRASP Laboratory applied the teleprogramming concept they developed in the frame of a subsea ROV equipped with a robotic arm (Sayers, 1999). An experiment has been conducted with the Deep Submergence Laboratory of the Woods Hole Oceanographic Institution (WHOI Laboratory). Bandwidth of some Kbits/sec and round-trip communication delays of 7 seconds are typical of the subsea acoustic transmission mean. The operator disposes of a VE remote site wherein control or supervision tasks can be achieved. Remote slave actions are governed by those resulting from the master station. Eventual discrepancies are resolved from a continuous comparison between the virtual (simulated) and the real internal and external embedded sensors. Subsequent mismatches and diagnosis are deduced by the operator that is responsible for the suitable recovery procedures to be taken (see Fig. 48.20).

FIG. 48.19. *Clockwise:* Elements of the VE interface before assembly; main rover control workstation program window; the actual Sojourner rover at work on Mars; and driver's VE interface with Waypoints shown. Upper row pictures design of the master station, lower row pictures show snapshots of the video feedback from the slave (JASON ROV) environment. Courtesy of Sayers, the GRASP laboratory, University of Pennsylvania and the WHOI Laboratory.

At the French Institute of Research and Exploitation of the Sea (IFREMER), the control of robots for intervention, reliability of these systems, and dynamic stabilization of the machines at low speed are the aspects under investigation. A VE technique named VESUVE (Virtual Environment for SUBsea VEhicles) has been developed for 3-D subsea scenes simulation and visualization.

VESUVE offers a general framework for creation, visualization, real-time animation, and interactive manipulation of any kind of virtual subsea scene involving deep sea vehicles. The main objective of VESUVE is to study, implement, and evaluate VE technologies for subsea vehicles. Its potential areas of application are: engineering of subsea vehicles (visual simulation for integration, test, and validation of the system, real-time visualization of CAD data, visual simulation for pilot training or scientist familiarization); operation of subsea vehicles (3-D piloting aid for ROV or towed vehicles, 3-D navigation aid, telepresence, visual simulation for mission rehearsal or debriefing, teleprogramming for autonomous or semi-autonomous vehicles); and subsea robotics R&D (virtual lab for experimental subsea robots in research fields like control, mission programming, navigation, fault detection diagnosis and recovery, and real-time presentation of simulation results, see Fig. 48.21).

Obviously there are still many other remote mobile robotic teleoperation systems using telepresence and VE interfaces, such as the VEV (a distributed Virtual Environment Vehicle Interface) developed at the NASA Ames Research Center's Intelligent Mechanisms Group (Hine et al., 1995), adopted to the Dante mission at Alaska, Antarctica, and other locations, and the advanced computer project to assess Chernobyl damage. We do hope that these few instances being used on actual hazardous environment missions have shown the benefits that VE brings to advanced teleoperator schemes in the special mobile robot teleoperation context.

4.4 Web-based Teleoperation

Some of the most challenging purposes for today's multimedia systems are to include haptic data exchange (see chaps. 5 and 6, this volume) and to allow physical teleworking, through the network (Internet World Wide Web, for instance, see chap. 16, this volume). Currently various remote robots can be controlled through the Internet network by means of any Internet browser. A number of Web addresses are available at: <http://ranier.oact.hq.nasa.gov/telerobotics.page/realrobots.html>.

Control interfaces are using Java Applets with different available command buttons allowing any user connected to the Internet to experience actual remote control of robots (see Fig. 48.22)—arms, mobile cameras, telescopes, and even toy trains!. Tasks are generally concerned with object assembly, exploration (of museums), among others. The user may see the result of his actions via continuous video feedback (in general, the refresh rate is too slow due to network traffic).

Many laboratory experiments involving teleprogramming through the Internet and diverse other network protocols have been conducted. Many of these, such as the ROTEX experiment and subsea teleoperation, have already been mentioned. An advanced ATM Network has been used by the Fukuda team in Japan for a multimedia telesurgery context. The satellite network has also been used in a telesurgery experiment between the Bejczy team at the Jet Propulsion Laboratory and Rovetta team at the Politecnico di Milano, Italy (references are quoted in Kheddar, Tzafestas, Coiffet, Kotoku, & Tanie, 1998).

Other experiments have been conducted between the Laboratoire de Robotique de Paris and the Mechanical Engineering Laboratory involving the control of parallel multirobots through a single operator and VE interface based on the hidden robot concept (Kheddar et al., 1998).

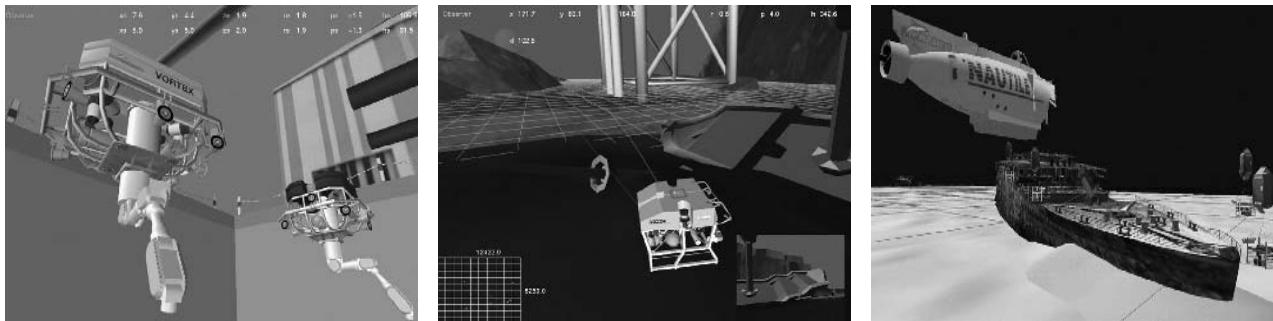

FIG. 48.21. VISUVE case studies: Cooperative ROVs and control simulation; offshore planning; and the *Titanic* mission simulation, an aid for the actual remote control of the VICTOR 6000 ROV. Courtesy of the IFREMER, France, <http://www.ifrem.fr/ditidsiw3.uk/engins/vesuve.html>.

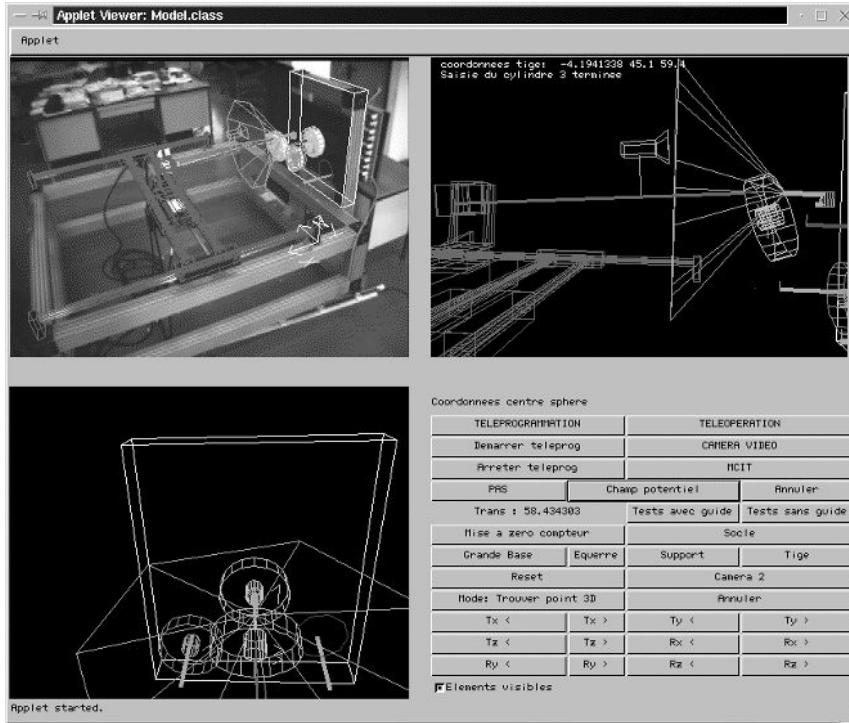

FIG. 48.22. An Internet Web-based teleoperation interface using augmented reality and online assistance by means of virtual fixtures. Courtesy of Otmane, the Complex Systems Laboratory, Evry University, France.

With different robots controlled in parallel, a common intermediary functional representation is imperative and enhances the interest of the proposed concept.

As shown in Fig. 48.23, the teleworking experiment consisted of a four-piece puzzle assembly within a fence on a table. The real remote assembly operation was to be performed by slave robots (one situated in Japan and three in France, for the first experiment, one in France for the experiment described herein). The operator performs the virtual puzzle assembly using his own hand, skill, and naturalness. Visual and haptic feedback is local and concerns only the graphic representation of the remote task features without any remote robot. Operator-VE interaction parameters are sent to another workstation in order to derive robot actions (graphically represented for software check and results visualization) and do not involve direct operator action/perception. Video feedback was kept for safety and error recovery purposes.

Web-based teleoperation has a direct impact on industry; possible applications include tele-maintenance, telemonitoring, and telesupervision. As an instance, an European project for maintenance system based on telepresence for remote operators was launched in September 1996 (Bisson & Conan, 1998). The resulting technology enabled remote users to train themselves to deal with maintenance tasks by connecting to a “virtual showroom” where they could learn maintenance procedures through computer augmented video based telepresence and augmented reality techniques.

The teleoperation environment consisted of (1) an extended prototype of the equipment to be maintained, that is, the target equipment, customized to allow remote control and extensive diagnostic, and (2) auxiliary devices such as manipulators and vision systems, used

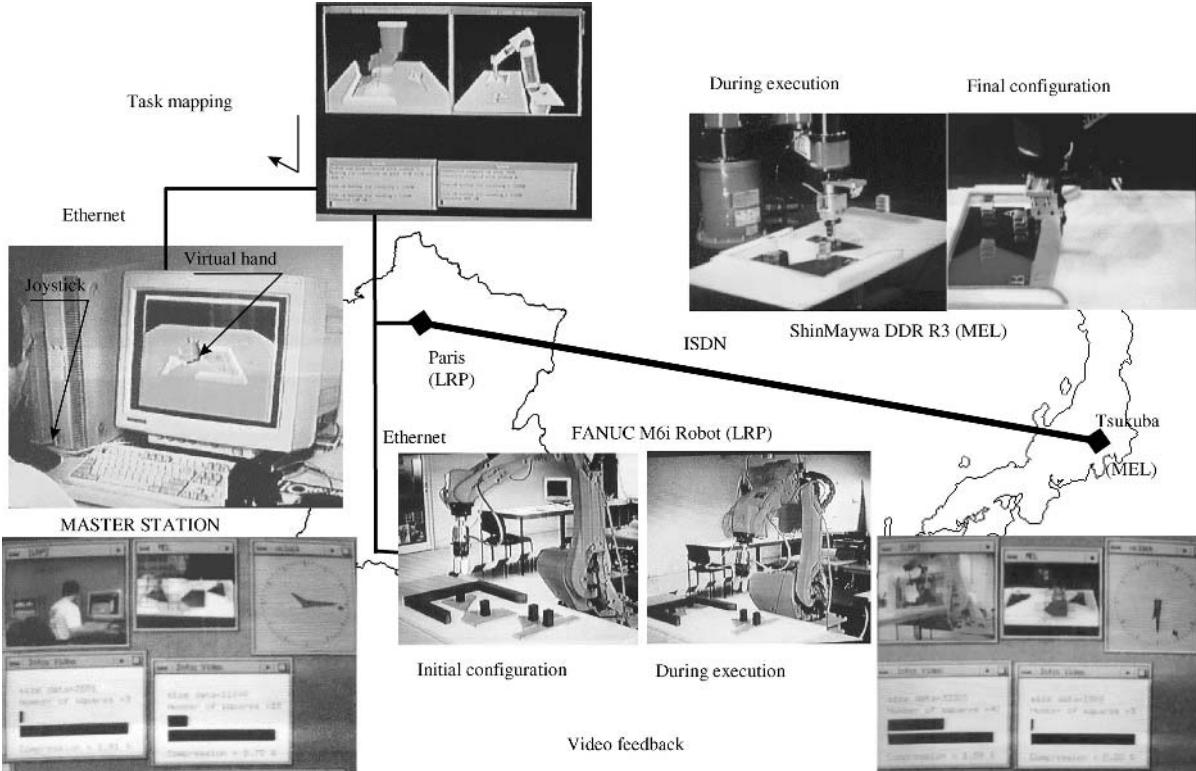

FIG. 48.23. Parallel long-distance multirobots teleoperation. Courtesy of the Laboratoire de Robotique de Paris and the robotics department of the Mechanical Engineering Laboratory.

both for equipment servicing and for enhancing user interoperability. Marking techniques allow registration of a virtual model of the video designed equipment provided by the remote camera. The virtual model is annotated with links to a multimedia database containing specific information (e.g., operating and maintenance instructions, functional data describing regular, or faulty conditions). Speech recognition is used as well to allow spoken commands. This system is dedicated to the training of complex maintenance and installation scenarios for industrial companies that cannot afford on-site complex training equipment (see Fig. 48.24).

NASA's Jet Propulsion Laboratory and Ames Research Center are developing a next-generation ground system called RoCS for (Rover Control Station) for use on planetary rover missions. The RoCS architecture includes a module called WITS for Web Interface for TeleScience (Backes et al., 1999). The latter serves two purposes: (1) an interface for scientists to use from their home institutions to view and download data and generate commands for the remote rover; and (2) to make the interface available to the public domain: <http://robotics.jpl.nasa.gov/tasks/scirover> or <http://mars.graham.com/wits>. Thus, any person connected to the server could downlink images, generate rover waypoints, science targets, and commands, which, however, cannot be sent to the actual or true rover.

5. PROGNOSIS AND CONCLUSION

Undoubtedly there is still much to say concerning the prosperous manner in which robotics can benefit from VE techniques (Burdea, 1999; see Burdea & Coiffet in Nof, 1999). It is impressive to note that, a cleverly conceived yet "simple" VE intermediary representation contributes to solving the time-delay problem, offers ingenious metaphors for both operator assistance and robot autonomy sharing problems, enhances operator sensory feedback through multiple sensory modalities admixtures, enhances operator safety, offers a huge possible combination of strategies for remote control and data feedback, shifts the well-known antagonistic transparency/stability problem into an operator/VE transparency one without compromising the slave stability, offers the possibility to enhance—in terms of pure control theory—remote robot controllers, allows new human-centered teleoperation schemes, permits the production of advanced user-friendly teleoperation interfaces, makes possible the remote control of actual complex systems, such as mobile robots, nano and micro robots, surgery robots, and others. Subsequently, VE techniques seem to provide the ultimate magic solution solving all the hard teleoperation problems at a glance. Nevertheless, this considerable opening gives rise to additional new problems.

One problem deals with VE modeling techniques (see chap. 12, this volume). There is a grand demand for robust software, which can reproduce the VE with high fidelity and sufficiently rich realism to allow both real-time user-friendly operator interaction and easy implementation of necessary metaphors, such as virtual guides, that allow operator assistance and enhance local sensory feedback and robot autonomy sharing in an intuitive way (i.e., without setting the operator at a determined control layer). Nevertheless, in some cases, namely when remotely controlled systems are complex, there is a need for a virtual representation that cleverly keeps only functional aspects of the complexity of the remote environment, thereby unburdening the operator and facilitating control or supervision. This aspect is only possible if a clever bilateral mapping exists between real environments and their virtual functional representations.

The other hard problem with using VE technology is the error detection and recovery inherent to VE—real-environment discrepancies. This problem has received little attention from the teleoperation researchers community. It could be tackled from two ways: a high-fidelity error detection strategy (eventually involving the operator) that matches what is expected to be

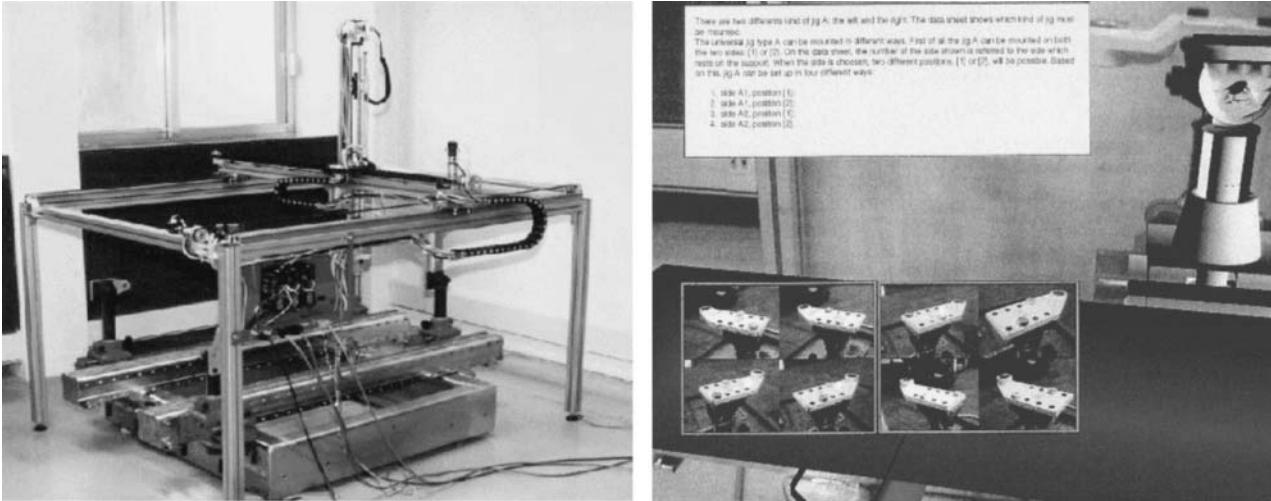

FIG. 48.24. Teleoperation environment. An XYZ table plus yaw pitch camera to explore the maintenance equipment (*left*). Output (AR picture) from the MAESTRO, answer to query: "What are the different jig types?" Courtesy of Bisson, Thomson CSF, France.

done in the VE and what is actually done in the real environment; and a strategy for recovery based on robot autonomy and local sensory robot perception. If this problem can be solved, a merely partial virtual representation of the real environment could be acceptable.

In conclusion, teleoperation efficiency was almost stagnant during several decades since the discovery of the master-slave structure by Goertz in the 1950s (Vertut & Coiffet, 1985), and that was in spite of technical improvements and the use of computers. It seems that VE brings total renewal through the development of telepresence or tele-existence concepts. Now, the desired efficiency could be a reality, allowing not only a clear improvement in traditional applications such as nuclear or space activities, but opening numerous new fields of interest. Thanks to VE technology, teleoperation/telepresence could soon represent a major percentage of robotics applications.

1. INTRODUCTION

The purpose of this chapter is to describe how virtual environments (VEs) can be utilized to facilitate motor learning in normal subjects and to enhance the rehabilitation of disabled subjects.

The chapter begins with a review of relevant literature on the use of VEs for training sensorimotor tasks in normal populations in two main areas, spatial-motor and navigation learning studies. Next, clinical literature on the potential and actual applications of VEs to the field of rehabilitation is reviewed. Advantages and disadvantages for the use of VEs, discovered through these studies, are identified and discussed.

Next, a system designed by the authors is described. The system provides a new method for motor learning, “by imitation,” within a virtual environment. A number of key design issues that were encountered during development of the system, along with the solutions chosen to address them, are described. Finally, summaries of results to date are provided, based on using the system to train normal subjects and patients with stroke on selected motor tasks. The chapter concludes with a short description of ongoing work and future directions.

2. LITERATURE REVIEW: MOTOR TRAINING USING VEs IN NORMAL SUBJECTS

In recent years, there has been great interest in using VEs for learning various types of motor and spatial tasks (Darken, Allard, & Achille, 1998; Kozak, Hancock, Arthur, & Chrysler, 1993; Regian, Shebilske, & Monk, 1992). This interest has been driven by a number of perceived advantages of virtual over real-world training. These advantages are both practical

and theoretical in nature. Practical advantages are discussed first; theoretical advantages are discussed later in the context of system design in section 4.1.

2.1 Practical Advantages of VE Training

Practical advantages of using VEs for training include safety, time, space and equipment, cost efficiency, and documentation considerations:

1. Safety—in practicing a virtual task that is potentially dangerous (such as flying a plane for a normal subject or lifting a pan of hot water for a disabled subject) there are no negative consequences to failure
2. Time—the training task can (in theory) be quickly altered to become easier or more difficult
3. Space and Equipment—requirements may be minimal compared to the real environment (for example, training military personnel on a “virtual” vs. a real ship)
4. Cost Efficiency—the possibility for fewer training personnel (or therapists in the case of patients) while still maintaining a similar outcome level following training or treatment. This may be achieved by semiautomating training on the computer, allowing subjects to work independently some of the time. In medical applications (see chap. 48, this volume), telemedicine has the potential to reduce the cost of providing care to remote areas while improving access for remote areas to higher quality of care
5. Documentation—automatic scoring and report systems can be developed to allow easy monitoring of progress of subjects using the VE training system.

Obviously, the potential to apply VEs for training to all sorts of sensorimotor tasks in fields as diverse as defense, medicine, industry, and sports is huge. In looking at the literature on VE applications to motor learning—broadly defined—in normal subjects, one finds that much work is geared toward very complex motor skills that have a large cognitive component (such as military training for flying planes or navigating ships (Kennedy, Lanham, Massey, Drexler, & Lilienthal, 1995; Lawson, Rupert, Guedry, Grissett, & Mead, 1997; Theasby, 1992), or a very high level of eye–motor coordination (such as VE training aimed at virtual surgical training for physicians (Docimo, Moore, & Kavoussi, 1997; see chap. 48, this volume). The issues important to researchers studying these types of problems are often quite different from those faced by the researcher whose goal is to develop a system that would be useful in helping disabled subjects relearn simple movement skills like lifting a cup or turning a key in a lock, or to train skills that are more predominantly perceptual–motor in nature, such as a tennis swing.

In fact, relatively few studies in the literature were found on using VEs to train such tasks. The most relevant studies fell into two classes: (1) studies of spatial–motor learning such as the “pick and place” task (Kozak et al., 1993) or procedural console-operations tasks (Regian et al., 1992); and (2) studies of learning to navigate in small- (Waller, Hunt & Knapp, 1998) or larger-scale environments (Ruddle, Payne, & Jones, 1999; Wilson, Foreman, & Tlauka, 1997; see chap. 24, this volume).

2.2 Spatial–Motor Learning in VE

Kozak et al. (1993) trained participants to move a series of cans, positioned in a line from left to right directly in front of them, to matching discs placed 6 inches forward of the start location. The sequence was then repeated in reverse order so that the cans ended up at the original starting location. Three groups were used; one group trained in a virtual environment, one trained on the real world task, and one group received no training but only testing. Participants who trained in the real world were significantly better than either the VE or no-training groups.

Participants who trained in the VE were no better at performing the real-world task following training than were participants who received no training.

However, participants who trained in VE *did* improve their performance *during* VE, at a rate comparable to participants who trained in the real world. That is, they learned the *virtual* task, but learning the virtual task did not *transfer* to improved performance on the comparable real-world task. Proposed reasons for the lack of transfer included subtle differences in the grasp required in the two situations (VE vs. real world), system time lag, differences in the field of view in which the hand could be seen, lack of tactile and acoustic feedback, and difficulty aligning some participants with different body sizes so that all the virtual cans could be reached. If participants were using the method of loci as a learning strategy (Bower, 1972; in this method, participants associate motor responses with imaged spatial locations), then slight differences in displayed locations relative to the participant's arm in the two conditions could have interfered with learning and transfer of skill to the real-world test (see chap. 19, this volume).

A later study by Richard et al. (1996) examined the influence of several of the factors identified by Kozak et al. (1993) as possible factors that interfered with transfer of learning. Richard et al. (1996) examined the effect of different graphics frame rates and viewing modes on grasp acquisition time, and the effect of force feedback and added acoustic signals on force regulation ability during grasp in a virtual environment. They found no difference in object capture times (time to grasp a virtual object) between stereo and mono displays for frame rates of 28 or 14 frames/sec (fps). However, when frame rate fell below 7 fps, stereo viewing increased performance by 50%. (Note that currently available graphics hardware allows higher frame rates at lower cost.) Direct haptic feedback (see chaps. 5 and 6, this volume) was found to be superior to pseudo-feedback (reduced error rates and improved performance of a force regulation task). The lowest error scores and task completion times occurred when direct haptic feedback was augmented by an acoustic signal that indicated the initial contact of the virtual hand with the virtual ball.

Regian et al. (1992) trained participants in a procedural learning task (a complex 17-step console operation task) using a virtual environment, and found that all 31 participants in the experiment were able to learn the task using VE for training. The purpose of the experiment was to compare the effects of two types of instructional strategies on learning, therefore, transfer to real-world performance was not tested. However, this study did serve to establish that it was possible to learn motor skills in a virtual environment.

2.3 Motor Learning and Transfer

The most essential issue in considering the usefulness of VE training for motor control in normal subjects, as well as for rehabilitation of patients, is the ability to transfer the performance that is learned in the virtual world to performance of that same task in the real world. It was surprising to see that many studies examined learning in a virtual environment but did not measure performance on similar real-world tasks following training (Gillner & Mallot, 1998; Ruddle, Payne, & Jones, 1999). Perhaps this occurs because researchers are aware of the many technical factors that account for discrepancies between the virtual and real worlds, and the goal of many studies is to understand these factors better so that the fidelity of VEs can be improved. However, without testing transfer to real-world performance, much effort could be consumed in improving fidelity in VE systems beyond the level that is really necessary to accomplish effective training.

2.4 Navigational Learning

Two studies using VEs to teach spatial-navigation knowledge found that under certain conditions training transferred well to the real-world environment (Waller et al., 1998;

Wilson et al., 1997). In the first of these studies, Waller et al. (1998) examined the effect of six different training environments on participants' ability to perform blindfolded in a real world 14 × 18-feet maze environment. The conditions compared were: (1) no training; (2) real-world training, (3) map; (4) VE desktop; (5) VE short immersive (1 min); and (6) VE long immersive (2 min). Participants ($n = 120$) received six consecutive bouts of training on one of these conditions. Each training bout was followed by a test trial on the real-world maze. Results showed that for early learning (defined as performance on test trials 1 and 2), real-world training was significantly better than all other methods, and although all other conditions were equal statistically there was a trend to worse performance for participants trained in VEs ($x = 270$ sec. for VE participants; 163 sec. for real-world trained participants). However, by the sixth trial, mean times for the real and long-immersed VE conditions were statistically equal and significantly shorter than for the other two VE conditions (desktop and short immersive). Although this implies superiority for immersive VE over desktop, it is not clear that the superior performance for the immersive condition would have held if participants had trained in the other conditions for equivalent amounts of time as in the long-immersive VE condition. In examining the issue of transfer from VE training to real-world performance this study is of interest because it shows that both desktop and immersive VE methods were capable of improving performance on a similar real-world task. In addition, when controlled for time spent in training, there was no difference in training effectiveness of the desktop and immersive VE methods.

Wilson et al. (1997) examined navigational learning in a large environment via exploration of a real multistory building and a to-scale computer simulation of the same building. The computer simulation was presented to participants using a desktop VE system. The computer keyboard was used to navigate. A control group received no training. The results showed that participants who received the simulation training were able to transfer the three-dimensional (3-D) spatial knowledge learned in the VE to a variety of spatial measures in the real world. For many measures, the VE trained participants performed as well as participants who trained in the real environment, and for most measures the VE participants performed better than the control group. This study is of interest because it shows that learning and transfer can occur with less sophisticated desktop systems.

2.5 Cybersickness and Negative Aftereffects

Another issue that stands out in many studies of VE training performed on normal subjects is the relatively common incidence of negative side effects (see chaps. 29–32, this volume). These side effects include cybersickness, altered visual-motor and sensorimotor coordination, and postural disequilibrium (Cobb, 1999; Nichols, 1999; Stanney, Kennedy, Drexler, & Harm, 1999; Stanney et al., 1998). These side effects have the potential to negatively affect motor coordination in the real-world posttraining (see chaps. 37–39, this volume).

Such problems are of even greater concern for patient populations, especially if central nervous system function is impaired due to disease or injury. Minor alterations in postural equilibrium or eye-hand coordination that could safely be handled by a subject with a normal nervous system, might, in a patient with impaired nervous system function, result in a fall due to loss of balance or inability to catch oneself with an arm that reaches to the incorrect location in space for support. Because the topic of negative aftereffects is covered in detail elsewhere in this volume, an extensive review is not provided here. However, in the sections on design (see sections 4, 5.1, and 6.1) a discussion is provided on how findings from research in this area have influenced design decisions in the system we are presently using. As more is learned about the exact causes of these side effects through studies on normal subjects, design changes in future systems and improved training routines will be better able to prevent the occurrence of unwanted side effects in normal, and, hopefully, disabled subjects as well.

3. CLINICAL LITERATURE: VIRTUAL ENVIRONMENT USE IN REHABILITATION

In the field of rehabilitation, VE application is still in its infancy. Much of the clinical literature published to date on VEs in rehabilitation has been focused on describing the potential applications of the method to different areas of rehabilitation (Greenleaf & Tovar, 1994; Kuhlen & Dohle, 1995; Rose, Attree, & Johnson, 1996; Wilson, Foreman, & Stanton, 1997). However, relatively few reports of actual use and effectiveness of VE with patient populations have been published. While many investigators are working in this field, much of the work is still under development or just beginning to move from the development to the clinical testing phase. In the first section below, different areas of application that are under development are briefly described to give the reader a broad sense of the field. In the second section, several reports relevant to motor learning of upper extremity tasks in disabled subjects are reviewed.

3.1 Overview of VE Applications in Rehabilitation

Proposed applications of VE to the field of rehabilitation fall into four major categories: (1) use in measurement/diagnostic tests; (2) assistive technology; (3) social and entertainment applications; and (4) training of impaired functions. Training of impaired functions may be divided into training of tasks which are primarily perceptual-motor or cognitive in nature.

3.1.1 Applications for Measurement and Diagnostic Tests

Kuhlen and Dohle (1995) describe a system designed to aid physicians in the analysis and diagnosis of movement disorders, such as different types of pareses and apraxias. With this system, movements of patients performing different motor tasks are recorded, then trajectories of these movements can be displayed in 3-D, viewed from different angles, and precisely quantified. Virtual environments can also be used to interactively explore medical imaging data such as MRI and PET scans of the brain, allowing physicians to gain a clearer understanding of the location and size of lesions. When paired with clinical evaluations from patients, such information should enhance the ability to predict structure-function relationships in the brain. Rose et al. (1996) propose using VE to make neuropsychological assessments of cognitive function in patients with brain injury more ecologically valid. This could be done in VEs by measuring cognitive function in the context of realistic everyday functions, such as cooking in a virtual kitchen. Another advantage of VE testing in brain injured subjects would be the ability to distinguish the contribution of cognitive vs. motor impairments in task performance. Because patients with brain injury often have both cognitive and motor impairments, these two factors are mixed together in real-world testing. Virtual environment testing could allow users to focus on only cognitive factors by reducing the motor parts of the task in VE to one simple movement.

3.1.2 Applications for Assistive Technology

Assistive technology in general is designed to help disabled persons use different types of technology to substitute for functional abilities they have lost. Virtual environments would be one more tool to extend the possibilities for such individuals. For example, telerobotics could be applied to allow users with very little motor control to manipulate objects in their environment by interfacing with a robot device. Warner, Anderson, and Johanson (1994) are working on a system to allow quadriplegics such control. In another example, Greenleaf and Tovar (1994) describe a Virtual Receptionist system that allows people with speech or motor impairments to perform the job of receptionist: answering and making phone calls, and other secretarial tasks. Two

groups have worked on systems that use a VE DataGlove to record sign language gestures, then translate these gestures into written or spoken words by using a speech synthesizer (Kramer & Leifer, 1989; Vamplew & Adams, 1992). Such a system would allow deaf individuals to converse freely with hearing persons who are not knowledgeable in sign language.

3.1.3 Social and Entertainment Applications

Individuals with severe disabilities often experience social isolation due to difficulties with transportation, energy levels, and access. Virtual environments have been proposed as a way of allowing handicapped individuals at remote sites to join together and interact in a virtual world (Smythe, 1993).

3.1.4 Training of Impaired Functions

In the field of locomotor training, a prototype device which can superimpose objects into the field of view of patients with Parkinson's disease, while still allowing them to see the real world, has shown promise as a method to counteract the slow shuffling gait which is characteristic of patients with this disorder (Emmet, 1994; Reiss & Weghorst, 1995). A method to teach children with orthopedic impairments to operate motorized wheelchairs has been developed by Inman, Peaks, Loge, and Chen (1994). Another VE system designed to train standing posture and dynamic balance control in the elderly is currently being tested (Cunningham, 1999). The system is based on video capture in a nonimmersive environment.

A method for treating strabismus (a deviation of the eye position in the socket, often due to weakness in one or more eye muscles) by exercising eye muscles in VE has been proposed (Lusted & Knapp, 1992). By attempting to keep objects in a VE aligned, the eye muscles could be exercised; the difficulty could be calibrated based on the degree of misalignment of the resting eye axis of the patient.

Finally, methods are being developed to assess and train patients with acquired brain injuries on cognitive function tasks (Christiansen, et al. 1998; Pugnetti et al., 1995). The method being developed by Christiansen et al. (1998) uses a virtual kitchen to assess performance on daily tasks, such as preparing a can of soup. The focus of the task is cognitive, as the subject uses a mouse click or joystick to navigate in the environment and accomplish each step of the task in sequence. That is, subjects are not required to move a virtual (or real) arm to actually do the task as they would in the real world. Such a test can help therapists determine the degree to which cognitive vs. motor deficits contribute to a patient's impaired function on a variety of activities of daily living (see chap. 50, this volume).

3.2 Reports on VE Training Results in Rehabilitation

3.2.1 Spatial Learning

Children with severe motor disabilities often have poorly developed spatial awareness (Foreman, Orenas, Nicholos, Morton, & Gell, 1989). One significant contributing factor to this deficit is thought to be reduced ability to explore the environment in an active way secondary to the mobility impairment. Virtual environment technology has been proposed as a way to offer such children a chance for active, independent spatial exploration.

Wilson, Foreman and Tlauka (1996) decided to test whether such training in a VE would result in improved spatial knowledge in a comparable real world setting. The authors used a desktop VE system to train large-scale spatial knowledge of a two-story building. Subjects ($n = 10$) were children with a variety of disabling conditions, including spina bifida, cerebral palsy, and muscular dystrophy. All relied on a wheelchair as their prime method of mobility,

though three subjects could walk short distances with a walker. They ranged in age from 7 to 11 years. A control group of eight healthy adults with a mean age of 23 years received no VE training, but underwent the same testing as the children. Children received one training session. They explored a virtual model of the actual building they were in for the experiment, with the goal of finding fire extinguishers and a fire exit door. Immediately following VE training they were tested on knowledge of fire extinguishers and fire door locations in the real building. This was done in two ways. First, while still in the training room with the computer, subjects used a pointer to aim at the expected location. This was followed by a wheelchair tour of the real building during which subjects were asked to guide the experimenter to two specific locations. Results showed that all the subjects were able to point to and find desired locations in the real world and to do so significantly better than control subjects who received no training.

The results of this experiment are significant for our work because the system used was a relatively simple VE desktop display. Subjects had no vestibular or kinesthetic feedback during their exploration of the virtual world; the feedback was purely visual in nature. Despite these limiting factors, the exposure of only one session resulted in significant learning.

3.2.2 Motor Learning

Researchers at Rutgers (Burdea, Deshpande, Liu, Langrona, & Gomez, 1997) have developed an interesting line of work using a VE system designed for hand rehabilitation and diagnosis. The system uses a PC workstation, Rutgers Master II force feedback glove, and a Multipurpose Haptic Control Interface, which allow measurement of grasping forces applied to 16 regions of the hand. The system was initially designed as a diagnostic tool for hand rehabilitation, then developed further to include rehabilitation capabilities. WorldToolKit was used to create exercise routines modeled after standard hand rehabilitation exercises. These include squeezing a ball, compressing “silly putty,” isolated finger flexion/extension, and functional tasks of pegboard insertion and ball throwing. The interaction with virtual objects is accomplished with different hand gestures, e.g., grasp, lateral pinch, pointing, release. A desktop display is used. The forces generated by the patient in the virtual movement are fed back through the glove with a mechanical feedback bandwidth of 10 to 20 Hz. The system is currently undergoing clinical trials at Stanford University. Telerehabilitation capability has recently been developed for the system (Popescu, Burdea, Bouzit, & Hentz, 2000), and plans are under way to extend the rehabilitation capability of the system to the elbow and knee.

Several additional studies on motor learning in normal subjects (Todorov, Shadmehr, & Bizzi, 1997) and subjects with stroke (Holden, Todorov, Callahan, & Bizzi, 1999; Piron, Dam, Trivello, Iaia, & Tonin, 1999; Piron et al., 2000) utilize the VE system we have developed. The results of these studies are therefore presented following a description of the “learning by imitation” system.

4. DESIGN OF A SYSTEM FOR “LEARNING BY IMITATION” IN VIRTUAL ENVIRONMENTS

4.1 Theoretical Considerations

Observations of human movement suggest that the nervous system uses some sort of abstract motor plan, and fills in details needed to instantiate that plan in specific situations (Schmidt, 1975). These observations fall into two categories:

- Certain geometric features of movement trajectories (individual writing style, shape of speed profiles) are preserved when movement is executed with different actuators (left or

right arm, foot), requiring very different muscle activation patterns and dynamic interactions with the environment (Atkeson & Hollerbach, 1985; Lacquaniti, Terzuolo, & Viviani, 1983; Morasso, 1981).

- If external forces repeatedly distort the movement trajectory or the subject perceives the trajectory as being distorted (due to distorted visual feedback), the motor system often adapts so that the (perceived) movement trajectory returns to normal (Lackner & DiZio, 1994; Shadmehr & Mussa-Ivaldi, 1994; Wolpert, Ghahramani, & Jordan, 1995).

Such observations have led a number of investigators to believe that the geometric (kinematic) aspects of a movement form a major component of the abstract motor plan. If this is the case, the acquisition and rehabilitation of motor skills should be enhanced by training methods that somehow create an internal representation of the desired kinematic pattern (Schmidt & Young, 1991). An obvious way to do this is to learn by imitation: show people a detailed movement, ask them to reproduce that movement, and provide feedback on the mismatch between desired and actual movement.

While this can be accomplished with traditional methods, such as demonstration or video playback, imitation learning systems utilizing VEs offer a number of advantages. Some of these practical advantages were discussed earlier and are common to VE systems in general, for example, space and equipment requirements are less, and mistakes made during practice have no negative consequences. The more important advantage of using VE technology for imitation learning, however, is its potential to enhance motor learning. This is due to several factors. The most important factor is the unique capability for real time feedback in the very intuitive and interpretable form that VE provides. Other advantages are that learners can see their own movement attempts in the same spatial frame of reference as that of the teacher (unlike practice with a real coach or therapist) and that the task can be simplified in early stages of learning, allowing the learner to focus on key elements of the task. Training environments can also be customized for different therapeutic purposes and the system designed to help the learner detect and correct errors more rapidly. Finally, practice, an essential element in motor learning, can be facilitated by making the task fun.

4.2 Design Considerations for Normal Subjects

The basic idea for implementing learning by imitation is illustrated in Fig. 49.1. A computer monitor is mounted at eye level with the screen facing down. A see-through mirror is mounted 20 centimeters below the screen. Thus, images displayed on the screen appear in a workspace below the mirror (in 3-D when stereo glasses are used). The user of the system can see both his hand and computer-generated images, in the same physical space (the picture is taken from the user's point of view while the user is looking down through the mirror). The user can "insert" his hand in the virtual hand and attempt to match the posture exactly. The virtual hand can display an animation of a desired movement that the user attempts to follow repeatedly. Both the animation and real movement occur simultaneously (overlaid or next to each other), making any deviations between the two immediately obvious.

While this would be the ideal form of imitation learning, it is hard to implement such training systems because existing technology does not always permit superimposing virtual images on the real world. In cases where the workspace is large and monitors/mirrors cannot be easily mounted, a head-mounted display (HMD) would have to be used to present the virtual image. That image will move with the head of the user unless head-tracking is used for correction. Our experience with head-tracking (even with highly accurate sensors, such as Optotrak 3020) suggests that it is extremely difficult to fool the human visual system (see chap. 3, this volume), virtual objects always look unstable due to tracking/calibration

FIG. 49.1. A photograph taken from the user's point of view, while the user is looking down through a semitransparent horizontal mirror. A monitor mounted above the mirror (facing down) projects virtual images that appear aligned with the physical hand in the same workspace. Note that appropriate illumination has to be used in order to see both hands.

errors and delays. This may not be a major problem when virtual objects are used to provide abstract information; however, in our case we are dealing with a real-time visuo-motor loop and a motor learning system that is accustomed to a perfectly “calibrated” physical world. So the ideal implementation was left for the future, and we focused on more feasible alternatives where both the desired and actual movements are presented in a virtual environment.

4.3 Design Considerations for Rehabilitation Subjects

In considering the kinds of system features that would make a VE system useful for motor training in patients with neurological impairments, one can begin by asking the question, What is different about training patients as compared to normal subjects?

In contrast to healthy subjects, where the focus of VE training is often complex perceptual-motor skills, such as flying a plane, in rehabilitation the goal is usually to relearn very simple motor tasks—ones we all take for granted—and to do so in the face of a variety of sensory, motor, and cognitive deficits. The exact type of deficit can vary tremendously from patient to patient, even with the same diagnosis. To accommodate for this variety, the first characteristic one needs to think about is flexibility so that the training can easily be adjusted to the needs of different patients. Another major focus is to facilitate transfer of motor learning that occurs in the virtual world to performance in the real-world. Flexibility in system design helps ensure that the virtual tasks created resemble real tasks as much as possible, particularly in terms of the movement required to perform the task.

Deficits that patients have can make learning even simple movements daunting. Thus, VE must be utilized in a way that will allow enhanced feedback to be provided to patients. The idea of augmented feedback is not a new one. But applying it in the context of VE in combination with learning by imitation of a virtual teacher, in real time, does differ from techniques used in the past. Thus, a number of ways for patients to detect the exact kinds of errors they are making during attempted movements have been incorporated into our system. Simply trying to imitate a desired movement may not be enough, particularly for patients with a sensory deficit who cannot "feel" exactly what their arm is doing. (Note, however, many of the features we have designed with patients in mind could well enhance motor learning in normal subjects as well.)

What about graphics displays? Although very complex, realistic, or fanciful graphics and fast-paced game formats are appealing to normal subjects for VE training, they may be overwhelming for patients. When the brain itself has been affected, as in stroke or acquired brain injury (in contrast to disabilities where the brain is intact, like spinal cord injuries), processing of all this information may be difficult. In contrast, a very simple display, with few movements, may help a patient to focus on the task at hand and enhance learning.

Next, the cardinal rule in medicine must be considered: "First, do no harm." The issue of possible negative side effects, such as cybersickness (see chap. 30, this volume), altered eye-motor coordination (see chap. 37, this volume), and postural disequilibrium (see chap. 39, this volume), must be carefully considered. To date, there seem to be fewer reports of negative side effects using desktop display systems for virtual environments. Most of the problems seem related to the immersive environment created by HMD-based systems (Cobb, 1999; Nichols, 1999; Stanney et al., 1999; Stanney et al., 1998). It seems obvious that feelings of disorientation, postural disequilibrium, or aftereffects in arm control that produce past-pointing could be much more dangerous for disabled subjects, in whom a fall and injury could more easily be elicited than in normal subjects. Another problem is that in an HMD, the patient cannot see the therapist or her instructions. Even with see-through HMDs, problems with postexposure alterations in eye-hand coordination and felt limb position have been noted (Biocca & Rolland, 1998; Rolland, Biocca, Barlow, & Kancherla, 1995). Even without aftereffects, HMDs present some problems. The extra weight imposed on the head will be much more difficult for patients to handle, because trunk and postural control muscles are often adversely affected by neurological impairments. Also, if a HMD is used without a head-position tracker (and the visual display is thus fixed relative to the head), the patient may become disoriented due to inaccurate cues for real-world horizontal and vertical, and begin tilting to one side while sitting or standing.

Finally, practical issues are important. Keeping costs down, making systems easy to use (see chap. 34, this volume) and minimizing the amount of equipment attached to the patient will offer the greatest potential for success and acceptance of VEs as a standard treatment procedure in rehabilitation clinics.

Because of many of the factors listed above, we have designed our system to be used with a desktop display. The display can also be projected on a large screen instead of a monitor to give a greater feeling of immersion (see chap. 40, this volume). A significant disadvantage of the desktop display is poor depth visualization. This can be compensated for in part by training features that allow playback of the recorded performance of a patient, then rotating the display in 3-D in any desired direction to show the patient where his or her errors are and how to correct them.

4.4 System Components

To date we have built and tested two virtual environments—one for training Ping-Pong shots and the other for rehabilitation of stroke patients (Bizzi, Mussa-Ivaldi, & Shadmehr, 1996; Holden et al., 1999; Todorov et al., 1997). The features common to both systems are described first, followed by a more detailed discussion of each system and experimental results.

Components described in sections 4.4.1 to 4.4.3 were used in our first two experiments. Based on results in these experiments, components listed in sections 4.4.4 to 4.4.6 were developed and are currently being tested.

In the two systems described below, both desired and actual movements were displayed in real time in a VE using a desktop computer. The main concern with using purely virtual training was that transfer from virtual to real tasks has sometimes been difficult to achieve in prior studies. To avoid such failure, every effort was made to “integrate” the VE into the physical context where the task normally takes place.

4.4.1 Scenes and Teacher

We created virtual worlds closely matching the desired task, that is, containing relevant objects with appropriate scale and distances among them. Instead of a fully immersive environment, a computer monitor was used that was properly aligned with the physical setting (as shown in Fig. 49.2). In the Ping-Pong experiment described below, training in the VE was interleaved with practice of the real task.

A human expert/therapist executed a desired movement that was recorded with a motion sensor (Polhemus FASTRAK) and imported in the simulation. An animated object (the Teacher object) displayed the desired movement. Another animated object (the User object) displayed, with minimum delay, the position and orientation of a physical object held by the user. The user was instructed to repeatedly produce movements such that the User and Teacher objects remained perfectly aligned at all times. Additional examples of scenes are shown in Figs. 49.3, 49.6, and 49.8. To aid the acquisition of the desired movement, a number of additional features were implemented, as described below. Movement parser, score calculation, and semiautomated training features were developed based on our experience with the system in experiments 1 and 2. They are being evaluated in our current experiments.

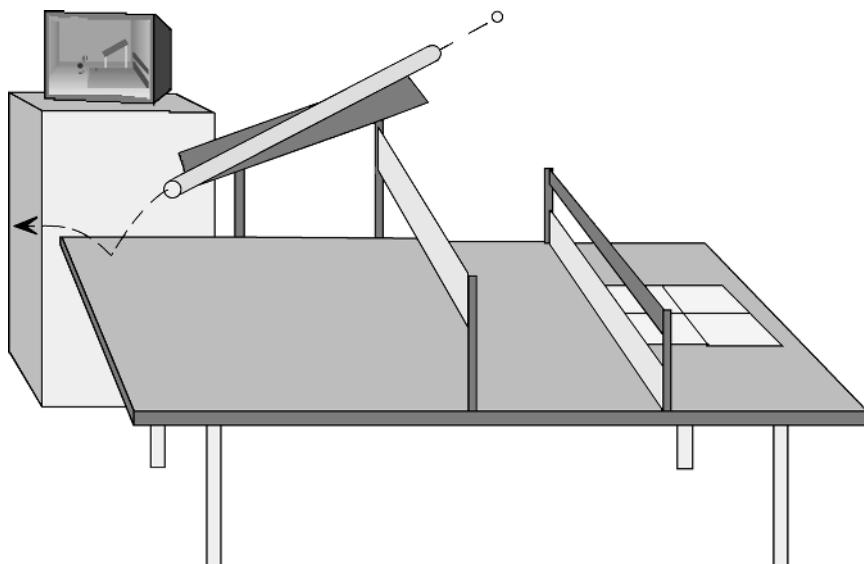

FIG. 49.2. A schematic diagram of the Ping-Pong experimental setup. Participants were standing in front of the table, hitting Ping-Pong balls with a paddle held in the left hand and trying to send them to the target zone. The balls had to pass through the opening and under the obstacle in the middle of the table. During training participants were standing in the same place required for the real task and looking at the monitor. Courtesy of Journal of motor Behavior.

4.4.2 Practice Modes

In the main practice mode, the Teacher animation was displayed repeatedly, while the user attempted to synchronize with it and track the desired movement accurately. It was possible to speed up or slow down the prerecorded animation, trigger the animation when the user started moving (see Movement parser), or display a static 3-D trace of the entire Teacher movement along with the animation (see Fig. 49.6).

It was also possible to work in passive mode, in which the Teacher “followed” the User while still remaining on the prerecorded trajectory. This was accomplished by rewinding the prerecorded animation (at each point in time) to the video frame in which the Teacher object was as close as possible to the current position and orientation of the User’s object. This provided a way for the user to learn the spatial path of the movement separately from the velocity profile. An active component was also included in this mode, where the Teacher moved a small distance along its trajectory if the User made no movements for a certain period of time. This provided guidance especially helpful for patients.

4.4.3 Augmented Feedback

In both practice modes, the mismatch between User and Teacher movements could be emphasized by connecting the two objects with lines or plotting circular arrows in the direction of the orientation error. The movements could be recorded and replayed later, and sound cues could be added to help timing. The visual display of either the teacher or patient trajectories could be altered so that the trajectory appeared as a wire frame or solid object. The size and frame frequency of teacher and patient “objects” could also be varied.

4.4.4 Movement Parser

The repeated Teacher animation described above required the user to synchronize with the system, which was difficult for some patients. To alleviate this problem we developed an automated movement parser, which monitored the FASTRAK sensor data and determined online when the user started and stopped moving. This information was used to trigger the Teacher animation and also to provide sound cues.

We have found it rather difficult to implement a movement parser that works reliably. After experimenting with various designs, we opted for a semiautomatic solution: The system provides a number of settings specifying velocity thresholds, distance thresholds, and other features and ways of combining them in Boolean expressions. These settings are adjusted by an expert user for each desired trajectory being trained with the system.

4.4.5 Score Calculation

An online scoring system has been developed to provide objective feedback as to how well the user is executing the desired movement. Since different movements require different scoring techniques, a general-purpose algorithm, with a number of parameters that an expert user could set, was implemented. The algorithm takes into account characteristics of the movement (average speed, duration, smoothness, etc.) as well as “closeness” to the desired trajectory. The latter is specified by entering weights for different types of error: position, orientation and velocity deviations, and different temporal misalignments.

4.4.6 Semiautomated Training

It was clear from the beginning that a fully automated training schedule would be unrealistic. In both training and rehabilitation, the system was originally operated by an expert instructor/

therapist who controlled transitions between different scenes, training modes, and feedback features. The expert was guided to a large extent by observing subject/patient performance. In our most recent version, however, a semiautomated “script” feature was implemented. The script feature allows specification, prior to training, of a series of scenes and teacher and feedback settings that progress automatically through a preset number of repetitions, simulating a treatment or training session. The scores computed online can be linked to this function so that the script will “jump ahead” if the task is too easy for the subject. The level of difficulty can be adjusted by changing the score value set as the goal. In general, our intention was to utilize the valuable expertise of a human instructor/therapist as much as possible while automating routine tasks and providing new sources of real-time feedback and motivation.

5. EXPERIMENT 1: TRAINING A COMPLEX MOTOR SKILL IN NORMAL SUBJECTS

5.1 System Design

Our first system was designed for training normal subjects to hit Ping-Pong balls and send them into a target zone (Todorov et al., 1997). The setup is shown in Fig. 49.2.

Participants were standing in front of the table, holding a Ping-Pong paddle in their left hand (to make the task more difficult). A ball was dropped through the tube shown in the figure, at an angle and speed corresponding to an intermediate to difficult shot. The task was to hit the ball after it bounced from the table and send it in the target area through the opening above the net. In the second experiment an additional obstacle was added in the middle of the table, in which case the ball had to pass under it.

During training the participants looked at the monitor, which was properly aligned with the physical setup. The desired movement was recorded from an expert hitting a real ball on the real task. When the recorded expert movement was transferred to the virtual environment the spatial alignment was preserved. In other words, in order to track the desired movement in the virtual environment, the participant had to make a movement in the real-world that would have accomplished the real task.

A snapshot of the simulation is shown in Fig. 49.3. Shadows, illumination cues, and occlusions were used to create a realistic simulation. The solid paddle shows the User position and orientation; the transparent paddle shows the Teacher recording.

The ball shown in the figure only interacted with the Teacher paddle; its dynamic simulation was adjusted so that the impact looked realistic. Participants were not allowed to interact with the simulated ball during training, since our simulation of the ball dynamics was not completely accurate. One might wonder then, why include the ball in the first place if it does not seem to provide any additional information? It turned out, however, that including the ball was crucial—without it learning in the simulator did not transfer to the real task (see later discussion).

During the development and fine-tuning of the system we experienced two main problems. Participants occasionally confused the Teacher and User objects. This resulted in an intriguing but very undesirable phenomenon: when the User was falling behind the Teacher and instead thought he was ahead, the User movement slowed down further, causing an even bigger error. To avoid such confusion the two paddles were made as distinct as possible; the transparent Teacher paddle shown in Fig. 49.3 solved the problem.

The other problem was synchronizing the two animations. We attempted to use a version of the movement parser described above, but that did not produce the desired effect. In order to make the parser robust (i.e., avoid signaling movement onset due to sensor noise), reasonably high-velocity thresholds had to be used. As a result the system detected movement onset with

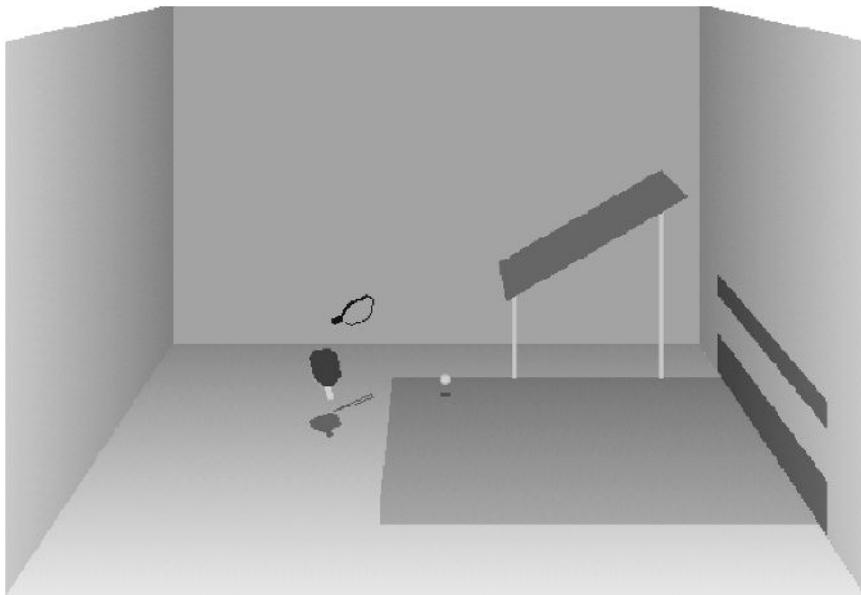

FIG. 49.3. A snapshot of the simulation. The transparent paddle displayed a prerecorded (teacher) animation, which the user attempted to follow in real time with the solid paddle. The simulated ball only interacted with the teacher paddle. The display was refreshed at about 40 Hz. Courtesy of Journal of Motor Behavior.

a delay, so the Teacher animation started after the User movement. Such timing misalignment was very detrimental, the participants spent most of their time trying to compensate for it rather than learning the teacher trajectory. This problem was solved by simply animating the Teacher at fixed intervals and asking participants to synchronize with it.

5.2 Experimental Results

In Experiment 1, volunteer college students were randomly assigned to one of three groups: a pilot group with 13 participants, a control group with 20 participants, and a training group with 19 participants. Each participant was introduced to the apparatus and the task, and given 10 practice balls, the score for which was not recorded. Then a baseline was recorded over 50 trials, which lasted approximately 10 minutes. Participants in all groups were able to see where the ball landed and therefore knew their score, but were not given any other feedback. After the first block the control group was given standard coaching by the experimenter, who was an experienced player. Coaching included discussion of what the participant was doing wrong, demonstration, and extra practice balls.

Participants in the pilot and training groups were trained in the simulator for the same amount of time as the coaching given to the control group. Training started with a slow version of the teacher trajectory, followed by 1 to 2 minutes of passive mode training. After that only the main mode (repeating the desired movement with the teacher) was used. The only difference between the pilot and training groups was that the pilot participants were not shown a ball in the virtual environment, whereas the participants in the training group could see the Teacher paddle hitting a simulated ball.

Results are shown in Fig. 49.4. Analysis of variance showed that all groups started with similar performance on the first 50 trials (no significant differences were found). At the end of the experiment the pilot group did not have better performance compared to the control group;

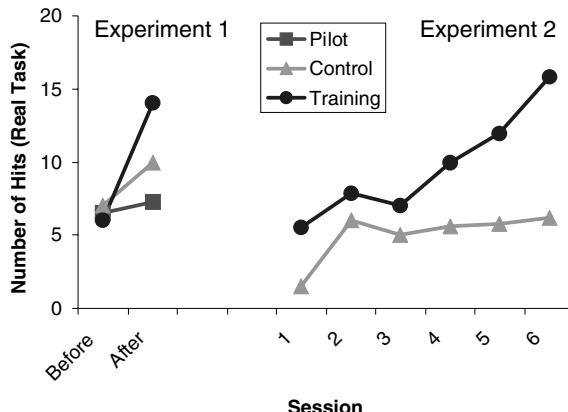

FIG. 49.4. Summary of experimental results, in numbers of successful trials (in Experiment 1 the maximum was 50; in Experiment 2 the maximum was 60).

pilot participants were actually worse, and their improvement was smaller (the differences were close to being significant). The training group, however, had significantly higher scores on the second block of trials ($p = 0.02$) and more improvement ($p = 0.01$) compared to the control group.

In Experiment 2, the task was made more difficult by increasing the speed of the bouncing ball and introducing the obstacle in the middle of the table (Fig. 49.2). This time six sessions (two sessions per day in three consecutive days) were included. In each session, control participants played 30 practice balls, followed by 60 test balls (scores in Fig. 49.4). Training participants used the simulator for the same amount of time that it took the controls to play the 30 practice balls. Then the training participants were also tested on 60 balls in the real task. Again, the results indicated significantly higher ($p = 0.02$) performance in the training compared to the control group on the last session. The improvement of the training group was also significantly higher ($p = 0.05$).

In summary, in two experiments involving more than 70 participants we demonstrated that training in the VE resulted in better performance than a comparable amount of coaching or extra practice on the real task.

It should be stressed, however, that while the observed performance gains are rather encouraging, our analysis revealed a complex relationship between the teacher trajectory and success on the task. On one hand, the increased performance of the training group suggests that learning a teacher trajectory is useful. On the other hand, if accurate reproduction of the teacher trajectory was related to task performance, one would expect to see within the training group a correlation between each participant's performance level and how well that participant followed the teacher trajectory. No such correlation was found. The trajectories used on the real task deviated significantly from the teacher trajectory, and for most participants these deviations increased over the three days (Fig. 49.5) while performance was improving. Brisson and Alain (1996) found a related result in a simpler interception task. These authors showed that training to reproduce a teacher trajectory improved performance, but the details of the teacher trajectory did not make a difference. In other words, imitating a teacher trajectory in the context of the task helps, but not because the exact trajectory being imitated was learned. The exact reason for this improvement remains unclear.

Furthermore, only when the teacher trajectory was coupled with a simulation of a ball did the training participants improve in the real task. This unexpected result suggests that seemingly minor changes in the simulator can dramatically reduce its efficacy, whereas details of the teacher trajectory remain identical. One possible explanation for this effect is that the ball

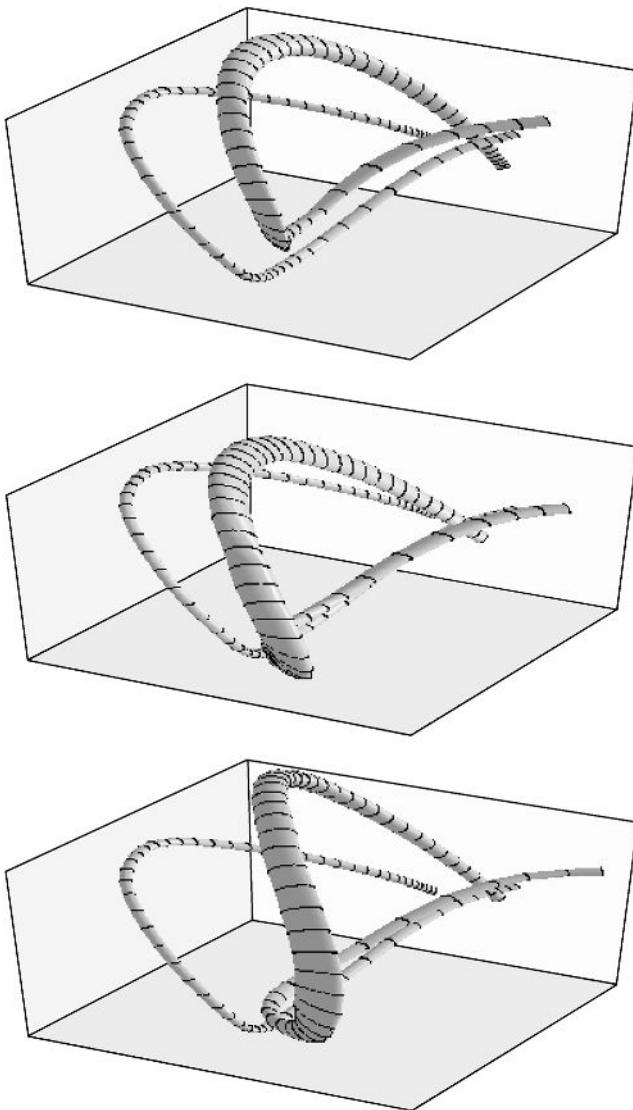

FIG. 49.5. Trajectories of one training subject on the real task, days 1 to 3 from top to bottom. The thin curve is the teacher trajectory. The thick curve is the average subject's trajectory on that day, where the width corresponds to one standard error of the mean. Black rings mark equally spaced points in time; that is, wider ring spacing corresponds to higher velocity. Note that the deviation between teacher and subject movements (on the real task) actually increases with practice, except for the region of impact with the ball (lower part). Courtesy of Journal of Motor Behavior.

simplified the synchronization task, because its flight could have been used to predict when the Teacher paddle started moving.

5.3 Ongoing and Future Work

So far we have focused on training end-effector trajectories, that is, only the paddle was displayed rather than the movement of the entire arm or body. While this is a good place to start, it certainly does not exhaust the possibilities. As Fig. 49.1 suggests, this form of

training can be used for more complex trajectories involving multiple body parts. For example, consider the game of golf. In this case there is a well-defined end effector (the golf club); however, training the movement of the golf club alone is probably insufficient. Instead, golf coaches insist that movement of the entire body is important. Another good example of a task where whole body movement matters is dance; in this case there is no end effector to begin with.

If our training method is to be extended to movements of complex objects with multiple joints, the problem of confusing the Teacher and User objects becomes much more severe. Preliminary attempts to resolve this issue in the system shown in Fig. 49.1 indicate that more advanced visualization techniques are needed before the motion of the entire hand can be tracked successfully. Once User and Teacher hands are overlaid, there are so many small discrepancies that it is difficult to focus on any one of them and correct for it. One method we are considering is an automated procedure that selects body parts with the largest errors, and highlights them by making all other parts semitransparent, for example.

In the case of hand posture, we recently studied a matching task (Todorov & Ghahramani, 2000) where participants were shown computer generated images of random hand postures and asked to reproduce them as accurately as possible. Hand joint angles were recorded using a Cyberglove. The surprising finding was that subjects were very inaccurate in matching individual joint angles; the average correlation coefficients (R^2) of desired and actual values ranged between 0.05 and 0.2. It turned out, however, that certain changes in overall hand shape (i.e., linear combinations of joints identified through Canonical Correlation Analysis) were matched better than any single joint; the first five such combinations had correlation coefficients of about 0.8! This result suggests that in the case of multiarticulate bodies, the human visual system may extract overall shape rather than individual joint angles. Information about such visually salient shape changes can be useful in the future for designing better feedback systems.

6. EXPERIMENT 2: REHABILITATION IN PATIENTS WITH STROKE

6.1 System Design

The second system was designed for the purpose of arm rehabilitation. The training method was very similar to the Ping-Pong study, however the rationale behind it was somewhat different. Consider a stroke patient who is currently incapable of lifting the impaired arm above shoulder level. What “desired movement” should be chosen for such a patient? There is an infinite variety of tasks (involving objects above shoulder level), which the patient is incapable of executing. This is where the skill of an experienced therapist is required. Based on therapy evaluation, the therapist will determine the family of movements that are likely to be useful for a particular patient and the family of tasks where such movements could arise naturally. In other words, we are now starting with a desired movement and constructing a task around it. This is the opposite to training a specific motor skill, where the task is primary and the desired movement is the one used by experts on that task.

Fig. 49.6 illustrates the main features of the system. The trace corresponds to a desired movement, which the User (cube located near the “hand”) is attempting to follow. The simplest way to create a task compatible with a given movement is to insert objects along the movement trajectory; in this case the donut was placed around the desired path, a second cube marked the beginning and end of the movement, and the task was defined as starting from the second cube and passing through the donut.

One major technical problem experienced with the rehabilitation system was alignment of the patient with the virtual environment. A scene contains a number of virtual objects and

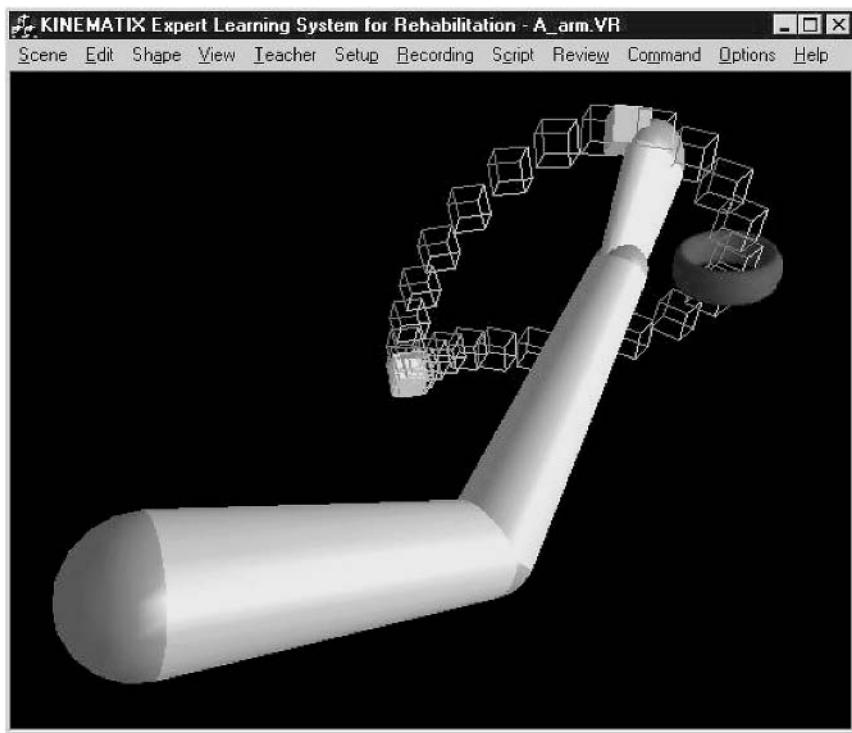

FIG. 49.6. An example of a virtual scene in the rehabilitation system (not used for training). The arm of the patient was tracked in real time, joint angles were estimated, and the virtual arm was rendered at about 40 Hz. The trace shows the teacher trajectory, for a task defined as starting from the solid cube (near elbow) and passing through the donut.

a teacher recording whose positions and orientations are determined in a coordinate system centered at the transmitter of the FASTRAK (and oriented along its axes). The sensor readings are also defined in that coordinate system. Thus, if a virtual object corresponding to some sensor location is inserted, the scene saved, and the sensor positioned at the same location in physical space on the next day, it will appear on top of the virtual object, assuming the transmitter did not move. Similarly, if the scene is adjusted so that the starting position and target correspond to the desired arm configurations of the patient, that correspondence will hold as long as the body of the patient is in exactly the same position and orientation relative to the transmitter.

In general, such alignment was not always easy to achieve. Although we attempted to position the patient in the same place relative to the computer in each training session, small differences inevitably occurred. Even small differences in patient position affected the alignment of the patient and teacher trajectories. While normal subjects could easily move to realign themselves, patients were slower and had much more difficulty with this task. Therefore, these alignment problems were resolved in software.

6.1.1 Scene Alignment

One of the objects in the virtual scene (corresponding to the desired starting position and orientation of the movement) was defined as the “starting position object.” To align the scene, the physical sensor was placed at the new starting position (and orientation). The system applied a rigid body transformation to the entire scene (i.e., a translation and a rotation) such

that the old starting position object moved to the current sensor location. All other objects (and the teacher) moved accordingly so that relative distances and orientations in the scene were preserved. Note that such a transformation is uniquely defined.

The problem with this procedure was that typically the whole scene tilted. In such cases, a different alignment command was used that aligns only the positions of the physical sensor and the starting position object, but leaves the orientation of the scene intact.

6.1.2 Teacher Alignment

Sometimes the scene was aligned properly, but the patient was incapable of assuming the starting arm configuration of the teacher because of weakness, decreased range of joint motion, or muscle contractures. In such cases the system adapted the teacher movement so that it started at a new starting position (one achievable by the patient) but ended in the old ending position, or passed through a previously specified target.

The algorithm used to solve this problem defined a transformation (which included both translation and rotation) that sent the beginning teacher frame into the new starting position. Also, the transformation could be scaled to allow us to apply the complete transformation, half of it, and so forth (for translations, scaling was straightforward; for rotations the quaternion representation was computed and the rotation angle was scaled; the rotation axis was unchanged). For each frame of the teacher animation, we determined how much of the transformation should be applied. For the beginning frame, the number was 1 (i.e., the beginning frame is transformed completely to match the new starting position). For the target frame the number was 0 (i.e., it was left unchanged). For intermediate frames we interpolated between 0 and 1. To preserve the shape of the speed profile of the teacher movement, the interpolation was based on distance from the target rather than time. Figure 49.7 illustrates the procedure. The transformed teacher movements produced by this algorithm were surprisingly similar to the original.

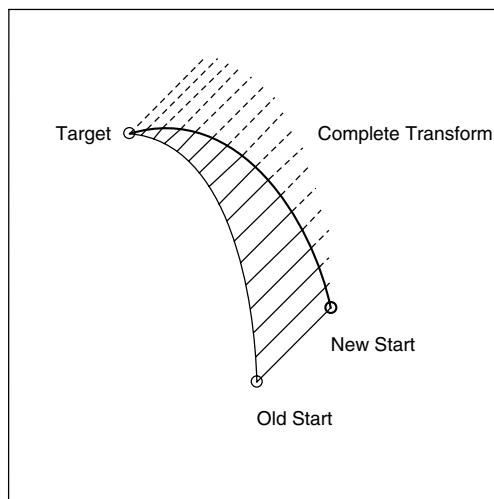

FIG. 49.7. Illustration of the teacher alignment algorithm. The straight lines correspond to applying a transformation that takes the old starting position to the new starting position. To each frame of the teacher animation, the same transformation is applied, scaled by the normalized distance (1–0) away from the starting position. This procedure results in a new teacher movement that looks very similar to the original but starts at the new desired position.

6.2 Experimental Results

In a pilot study (Holden et al., 1999), two patients were treated with hemiplegia using a computer-generated VE to train upper extremity reach in the impaired limb. The goal of the experiment was to answer three questions:

1. Can hemiplegic subjects improve in a virtual task following virtual practice?
2. Does learning which occurs in a VE transfer to a similar real task?
3. Does learning in a VE transfer to related but untrained real tasks, or to functional activities not specifically trained?

Subject 1 (S1) was a 76-year-old male, 3.5 years post left (L) cerebrovascular accident (CVA) due to thrombotic occlusion of the left internal carotid artery (ICA), confirmed by magnetic resonance imaging (MRI). He had resultant right hemiparesis, significant expressive aphasia, but excellent receptive abilities. This stroke was his first, with no evidence of bilateral or brain-stem stroke. He displayed no evidence of ongoing motor recovery in the right arm.

Subject 2 (S2) was a 76-year-old female, 1.5 years post right CVA due to thrombotic occlusion of the right internal carotid artery, confirmed by computerized tomography (CT) scan. She had resultant left hemiparesis. This stroke was her first, with no evidence of bilateral or brain-stem stroke. She displayed no evidence of ongoing motor recovery in her left arm.

We selected only one movement for training in the virtual environment, with the criterion that it be a functional, goal-oriented movement that highlighted typical motor control problems seen in patients with stroke. To train this movement a reaching task was devised, in which the subject held a styrofoam "envelope" (using a lateral grasp), then extended the arm to place the "envelope" in a "mailbox" slot.

Next, we created a series of scenes in the virtual environment. The scenes had a one-to-one spatial correspondence with the real world and were displayed on a desktop computer. They were simple, containing only a virtual mailbox and two virtual envelopes. One envelope was a "teacher" who performed the correct movement over and over again (see Fig. 49.8). The teacher animation was a recording of a well-practiced normal subject performing the virtual task. The second envelope was a virtual representation of the real envelope that the patient held and moved during practice. Thus, the patient could match the endpoint trajectory of his or her movement with that of the teacher during training, in real time. (Movements of the patient were monitored using a Polhemus FASTRAK, then displayed on the computer in the context of the virtual scene.) The scenes progressed from easy to more difficult in order to train the movement in a sequential fashion. The sequence used was near and far reach, first with forearm pronation, then forearm neutral, and lastly with supination. This resulted in three different hand orientations: palm down; palm facing right (when left arm was trained) or left (when right arm was trained); and palm up. The endpoint of the near reach for each different hand orientation was set at the distance midpoint of the normal trajectory for the far reach for that hand orientation.

The "teacher" movement could be altered in a number of ways designed to facilitate learning. The animation could be adjusted in speed to any level slower or faster than original; it could be paused at any point, displayed as a trace (solid line vs. moving object), or hidden from view entirely. The teacher could also be made to "follow" the trajectory of the subject, that is, temporal information could be eliminated, and the learner could focus exclusively on learning the spatial elements of the movement. Additional features (audio and visual) were designed to assist the patient with error detection, timing, and positioning. A model of the entire arm, as well as the held object, could also be displayed on the screen in real time, if desired. This was used intermittently in training to correct the patient's tendency to try to achieve the task with compensatory movement patterns such as excessive shoulder abduction with elbow flexion, which were ineffective.

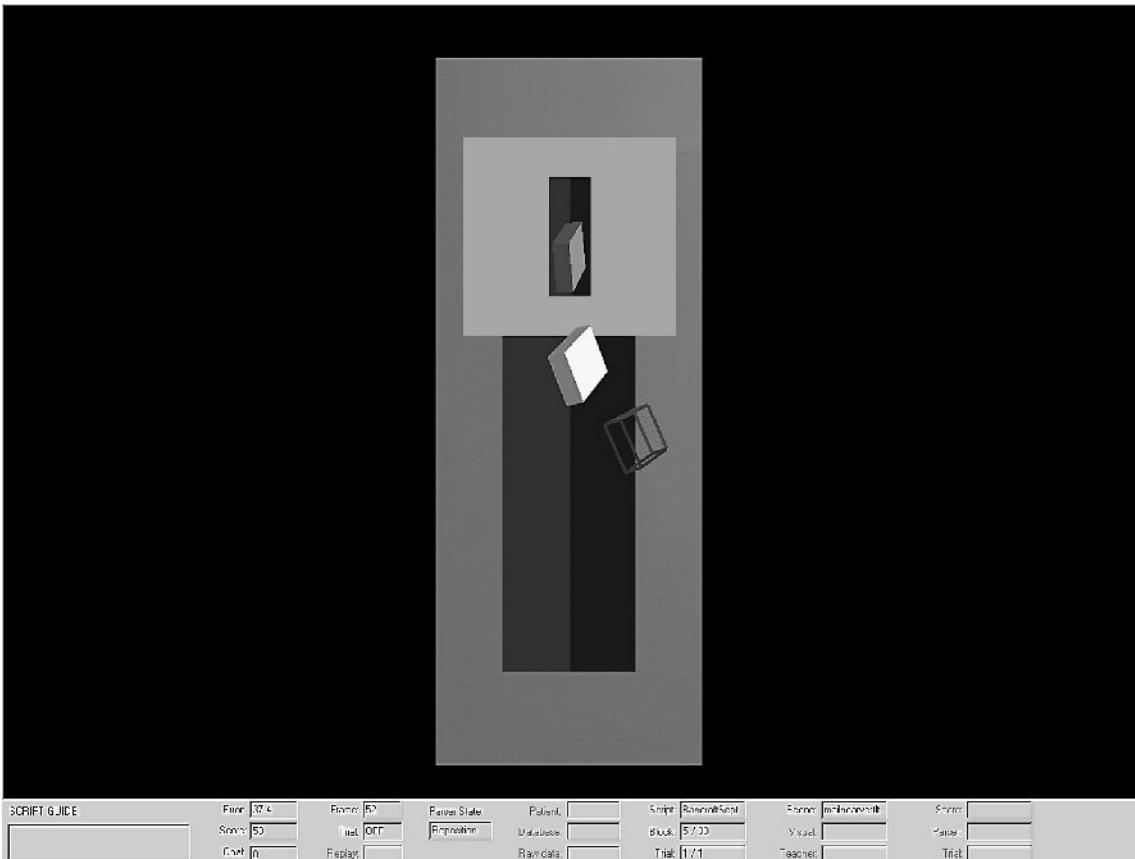

FIG. 49.8. Example of a “mailbox” scene used for VE training. The “teacher” envelope is shown entering the target slot. (In VE, the entire trajectory is animated, and objects appear in color against a black background.) Below the teacher, the white “patient” envelope is shown; this envelope moves when the patient moves his or her hand. Below the patient envelope, a wire-frame rectangle identifies the start position, used to align the teacher and patient trajectories at movement onset. Courtesy of Neurology Report.

Each subject received a series of 16 treatment sessions of 1 to 2 hours duration, conducted by a physical therapist. The planned treatment frequency was two times per week, although subjects actually came less frequently than this due to problems with transportation and minor illnesses. Virtual performance improved over the 16 sessions, as measured by assessing how many scenes a subject could progress through in a session. (Once subjects could perform the movement in a scene correctly for three consecutive trials, they progressed to the next scene.) Real-world performance in the “mailbox” task showed improved reaching in both the trained and untrained parts of the workspace for both subjects. The distance and orientation error for the “envelope” relative to the slot was calculated (see Fig. 49.9 for real-world test setup.)

S1 showed an average pre-/post-decrease in reach excursion error of 18 cm (i.e., 64% reduction in error); S2 showed a decrease of 9 cm, representing a 50% reduction in error (Fig 49. 10). The 9 and 18 cm gains represented roughly a 25% improvement in reach excursion. In both subjects, some of the largest improvements occurred in untrained parts of the workspace. S1 showed better transfer to upper regions of the workspace; S2 showed better transfer to lower regions (Figs. 11 and 12). Similar, but smaller magnitude results were found for hand orientation errors.

Several findings in this study have important clinical implications. The most important finding was that subjects not only improved on the virtual task, but also showed transfer of that improvement to similar real-world tasks—both trained and untrained.

6.3 Ongoing and Future Work

The VE training system we have developed is currently being utilized in Italy in a clinical study of stroke patients who have upper extremity impairments (Piron et al., 1999; Piron et al., 2000). This study is an ongoing randomized, controlled clinical trial designed to evaluate the effectiveness of VE training as a complementary therapy for motor rehabilitation following stroke. Experimental group subjects receive 1 hour of VE therapy plus 1 hour of conventional physical therapy, daily for 4 weeks (20 two-hour treatments total); control group subjects are treated for 2 hours of conventional therapy daily for 4 weeks (20 two-hour treatments total). Both acute (less than 6 months following stroke) and chronic (6–72 months following stroke) duration patients are being studied. Therapy in both virtual and conventional sessions is focused on the arm. All patients are evaluated before and after training, using the Fugl-Meyer scale for motor recovery (Fugl-Meyer, Jaasko, Leyman, Olsson, & Steglind, 1975) and the Functional Independence Measure (Hamilton, Granger, Sherwin, Zielezny, & Tashman, 1987), a scale that measures the amount of assistance needed to perform activities of daily living (such as eating and dressing). Forty-three subjects (28 experimental and 15 control) have been tested to date. Preliminary analysis suggests that the subjects who received combined virtual and conventional therapy improved more than subjects who received conventional therapy alone, on both the test of motor recovery (Fugl-Meyer arm subscore) and the functional scale. However, the study is still ongoing, and detailed statistical testing has not been performed. The response to the VE training on the part of both therapists and patients who have used the system has been quite positive. No negative side effects have been reported, and both patients and therapist feel it provides enhanced motivation for the rehabilitation program.

We have recently begun a second study utilizing the VE system to study aspects of motor learning and motor generalization in patients with stroke. In addition to knowledge about generalization, we hope to gain further practical experience with the newly developed features of our system (scoring, movement parser, and semiautomated functions.)

An extension of this work, currently being developed, is a networked virtual environment that will allow the therapist to work with patients remotely. The current software is being modified so that new virtual scenes can be loaded remotely, alignment commands can be

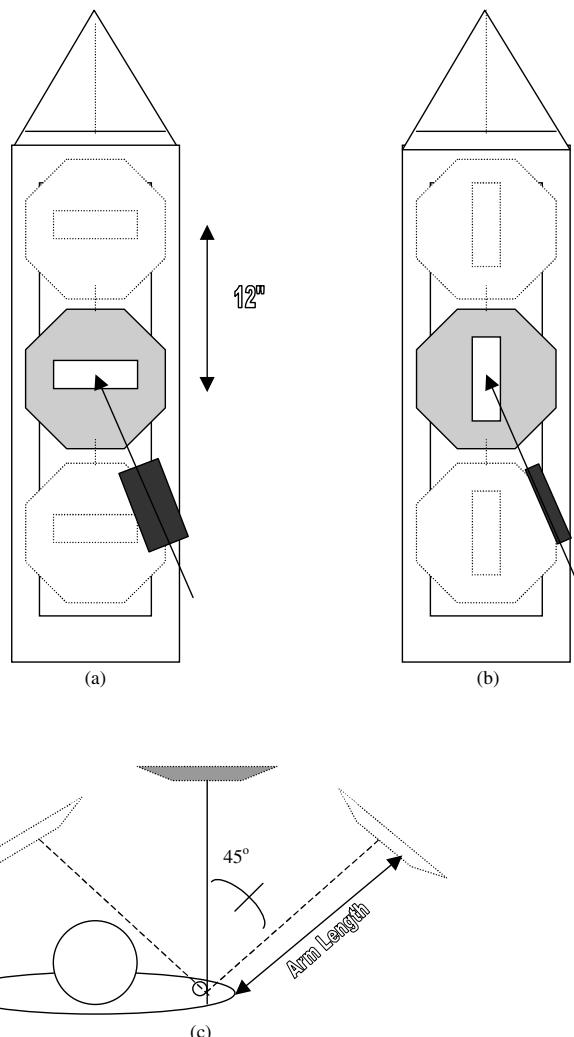

FIG. 49.9. Schematic of real-world reaching setup used to test subjects before and after training in a similar virtual task: (a) a 3-D “mailbox” with movable target slot ($1'' \times 5''$) horizontal orientation was used for supinated and pronated reach attempts. The “envelope” ($4'' \times 8' \times 1/4''$) is shown moving toward the target. The center target was positioned at a location corresponding to the hand position when the upper extremity was in 90-degree shoulder flexion/neutral abduction, and elbow fully extended (i.e., the distance equal to arm length and height equal to the height of the acromion in sitting position). For testing upper and lower workspace reaching, the slot was positioned 12 inches above and below the center position. Target positions later trained in VE are shown in gray; untrained locations are shown in white, (b) vertical slot orientation was used for reaching with forearm in neutral position; (c) testing in transverse plane (view from above); slot was positioned 45 degrees medial (adducted reach) and lateral (abducted reach) to the center position (shoulder-centered frame of reference). Only the center forward position (gray) was trained in VE. Courtesy of Neurology Report.

applied, and key feedback features can be turned on and off. We are also incorporating an Internet videophone to provide an audio-visual link between patient and therapist.

A third ongoing project is a study that uses the VE system to train subjects with acquired brain injury (ABI) to learn a task-oriented movement with the upper extremity (Holden, Dettwiler, Dyar, Niemann & Bizzi, 2001). The task we are presently working with is pouring from a cup

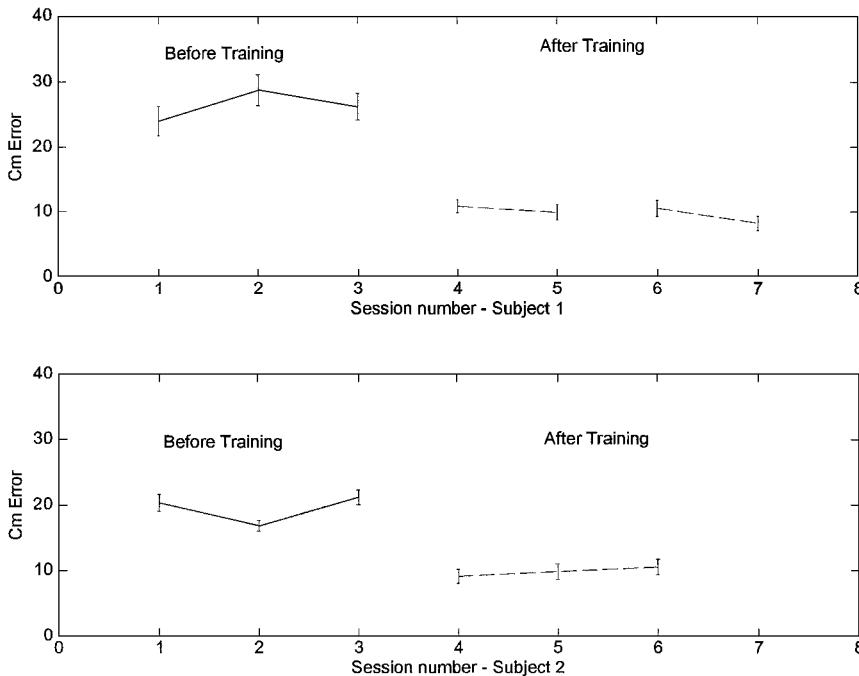

FIG. 49.10. Performance on real-world reaching task pre- and post-virtual training. *Top panel:* The mean error scores \pm one standard deviation for distance (cm) from target (averaged across all nine target positions) plotted by session number for subject 1, involved arm. Sessions 1 to 3 (solid line) equal to pretraining scores; sessions 4 and 5 (dotted line) equal to scores after eight training sessions; session 6 and 7 (dotted line) equal to scores after 16 training sessions. The magnitude of the pre- and postdifferences would be considered statistically significant, based on nonoverlap of the standard deviation values. Values for the noninvolved arm are not shown, but were ~ 1 cm with little variability for all sessions, with the exception of session 1, when error value was ~ 5 cm with ± 2 cm standard deviation. *Bottom panel:* Mean error scores for distance (cm) from target (averaged across all nine target positions) plotted by session number for subject 2, involved arm. Sessions 1 to 3 (solid line) equal to pretraining scores; sessions 4 to 6 (dotted line) equal to scores after 16 training sessions. Values for noninvolved arm are not shown, but were ~ 1 cm with little variability for all sessions. (The values for the noninvolved arm do not represent true "errors," i.e., subjects could readily perform the task; rather, they result from the sensor position on the envelope.) Courtesy of Neurology Report.

held in the impaired hand, at different locations in the workspace. During training, subjects hold a real cup in their hand while practicing the pouring movement and viewing their virtual performance (and that of the teacher) on the computer screen. One purpose of this study is to gain more knowledge about how different clinical symptoms and impairments affect the ability of subjects with ABI to benefit from training with the system, and to identify equipment and software adaptations that might enhance the ability of subjects with acquired brain injuries to improve from motor training in virtual environments.

In the future, we would like to make the VE used in our system more interactive and also incorporate a haptic interface (see chaps. 5 and 6, this volume). This would allow training of a greater variety of movements in more interesting ways. Currently static objects define the task, and the only moving parts are the teacher and patient animations. One can imagine instead a gamelike scenario, where the objects respond to patient movements in various ways. For many patients, the response would need to be very simple, but for others we could adapt state-of-the-art computer games with advanced graphics, sound effects, realistic physics engines, and

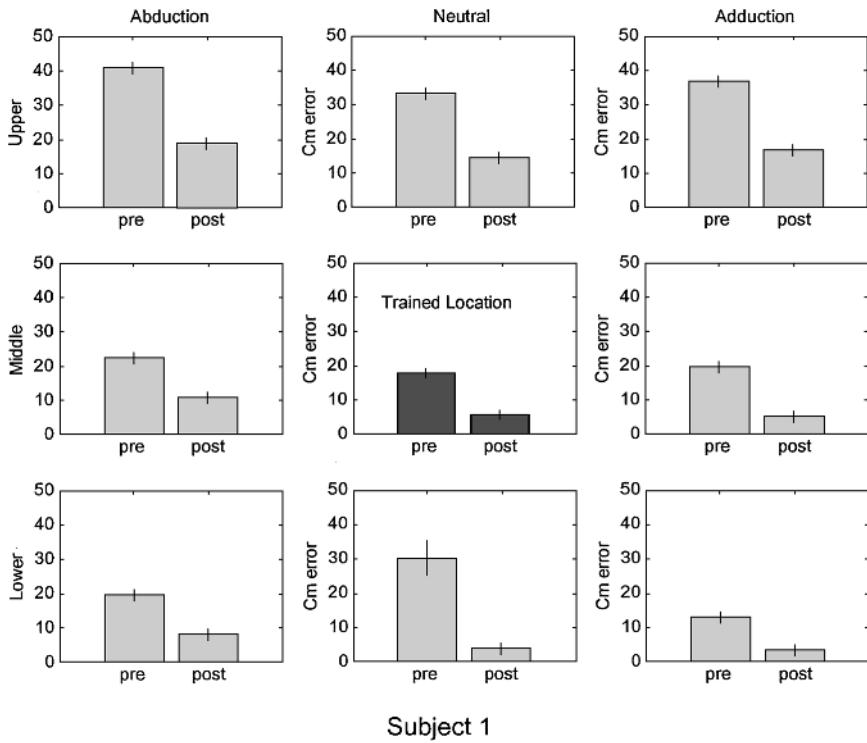

FIG. 49.11. Distance errors (cm) \pm one standard deviation for real-world reaching task, plotted by target location in the workspace, for subject 1, involved arm. Values are means across three sessions pre- and four sessions posttraining on a similar virtual task. Error scores for the trained movement are in the center of the middle row. Note that all locations show a reduction in error despite no specific training in those locations. Note better transfer to upper parts of the workspace for this subject. Values for noninvolved arm (not shown) were close to 1 cm and were nearly identical pre- and posttraining with the exception of upper adduction, which had a 10 cm mean error pretraining, 1 cm post. (The 1 cm error score for noninvolved arm was a function of the sensor position on the "mail" piece, and not due to inability of the subject to perform the task.) Courtesy of Neurology Report.

entertaining story lines to appropriate therapeutic levels. The problem is that current computer games are designed with traditional input devices in mind, such as a keyboard, joystick, or mouse. For the purpose of motor rehabilitation, games are needed that accept input from 3-D motion capture hardware and use it in some meaningful way. If such games become available in the future they could be used not only for entertainment, but also as therapeutic tools.

7. SUMMARY

In this chapter, first literature relevant to spatial-motor learning in VE in normal subjects was reviewed, as well as the literature on clinical applications of VE in rehabilitation. Next, a system that we developed to enhance motor learning in healthy and disabled individuals was described. The system is based on learning by imitation and uses a VE to implement training routines. The chapter concluded with a description of our experimental results to date and a discussion of design issues that arose during use of the system, along with a brief description of ongoing work and future research directions.

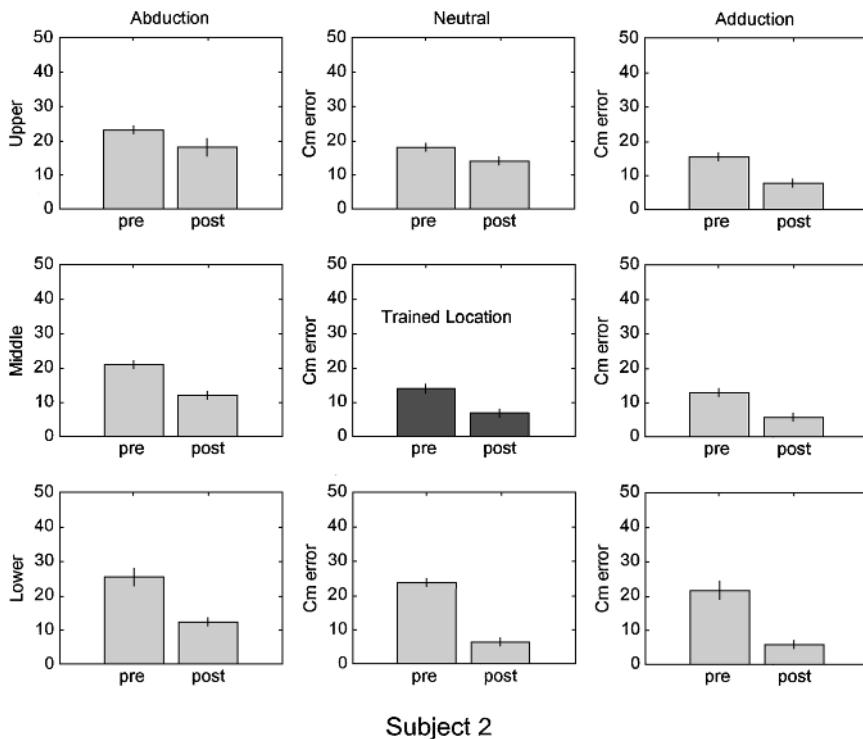

FIG. 49.12. Distance errors (cm), \pm one standard deviation, for real-world reaching task, plotted by target location in the workspace, for subject 2, involved arm. Values are means across three sessions pre- and posttraining on a similar virtual task. The trained movement is in the center of the middle row. Note that most locations show a reduction in error despite no specific training in those locations. Note better transfer to lower parts of the workspace for this subject. Noninvolved arm values are not shown, but were ~ 1 cm for all locations and essentially identical for pre- and posttests. Courtesy of Neurology Report.

1. INTRODUCTION

Virtual environments (VEs) have undergone a transition in the past few years that has taken from the realm of expensive toy into that of functional technology. This emerging computer-driven simulation technology appears to be well matched to the assessment and rehabilitation needs of persons with cognitive impairments and functional disabilities due to various forms of central nervous system (CNS) dysfunction. The capacity of VE technology to create dynamic three-dimensional (3-D) stimulus environments, within which all behavioral responding can be recorded and measured, offers clinical assessment and rehabilitation options that are not available using traditional neuropsychological methods. This work has the potential to advance the scientific study of normal cognitive and behavioral processes and to improve our capacity to understand, measure, and treat the impairments typically found in clinical populations with CNS dysfunction. Clinical populations that could benefit from VE approaches include persons with cognitive and functional impairments due to traumatic brain injury (TBI), neurological disorders, learning/developmental disabilities, as well as the elderly. This chapter begins with a brief description of the relevant clinical populations and an introduction to neuropsychological assessment (NA) and cognitive rehabilitation, (CR), with rationales presented for the use of VE for these purposes. The literature on research done thus far in these areas is then reviewed. The final section of this chapter details the basic clinical, human factors, and theoretical issues for the rational and effective targeting, development, and implementation of these applications.

2. BACKGROUND

Virtual environment technology is increasingly being recognized as a useful tool for the study, assessment, and rehabilitation of cognitive processes and functional abilities. Much like an aircraft simulator serves to test and train piloting ability, virtual environments can be developed to present simulations that target human cognition and behavior in normal and impaired populations. In this regard, a growing number of laboratories are developing research programs investigating the use of VEs for these purposes, and initial exploratory studies reporting encouraging results are now beginning to emerge. Virtual environment applications are now being developed and tested that focus on component cognitive processes including: attention, executive functions, memory, and spatial abilities. Functional VE training scenarios have also been designed to test and teach instrumental activities of daily living such as street crossing, automobile driving, meal preparation, supermarket shopping, use of public transportation, and wheelchair navigation. These initiatives have formed a foundation of work that provides support for the feasibility and potential value of further development of neuropsychological VE applications. If the associated technology continues to advance in the areas of computing power, graphics and image capture, display technology (see chap. 3, this volume), immersive audio (see chap. 4, this volume), haptics (see chaps. 5 and 6, this volume), wireless tracking (see chaps. 8 and 9, this volume), gesture recognition (see chap. 10, this volume), voice recognition, intelligent agents (see chap. 15, this volume), and VE authoring software (see chap. 12, this volume), then more powerful and naturalistic VE scenarios will be possible. These advances could result in more readily available desktop-powered VE systems (see chap. 13, this volume) with greater sophistication and responsiveness. Such increases in access would allow for more widespread application of VE technology for clinical purposes and promote the independent replication of research findings needed for scientific progress in this field.

Indeed, mainstream researchers and clinicians in neuropsychology are “wanting” for these advances in VE technology—whether they realize it or not. For example, in a recent National Institutes of Health (NIH) Consensus paper entitled “Rehabilitation of Persons with Traumatic Brain Injury (TBI),” two recommendations were made that suggest research directions that VE technology appears well poised to address. The report recommended that “Innovative study methodologies that enhance the ability to assess the effectiveness of complex interventions for persons with TBI should be developed and evaluated.” (p. 27) and that “Innovative rehabilitation interventions for TBI should be developed and studied. . .” (p. 26, National Institute of Health [NIH], 1998a). Further, indirect support for VE technology’s potential contribution to neuropsychology can be implied in an *American Psychologist* article by the well-respected intelligence theorist, Sternberg (1997). In this paper, he contends that with the exception of “cosmetic” changes, the field of cognitive ability testing has progressed very little in the last century in contrast to the advancements seen in other technologies over this same period. He posits that “dynamic” interactive testing provides a new option that could supplement traditional “static” tests. The “dynamic” assessment approach requires the provision of guided performance feedback as a component in tests that measure learning. This method appears well suited to the assets available with VE technology. In fact, VEs might be the most efficient vehicle for conducting dynamic testing in an ecologically valid or “real-world” manner while still maintaining an acceptable level of experimental control. A more specific recommendation for future research into the possibilities of VE technology appeared earlier in a 1995 NIH report of the National Advisory Mental Health Council (NIH, 1995). In this report, the impact of VE on cognition was specifically cited with the recommendation that “Research is needed to understand both the positive and negative effects of such participation on children’s and adults’ perceptual and cognitive skills . . . (p. 51, NIH, 1995). These observations suggest that

the disciplines of NA and CR are fertile ground for developing the innovative applications that are possible with VE technology.

The current status of VE technology applied to clinical populations, while provocative, is still limited by the small (but growing) number of controlled studies in this area. This is to be expected, considering the technology's relatively recent development, its high initial development costs, and the lack of familiarity with VE technology by established researchers employing the traditional tools and tactics of their fields. In spite of this, a nascent body of work has emerged that can provide knowledge for guiding future research efforts. Although much of the work does not involve the use of fully immersive head-mounted displays (HMDs), studies reporting 3-D projection screen and PC-based flat-screen approaches are providing useful information necessary for the reasoned development and implementation of VE technology with clinical CNS populations. This chapter will provide a rationale for the application of VE technology in the areas of neuropsychological assessment and cognitive rehabilitation, review the VE literature targeting cognitive-functional processes in clinical CNS populations, and discuss the issues that are relevant for the rational development of VEs designed for neuropsychological applications. Although considerable information is available on the use of VEs with unimpaired populations (as evidenced in the numerous chapter in this volume), our focus will be primarily on VE applications targeting clinical groups having CNS-based cognitive-functional impairments.

2.1 Clinical Populations

CNS dysfunction, resulting in cognitive and functional impairments, can occur through a variety of circumstances. The most frequent causes include TBI due to accidents, neurological disorders, developmental and learning disorders, as well as complications from medical conditions and procedures. The resulting impairments commonly involve processes of attention, memory, language, spatial abilities, higher reasoning, and functional abilities. Significant emotional, social, vocational, and self-awareness components that typically co-occur can also further complicate these areas. Because of the pervasive nature of CNS dysfunction, the cost to individuals and society is significant.

TBI is the most common cause of CNS dysfunction and is broadly defined as brain injury resulting from externally inflicted trauma. Such injury is often the result of automobile accidents, falls, sports accidents, and bullet wounds. In the United States, estimates range from 500,000 to two million new cases per year (National Center for Injury Prevention and Control, 1999). The peak age of incidence is in the 15- to 24-year range (closely followed by the birth to 5 years group). In addition to the cost of human suffering, one estimate places the economic costs in terms of medical care, rehabilitation, and lost work potential at \$48.3 billion annually (NIH, 1998b).

Neurological disorders that cause CNS dysfunction include Alzheimer's disease (AD), vascular dementia, Parkinson's disease, Huntington's disease, cerebral palsy, epilepsy, and multiple sclerosis. In addition, other relatively common causes of CNS dysfunction include strokes, drug reactions, thyroid disease, nutritional deficiencies, tumors, alcoholism, and infections. Alzheimer's disease has been estimated to afflict nearly four million Americans, or between 2% to 4% of the population over the age of 65. It is estimated that the prevalence of AD doubles every five years beyond 65 to the point that nearly half of all people 85 and older display symptomatology. Alzheimer's disease is the third most expensive disease in the United States (following heart disease and cancer), with associated costs close to \$100 billion per year. With the increase in life expectancy, it is estimated that the number of Americans aged 85 and over will double by the year 2030 (*NIA Progress Report on Alzheimer's Disease*, 1998), an estimate that has alarming social, economic, and public health implications.

Approximately three million Americans also suffer with some degree of disability from stroke (Gresham, Duncan, Stason et al., 1995). Although a stroke can occur at any age, for every decade after the age of 55 the risk doubles. Of the nearly 500,000 individuals annually who have a first-time stroke, 55% experience varying degrees of disability, including a range of deficits in language, cognition, and motor functions. The total cost of stroke to the United States is estimated to range from \$30 to \$43 billion per year (National Stroke Association, 1997).

Many others, particularly the young, experience cognitive-functional impairments due to various developmental and learning disabilities. Estimates place the number of children receiving special education services at between 2.5 to 4 million (Barkley, Fisher, Edelbrock, Smalish, 1990). Rates of other childhood learning disorders, such as attention deficit hyperactivity disorder (ADHD) and reading disorders, push estimates even higher. Methodological complications preclude precise estimates of the cost of ADHD to society, but according to 1995 statistics, additional national public school costs for these students may have exceeded \$3 billion. Taken together, the above outlined statistics suggest a significant clinical population of persons with CNS dysfunction that may be better served by the types of advanced assessment and rehabilitation tools that are possible via the emerging application of VE technology.

2.2 Brief Introduction to Neuropsychological Assessment

In the broadest sense, neuropsychology is an applied science that evaluates how specific activities in the brain are expressed in observable behaviors (Lezak, 1995). Effective NA is a prerequisite for both the treatment and scientific analysis of any CNS-based cognitive-functional impairment. The NA of persons with CNS disorders serves a number of functions. These include the determination of a diagnosis, provision of normative data on the status of impaired cognitive and functional abilities, production of information for the design of rehabilitative strategies, and measurement of treatment efficacy. Neuropsychological assessment also serves to create data for the scientific understanding of brain functioning through the examination of measurable sequelae that occur following brain damage or dysfunction. Our understanding of brain morphology and activity has undergone a revolution in the past three decades that is akin to the revolution seen in microtechnology. However, the increase in our knowledge of the genetics, chemistry, molecular biology, and "physics" of the brain is mitigated by our understanding of the behavior that is related to specific brain activity. The fact that postmortem studies of AD have identified the entorhinal cortex as the area where the pathological changes of AD are first noted (Braak, Braak, & Bohl, 1993) is of little clinical value unless the cognitive and behavioral processes that are serviced by this region can be identified. Once such processes are identified, it becomes possible to diagnose more effectively and intervene at an earlier stage of this neurodegenerative process. Virtual environment technology offers the potential to develop human performance testing environments that could supplement traditional NA procedures and conceivably produce new methodologies that support earlier diagnosis by improving on standards for psychometric reliability and validity.

The assessment of cognitive abilities has a long and, at times, explosive history. In 1921, at a contentious symposium on what comprises intelligence, the historian and experimental psychologist Edwin Boring asserted that "intelligence is what the tests test" (Boring, 1923, p. 35). This notion of making a test and then accepting the results as indicative of an aspect of brain performance may be the classic case of putting the cart before the horse, but to some extent it is a pragmatic reality of our ability, or inability, to measure behaviors. Neuropsychology has proceeded by reducing complex behaviors to component cognitive domains. Domains of cognitive functioning identified by neuropsychologists are numerous and many subcomponents have been identified and studied. Some examples of more global cognitive processes

include attention, executive functions, memory, language processing, spatial abilities, problem solving, and higher level abstract reasoning. Neuropsychological assessment also attempts to define and measure functional processes, which are assumed to be comprised of the integration of component cognitive processes that are manifested in everyday human behavior. Functional processes might include such instrumental activities of daily living (IADLs) as meal preparation, using transportation, shopping, housework, vocational activities, and handling finances. These cognitive–functional processes are commonly assessed using such NA methods as psychometric testing, behavioral observation, and an examination of past historical information.

The measurement of cognitive–functional processes is based on two criteria: reliability and validity (see chap. 35, this volume). Reliability is the capacity of an instrument to consistently obtain the same results. Validity is concerned with how well an instrument actually measures what it purports to measure. Traditional assessment methodology, primarily based on the use of pencil and paper tests, presents the neuropsychologist with both reliability and validity problems. The reliability of these instruments is adversely affected by the variability of administration procedures due to differences in examiners, testing environment (i.e., lighting, room size, background noise), quality of the stimuli presented to the subject, and by inevitable scoring errors. The validity of traditional methods is attenuated by the fact that some tests require multiple cognitive domains for successful completion, and thus it remains unclear what specific cognitive domain is being evaluated. It is likely that both reliability and validity can be improved on with the use of VE technology. Reliability can be enhanced by better control of the perceptual environment, more consistent stimulus presentation, and by more precise and accurate scoring. Virtual environments may also improve on the validity of measurement via the quantification of more discrete behavioral responses, allowing for the identification of more specific cognitive domains.

Traditional NA testing has also been criticized as limited in the area of ecological validity, which is concerned with the degree of relevance or similarity that a test has relative to the “real” world (Neisser, 1978). While existing neuropsychological tests obviously measure some behavior mediated by the brain, it is difficult to say with any certainty how performance on a contrived assessment task relates to complex performance in an “everyday” functional environment. Cognitive–functional performances could be tested in simulated “real-world” VE scenarios, thereby improving on the ecological validity of measurement. In this way, the complexity of stimuli found in naturalistic settings could be presented while still maintaining the experimental control required for rigorous scientific analysis. Thus, results would have greater clinical relevance and could have direct implications for the development of functional cognitive rehabilitation approaches. However, it is also important to recognize that in all cases it may not be desirable for VEs to fully “mimic” reality. Another strength of VEs for assessment purposes may include the capacity to present scenarios that include features not available in the “real world.” This would be the case when “cueing” stimuli are presented to examine at what level “augmentive” information can be used by patients to assist in compensatory strategies aimed at improving day-to-day functional behavior.

It is possible that the use of VE technology could revolutionize our approach to neuropsychological assessment. While formidable problems remain, the potential is impressive. The possibility of linking VE assessment with advanced brain imaging and psychophysiological techniques (Aguirre & D’Esposito, 1997; Decety et al., 1994; Pugnetti, Mendozzi, Barbieri, Rose, & Attree, 1996) may allow neuropsychology to reach its stated purpose, that of determining unequivocal brain-behavior relationships. While pragmatic concerns need to be addressed in order for this technology to come close to meeting this lofty goal, the benefits that could be accrued appear to justify the effort.

2.3 Brief Introduction to Cognitive Rehabilitation

Many definitions of what CR involves have been put forth, with Parente and Herrmann (1996) describing it in general terms as “the art and science of restoring . . . mental processes after injury to the brain” (p. 1). Sohlberg and Mateer (1989) define CR as “the therapeutic process of increasing or improving an individual’s capacity to process and use incoming information so as to allow increased functioning in everyday life” (p. 3). As with NA, both component cognitive processes and functional activities of daily living are typically targeted with cognitive rehabilitation. Cognitive processes are often further broken down into subcomponents and addressed. For example, attention can be partitioned into focused, sustained, selective, alternating, and divided components that are targeted with different tactics (Sohlberg & Mateer, 1989). Likewise, memory is often broken down into traditional cognitive psychology categories such as iconic, working, procedural, declarative, prospective, and episodic memory domains. IADLs are also targeted with functional CR strategies. Between the complexity of the subject matter and the nascent status of work in this area, considerable controversy exists as to the relative effectiveness of various CR approaches (Wilson, 1997). Rather than debating the merits of any specific CR approach, this discussion will focus primarily on how VE technology may be a useful tool for administering a wide range of CR strategies.

Cognitive rehabilitation approaches can differ based on a variety of conceptual criteria (Kirsch, Levine, Lajiness-O’Neill, & Schnyder, 1992). For the purposes of describing the application of VE technology to CR, these conceptual dimensions can be “collapsed” into two general domains, restorative approaches that focus on the systematic retraining of component cognitive processes (i.e., attention, memory, etc.) and functional approaches that emphasize the stepwise training of observable behaviors, skills, and IADLs. These domains can be viewed as opposite ends of a continuum of methods, with many specific CR approaches falling somewhere between these poles. The restorative and functional approaches to CR have different methods and goals. The primary objective of the restorative approach is to retrain individuals how to *think*, whereas the emphasis of the functional approach is to teach individuals how to *do*. For example, the treatment direction for a 20-year-old with mild head injury may primarily have a restorative focus and target component thinking processes with a goal of improving cognitive flexibility. By contrast, an elderly patient with dementia may be better suited to a functional approach targeting compensatory, environment-centered goals needed to maintain independent living. An example of the differential emphasis contained within these approaches can be seen in the area of memory rehabilitation. The restorative approach emphasizes a “drill and practice” method in which the person is challenged to attend to, remember, and/or manipulate increasingly more difficult pieces of information contingent on success (Lynch, 1992) and hence, cognitive ability is expected to improve, much like a muscle gets stronger with increased exercise. Stimuli that are easily quantifiable and can be gradually increased in difficulty level are often used with this approach (i.e., lists of letters, numbers, words, sentences, directions, geometric designs, etc.). Functional approaches generally focus on training IADLs, such as practicing a sequence of events to prepare for work in the morning or a set of structured steps for completing day-to-day functional activities. These strategies attempt to rehabilitate the person by training the actual IADL skills using well-practiced routines within the target environment, sometimes incorporating compensatory mental “prosthetic” devices, such as alarms and reminder notes, located in strategic positions around the environment.

Specific weaknesses have been identified in both of these approaches. One often cited criticism of restorative methods is the reliance on test materials or tasks that are essentially artificial and have little relevance to real-world functional cognitive challenges. This criticism holds that “memorizing” increasingly difficult lists of words or activities within a therapy or school environment does not support the transfer or generalization of memory ability to

the person's real-world situation (Chase & Ericsson, 1981; O'Connor & Cermack, 1987). The fundamental criticism of functional methods is that the learning of standard stereotyped behaviors to accomplish IADLs assumes that the person lives in a static world where life demands do not change and that the person's underlying cognitive processes are not addressed. This is believed to limit the flexible and creative problem solving required to adjust to and think through changing circumstances in the real world (Kirsch et al., 1992).

The application of VE technology for the rehabilitation of cognitive-functional deficits could serve to limit the major weaknesses of both the restorative and functional approaches, and actually produce a systematic treatment method that would integrate the best features from both methods. In essence, it may be possible for a VE application to provide systematic restorative training within the context of functionally relevant, ecologically valid simulated environments that optimize the degree of transfer of training (see chap. 19, this volume) or generalization of learning to the person's real-world environment. Virtual environments could also serve to provide a more controlled and systematic means for separately administering restorative or functional techniques when this direction is deemed appropriate. An analysis of the suitability of VE technology in meeting the minimum criteria for both restorative and functional approaches can be found in a previous paper (Rizzo, 1994).

It should also be noted that underlying the goals of both of these conveniently termed treatment directions (thinking vs. doing) is the concept of *neural plasticity*. Neural plasticity refers to the capacity of the brain to reorganize or repair itself following injury, through various mechanisms (i.e., axonal sprouting, glial cell activation, denervation supersensitivity, and metabolic changes) in response to environmental stimulation. Recognition of neural plasticity in response to both environmental enrichment and impoverishment has its roots in the animal literature (Renner & Rosenzweig, 1987), and detailed reviews of this increasingly favored view of the brain can be found elsewhere (Rose & Johnson, 1992). Consequently, it can be appreciated that the stimulation or "enrichment" provided by both restorative and functional approaches may each have some effect on physical brain structure, and hence training with both methods would be assumed to affect brain plasticity. If this view is accepted, stimulating virtual training environments would seem well suited to support this process and new approaches to CR would be warranted.

3. REVIEW OF VE APPLICATION AREAS TARGETING CLINICAL POPULATIONS

Virtual environment technology may offer specific advantages for the assessment and rehabilitation of cognitive-functional processes (see Table 50.1). While encouraging on a theoretical level, the utility of this technology still needs to be substantiated via systematic empirical research with normal and clinical populations. It is also necessary to determine whether these advantages add value to existing technologies targeting these aims. Nonimmersive computerized testing and training tools have been available for some time and a case can be made that they offer many of the same advantages found with virtual environments. It is therefore imperative that research be conducted to determine the incremental value of VE-specific assets (immersive naturalistic or supranormal interaction) in this area. Over the last 6 years, a growing number of researchers have begun the initial work of exploring the use of VE technology for applications designed to target cognitive-functional performance with populations having CNS dysfunction. While a good deal of this initial work employs non-HMD flat-screen environments, these less immersive systems have produced useful results, which could inform future applications that attempt to leverage the assets available with the more immersive approaches. In addition, with certain clinical populations, less immersive systems may be sufficient for the designated

TABLE 50.1
VE Advantages for Neuropsychological Assessment and Cognitive Rehabilitation Applications

1. The presentation of ecologically valid testing and training scenarios and/or cognitive challenges, which are difficult to present using other means (i.e., dynamic, interactive 3-D stimuli).
 2. Total control and consistency of stimulus delivery.
 3. The presentation of hierarchical and repetitive stimulus challenges, which can be varied from simple to complex, contingent on success.
 4. The provision of cueing stimuli or visualization tactics (i.e., selective emphasis) designed to help guide successful performance within a “dynamic” testing or errorless learning paradigm.
 5. The delivery of immediate performance feedback in a variety of forms.
 6. The capacity to pause assessment and training for discussion or other means of instruction.
 7. The option for self-guided exploration and independent testing and training when deemed appropriate.
 8. The modification of sensory presentation and response requirements based on the user’s impairments (i.e., movement, hearing, and visual disorders).
 9. The capacity for complete performance recording.
 10. The availability of a more naturalistic, or intuitive, performance record for review and analysis by the user.
 11. The design of safe learning environments, which minimize risks due to errors.
 12. The introduction of “gaming” factors into the learning situation to enhance motivation.
 13. The ability to create low-cost functional training environments.
 14. The creation and integration of virtual human representations (avatars/agents) to foster interaction and to enhance sense of presence.
-

purposes. Although the breadth of the clinical VE literature pales by comparison to work done in the testing and training area (see chaps. 43–46, this volume) with normal populations, the initial efforts with applications designed for impaired clinical groups are encouraging and will be reviewed in this chapter. It should also be noted in advance that some applications reviewed under one category could conceivably be described in another. For example, much of the work subsumed under the “memory” category involves research on spatial memory in VEs modeled from real environments and could as easily be discussed in the “spatial ability” or “functional” sections. An effort is made in these cases is to categorize applications based on the cognitive area or clinical population issue of primary focus to the researcher. In this way, an application that in one view may address training of visuospatial wayfinding (see chap. 24, this volume), may in fact be covered in the “memory” section because the researcher’s emphasis appears to be on the rehabilitation of memory of an amnesic patient (although it is acknowledged that part of the memory targeted is spatial, and the application addresses a functional target—learning a rehabilitation unit layout).

3.1 Attention Processes

Little VE work has been done with this “basic” cognitive process thus far, which is surprising in view of the widespread occurrence and relative significance of attention impairments seen in a variety of clinical conditions across the human life span. Most notably, attention difficulties are seen in persons with ADHD, TBI, and as a feature of various forms of age-related dementia (i.e., AD, vascular dementia, etc.). For example, the prevalence of ADHD is estimated at 3% to 5% in school-age children in the United States and attention deficits are frequently cited as the chief disability following the occurrence of TBI (Sohlberg & Mateer, 1987). Attention difficulties also commonly occur in the elderly due to dementing conditions and may also result from a lack of oxygen or nutrients to the brain secondary to strokes and myocardial infarctions. More effective assessment and rehabilitation tools are needed to address attention abilities for

a variety of reasons. In children, attention skills are the necessary foundation for future educational activities. Better attention process assessment is also vital for decision making regarding special education placement decisions, determination of the use and effectiveness of pharmaceutical treatments, and for treatment efficacy and outcome measurement. Persons with TBI also require focus on attention abilities as a precursor to rehabilitative work on higher cognitive processes such as memory, spatial abilities, executive functions, and problem solving. Even if higher processes are less amenable to remediation, as in cases of severe TBI, some level of attention ability is essential for vocational endeavors, functional independence, and quality of life pursuits. A more fine-grained assessment of basic attention deficits may also provide an early indicator of dementia-related symptoms and could suggest functional areas where an older person might be at risk (i.e., automobile driving, operating machinery, etc.) or where compensatory strategies may be needed in order to maximize or maintain functional independence.

Virtual environment technology appears to provide specific assets for addressing these impairments that are not available using existing methods. In this regard, our lab is currently developing an HMD-delivered VE system for the assessment and possible rehabilitation of attention processes. This work was motivated by the view that HMDs are well matched for these types of applications, as they provide a controlled stimulus environment where cognitive challenges can be presented along with the precise delivery and control of "distracting" auditory and visual stimuli. This level of experimental control could potentially allow for the development of attention assessment and rehabilitation tasks that are more similar to what is found in the real world, and hence the ecological validity of measurement and treatment methods for this process could be improved. Our first effort in this area has involved the development of a virtual classroom specifically aimed at the assessment of ADHD (Rizzo et al., 1999). A recent consensus report by the National Institutes of Health on ADHD suggests a variety of areas where better assessment tools would be of value and specifically cited the need for better definition of the nature of this disorder and an emphasis on measuring the effectiveness of intervention strategies (NIH, 1998a). These recommendations supported our interest in addressing this clinical group in our initial VE–attention application. The scenario consists of a standard rectangular classroom environment containing three rows of desks, a teacher's desk at the front, a male or female teacher, a blackboard across the front wall, a side wall with a large window looking out onto a street with background buildings, vehicles, and people, and on each end of the wall opposite the window—a pair of doorways through which activity occurs. Within this scenario, children's attention performance will be assessed while a series of typical classroom distractors (i.e., ambient classroom noise, movement of other pupils, activity occurring outside the window, etc.) are systematically controlled and manipulated within the virtual environment. The child sits at a virtual desk within the virtual classroom, and the environment can be programmed to vary with regards to such factors as seating position, number of students, gender of the teacher, and other factors. On-task attention can be measured in terms of performance (reaction time) on a variety of attention challenges that can be adjusted based on the child's age or expected grade level of performance. For example, on the simpler end of the continuum, the child can be required to press a "colored" section of the virtual desk on the direct instruction of the teacher or whenever the child hears the name of the color mentioned by the teacher (*focused* or *selective* attention task). *Sustained attention* can be assessed by manipulating the time demands of the testing. More complex demands requiring *alternating* or *divided attention* can be developed whereby the student needs to respond by pressing the "colored" section only when the teacher states the color in relation to an animal (i.e., the brown dog, as opposed to the statement "I like the color brown") and only when the word *dog* is written on the blackboard. In addition to attention-driven reaction-time performance, behavioral measures that are correlated with distractibility and/or hyperactivity components (i.e., head turning, gross motor movement) and impulsive nontask behaviors (time playing with

“distracter” items on the desk) can be measured. Other scenarios (i.e., work situations, home environments, etc.) using the same logic and approach are being conceptualized to address these issues with other clinical groups. This work is currently in progress and results from our first pilot study should be available by early 2000. Figure 50.1 contains images of the Virtual Classroom.

Another form of attention disorder that has been addressed with VE technology concerns the area of visual neglect, or inattention to a specific visual field, which is sometimes seen following a stroke or TBI. Visual neglect is defined as inattention to objects or events positioned in the visual space opposite to a brain lesion. It is not a vision problem, but a disorder of the integrated functioning of vision and attention. Classic signs of neglect are combing hair on only one side of the head, reading words only from the unaffected half of a printed page, or eating food that is on one side of the plate and believing it to be empty. Standard assessments for visual neglect commonly use static two-dimensional (2-D) materials, such as requiring the patient to determine the center of lines on a piece of paper (line bisection task) or the crossing out of specific targets on a page containing an array of stimuli. Virtual environment technology offers the potential to expand traditional assessment methods by providing a controlled 3-D assessment environment, which allows for assessment of depth and motion factors and these capabilities could serve to support new NA and CR strategies. For example, Rushton, Coles, and Wann (1996) propose using VEs to remove vestibular and visual frames of reference by rotating the visual world and directing to attention, objects that are in the neglected field. In their current application, a flat-screen VE scenario consisting of a series of mazes is presented, which requires varying levels of attention and decision making for navigation (Wann, Rushton, Smyth, & Jones, 1997). This type of application can provide extended practice, systematic stimulus delivery of cueing stimuli contingent on level of impairment, and constant feedback of the type that is not available in conventional settings. Results from clinical trials with these patients are anticipated. Another group is targeting the assessment of neglect using an HMD with eye-tracking capability in order to record eye movements across an array of 3-D virtual objects (Kodgi, Gupta, Conroy, & Knott, 1999). Initial results from a pilot study of four neglect patients confirmed that the subjects made eye movements only to the objects they reported seeing. The integration of eye-tracking technology (see chap. 9, this volume) with this VE scenario is well matched to the aims of this assessment challenge and future work with moving stimuli could present new NA and CR options for this impairment.

3.2 Executive Functioning

The reasoning that supports the use of VE technology to address impairments with more complex attention processes can also be applied to the more integrative cognitive domain referred to as executive functions. This cognitive process generally refers to “a set of behavioural competencies which include planning, sequencing, the ability to sustain attention, resistance to interference, utilization of feedback, the ability to coordinate simultaneous activity, cognitive flexibility (i.e., the ability to change set), and, more generally, the ability to deal with novelty” (Crawford, 1998, p. 209). The complexity of this cognitive process makes assessment and rehabilitation a questionable process using traditional psychometric methodologies (Elkind, 1998; Pugnetti et al., 1995a). However, as with the attention examples cited above, the attributes of a VE offer a unique capacity to address this cognitive process. More complex VEs targeting executive functioning would be of particular value as CNS patients often perform well on traditional neuropsychological tests of specific cognitive ability (i.e., attention, memory, visuospatial, language, etc.), yet may display impairments in the ubiquitous day-to-day activities that require planning, initiating, multitasking, and self-assessment competencies that are believed to be part of this integrative function. From this perspective, VEs may offer a way

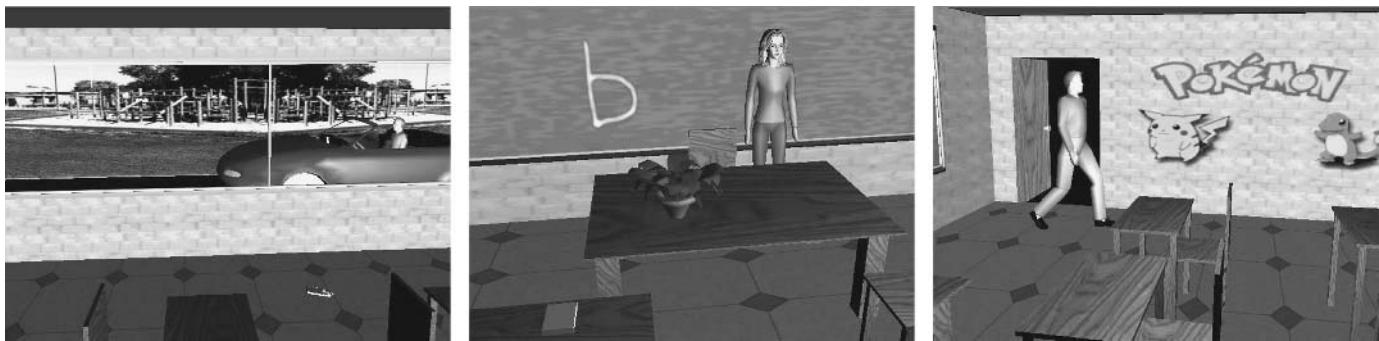

FIG. 50.1. Scenes from the Virtual Classroom for assessment of attention deficit hyperactivity disorder.

to systematically assess and rehabilitate these competencies within the context of the demands found in everyday settings modeled in a virtual environment.

One group of researchers has begun the work of developing an HMD-based VE system specifically designed for the assessment and rehabilitation of this process in persons with TBI, multiple sclerosis, and stroke (Pugnetti et al., 1995a, 1995b, 1996, 1998a, 1998b). Using a standard tool of neuropsychological assessment as a model (the Wisconsin Card Sorting Test—WCST), these researchers have created a virtual building that requires the person to utilize environmental clues in the selection of appropriate choices (doorways) in order to navigate from room to room in the structure. The doorway choices can vary according to the categories of shape, color, and number of portholes and the person is required to refer back to the previous doorway for clues as to the appropriate next choice. When the choice criterion is changed, the person is then required to shift cognitive set, analyze clues, and devise a new choice strategy. The parameters of this system are fully adjustable so that training applications can follow initial standardized assessments. In light of the large body of literature that exists on the WCST (Kolb & Wishaw, 1990), its choice as a model for this initial VE application is potentially quite useful, and results from this application have been encouraging. Pugnetti et al. (1998a) reported a study comparing a mixed group of neurological patients (MS, stroke, and TBI) with normals on performance on both the WCST and on their HMD executive function system. The results confirmed previous anecdotal observations with patient populations. While the psychometric properties of the VE task were comparable to the WCST in terms of gross differentiation of patients and controls, weak correlations between the two methods suggest that they are measuring different functions. In this regard, the VE task was seen to specify impairments earlier in the test sequence compared to the analogue pencil and paper test. The authors suggest that "this finding depends on the more complex (and complete) cognitive demands of the VE setting at the beginning of the test when perceptuomotor, visuospatial (orientation), memory, and conceptual aspects of the task need to be fully integrated into an efficient routine" (p. 160). The detection of these "integrative" difficulties for this complex cognitive function is of vital importance when predicting real-world capabilities from test results. Further support for this more ecologically valid VE assessment method can be seen in a detailed single subject case study of a stroke patient using this system. In this report (Mendozzi, Motta, Barbieri, Alpini, & Pugnetti, 1998), results indicated that the VE was more accurate in specifying executive function deficits in a highly educated patient two years following a stroke. The VE was successful in detecting deficits that had been reported to be limiting the patient's everyday performance, yet were missed using traditional neuropsychological tests. Additionally, this group has reported findings pertaining to psychophysiological variables (EEG, heart rate) that were recorded during participation in their VE system (Pugnetti et al., 1995b), and this area is continuing to be explored (L. Pugnetti, personal communication, February 8, 1999).

3.3 Memory

The assessment and rehabilitation of memory disorders have received considerable attention in the neuropsychological literature. This has resulted in the better specification of memory processes, elucidation of underlying CNS mechanisms, and a greater effort to determine the problems that occur in everyday life due to clinical memory disorders. Targeting the memory deficits seen with TBI, learning disabilities, and neurodegenerative disorders is also vital for immediate and long-term functional rehabilitation purposes. The diagnosis of age-associated dementia also focuses on memory processes and requires the presence of explicit verbal memory deficits as a criteria for the diagnosis of dementia established by the *DSM-IV* (American Psychiatric Association, 1994). The increased emphasis in diagnosing dementia at its very

earliest stage in order to deliver treatments that could slow the progression of the disorder and maximize functional independence, increase longevity, and improve quality of life has spurred on research to discover more sensitive tools for addressing memory functioning. This is an area where VE technology could be of value for improving the specificity of memory assessment for more effective diagnosis.

When speculating on possible VE applications for CR purposes, it is also helpful to consider findings pertaining to preserved memory, or learning abilities, following brain trauma and occurring with some forms of dementia. A number of studies have shown that in persons with neurologically based memory impairment, certain memory/learning subprocesses often remain relatively intact. *Procedural*, or skill memory, is one such cognitive operation (Charness, Milberg, & Alexander, 1988; Cohen & Squire, 1980). This type of memory ability concerns the capacity to learn rule-based or automatic procedures including motor skills, certain kinds of rule-based puzzles, and sequences for running or operating things (Sohlberg & Mateer, 1989). Procedural memory can be viewed in contrast to *declarative*, or fact-based memory, which is usually more impaired following CNS dysfunction and less amenable to rehabilitative improvement. Additionally, these patients often demonstrate an ability to perform procedural tasks without *any* recollection of the actual training. This is commonly referred to as *implicit* memory (Graf & Schacter, 1985), and its presence is indicative of a preserved ability to process and retain new material without the person's conscious awareness of when or where the learning occurred. These observations provide encouragement for the idea that VEs, by way of their interactive and immersive features, could provide training environments that foster cognitive improvement by exploiting the person's preserved procedural abilities. Hence, cognitive processes could be restored via procedures practiced repetitively within an environment that contains functional real-world demands. Whether the person could recall the actual training episodes is irrelevant, as long as the learned process or skill is shown to generalize to functional situations. An additional challenge would then be to somehow translate difficult declarative (and semantic) tasks into procedural learning activities, with the goal being the restoration of more complex higher reasoning abilities.

Following the reasoning from the cognitive process scenarios described above, it is also possible to design VE approaches that could target memory abilities systematically within simulated functional environments. Efforts in this area would be particularly useful as results using traditional methods for memory rehabilitation have been inconsistent at best (Schacter & Glisky, 1986; Wilson, 1997). One possible reason for the poor results in this area may be due to the inability to maintain a patient's motivation when confronting them with a repetitive series of memory training challenges, whether using word-list exercises or real-life functional activities. Virtual environment training might address this problem by providing environments that initially utilize gaming incentives followed by the gradual fading in of functional environments with the aim of developing domain-specific memory (Glisky, 1992).

Research examining memory for objects and the spatial layout contained in a VE has been under way since the mid-1990's at the University of East London. The targeting of memory processes in environments designed to test and train clinical groups is closely related to the VE work in the area of "spatial orientation and wayfinding," and a more specific review of applications targeting these processes with unimpaired groups can be found in the chap. 24 (this volume). The UEL group has focused on specifying the types of memory that may be enhanced during a four-room house navigation task (Attree et al., 1996; Rose, 1996) with an aim toward targeting memory deficits in clinical populations. This approach uses a non-HMD flat-screen system with a joystick interface that allows one subject to navigate the house (active condition), whereas a yoked subject is simply exposed to the same journey but has no navigational control (passive condition). Both subjects are directed to seek out an object (toy car) during the exploration and differential memory performance between the two groups on spatial

versus object memory of the environment is tested. In initial tests with normal populations, it was observed that the active groups showed better spatial memory for the route, whereas the passive group displayed superior object recall and recognition memory for the items viewed along the route (Attree et al., 1996). These results have been replicated by collaborators with this group (Pugnetti et al., 1998a), whereas mixed results have been reported by other non-HMD VE studies in this area, one showing active participation enhancing spatial memory (Peruch, Vercher, & Gauthier, 1995) and no differences reported in the others (Wilson, 1993; Wilson, Foreman, Gillet, & Stanton, 1997). However, the spatial orientation tasks used in these latter studies differed in the degree to which subjects were allowed to "retrace their route," and this may have mitigated the procedural training component's contribution to the observed outcomes (no difference between "active" vs. "passive" exposure; Rose et al., 1999).

Research using this scenario with clinical populations (multiple sclerosis and stroke) has produced results that suggest the value of this sort of VE application to inform NA and CR with these groups. In a recent study using this VE application, as expected, stroke patients performed more poorly than normals. What is more interesting though, is that whereas the typical spatial-content memory dissociation was found with unimpaired groups (i.e., active equal to better spatial memory; passive equal to better object memory), and the active stroke group displayed better spatial memory compared to the passive group, the stroke patients displayed no advantage on object memory while in the passive condition (Rose et al., 1999). Similar findings using the UEL scenario were also reported by Pugnetti et al. (1998b) in a study comparing multiple sclerosis (MS) patients with a normal group. These findings also could not be accounted for via relationships with standard pencil and paper memory assessment tools. This type of impairment in explicit incidental memory observed in MS patients suggests that a VE approach may be of particular value in detecting subtle deficits in these patients (Pugnetti et al., 1998b). This is in line with previous work by Andrews, Rose, Leadbetter, Attree, & Painter (1995), who found that subjects recalled half as much in a VE that contained the sort of distracters present in everyday life when compared to "static" presentations, as are typically used in standard NA methods. From this, the targeting of memory processes within a VE may provide more unique and specific information that could enhance our understanding of impaired cognitive processes, as well as underscore the potential value of immersive approaches that promote "procedural" involvement in the design of better rehabilitative memory approaches.

In this regard, Brooks et al. (1999) reported the case of a female stroke patient with severe amnesia who showed significant improvements in her ability to find her way around a rehabilitation unit following training within a VE modeled after the unit. Prior to training, the patient had lived in the unit for 2 months and was still unable to find her way around, even to places that she visited regularly. In the first part of the training, improvements on two routes were seen after a 3-week period of VE route practice lasting only 15 minutes per weekday, and retention of this learning was maintained throughout the patient's stay on the unit. In the second part of the study, the patient was trained on two more routes, one utilizing the VE and the other actually practicing on the "real" unit. Within 2 weeks the patient learned the route practiced in the VE, but not the route trained on the real unit, and this learning was maintained throughout the course of the study (Brooks et al., 1999). The authors account for this success as being due in part to the opportunity in the VE for quicker traversing of the environment than in the real world, which allowed for more efficient use of training time. Another factor in this success may be that the VE training did not contain the typical distractions normally present when real-world training is conducted, which might have impeded route learning. Additionally, VEs allow for repeated independent explorations that may be limited in the real world for persons with motoric impairments, and this asset may offer additive value for these types of spatial memory rehabilitation approaches. This asset was also alluded to by way of similar findings reported in a series of studies (Foreman, Wilson, & Stanton, 1997; Stanton, Foreman, & Wilson,

1998), where children with severe physical disabilities were able to transfer learning from a virtual school environment to the actual school environment. Further research examining these issues and other memory subprocesses with clinical populations needs to be conducted taking into account findings with normal populations concerning different levels of immersion (Lackner & DiZio, 1998; Waller, Hunt, & Knapp, 1998) and with controlled variations in the multisensory characteristics of the VE (Dinh, Walker, Hodges, Song, & Kobayashi, 1999).

Lastly, a unique VE learning and memory application has been developed by Grealy, Johnson, and Rushton (1999), who created three flat-screen VE scenarios that allow a patient to navigate environments via a recumbent bicycle and exercise equipment interface. The task requires the person to sequentially visit various objects, or locations, in the virtual environment. The authors present the interesting concept that the VE training will improve fitness level, which is hypothesized to enhance brain activation, as well as other variables relevant to rehabilitative concerns. Related support for integrating exercise in a VE to enhance the effect of CR can be found in recent reports indicating that cell growth in the hippocampus (a key brain center for memory) was promoted in mice following both mental and physical exercise (Gould, Beylin, Tanapat, Reeves, & Shors, 1999; van Praag, Kempermann, & Gage, 1999). In an initial study by Grealy et al. (1999), TBI subjects trained with the VE-exercise system performed significantly better than controls on digit coding, visual, and verbal learning tasks. These provocative findings suggest areas of application where the assets available with VE technology combined with exercise might be creatively applied to the rehabilitation of learning and memory with clinical populations.

3.4 Spatial Ability

Tests of spatial ability are commonly used for the study of brain behavior relationships and for measuring the consequences of various forms of CNS dysfunction. Spatial ability is commonly broken down and defined in terms of the tests used to measure its various subcomponents (i.e., spatial perception, orientation, visualization, mental rotation, etc.). However, Carpenter and Just (1986) present a general definition of this process as the ability to generate "a mental representation of a two or three-dimensional structure and then assessing its properties or performing a transformation of the representation" (p. 221). The analysis of human spatial processing is of value for diagnosing brain dysfunction in a variety of domains and for addressing the "topographical disorientation" (De Renzi, 1985) that is sometimes seen in these conditions. Also, the rehabilitation of spatial abilities may be vital to supporting the reacquisition of many functional abilities including driving, navigating environments, and other IADLs commonly found to be impaired due to CNS dysfunction. Virtual environment technology may provide unique assets for targeting spatial abilities with its capacity for creating, presenting, and manipulating dynamic 3-D objects and environments in a consistent manner and for the precise measurement of human interactive performance with these stimuli. These types of VE spatial ability assessment and rehabilitation systems may provide ways to target these cognitive processes beyond what exists with methods relying on 2-D pencil and paper representations of 3-D objects (or methods using actual real objects) that are typically found with traditional tools in this area. These traditional methods are often limited by poor depth, motion, and 3-D cues needed for proper stimulus delivery and have limited capacity for the precise measurement of responses. Virtual environments also offer the potential to address these variables in an ecologically valid manner (functional simulations) without the loss of experimental control common with naturalistic studies in this area relying on observational methods.

A number of flat-screen VE systems have been developed to target spatial ability variables. For example, results from studies of human "place learning" ability have been reported (Astur, Ortiz, & Sutherland, 1998; Jacobs, Laurance, & Thomas, 1997; Jacobs, Thomas, Laurance, &

Nadel, 1998; Sandstrom, Kaufman, & Huettel, 1998; Skelton, Bukach, Laurance, Thomas, & Jacobs, 1999), with researchers having designed VEs modeled after the Morris water task (Morris, 1981). The Morris water task was developed as a systematic method for the study of spatial abilities in rodents and requires subjects placed in a pool of water to swim from various starting points and find a fixed hidden platform located below the water surface. Since rodents are unable to see or smell the platform, they must rely solely on the spatial arrangement of cues on the walls outside of the pool in order to locate it. Reports of animal performances on this task have produced useful findings relating to spatial ability differences due to gender, age, drug effects, and brain lesions (Astur, Ortiz, & Sutherland, 1998). However, although the Morris water task is the "gold standard" for measuring place learning in animal studies, it is not a practical test for use with human subjects. Flat-screen, joystick-controlled VEs modeled after the Morris task, which allow a person to navigate an environment in search of a hidden platform, have produced a useful method for studying this process in humans. Studies using this VE have reported significant effects in the areas of aging, CNS dysfunction, and gender differences (Astur et al., 1998; Jacobs et al., 1997; 1998; Sandstrom, Kaufman, & Huettel, 1998; Skelton et al., 1999; Thomas, Laurance, Luczak, & Jacobs, 1999). For example, a recent study showed TBI patients to have significantly impaired VE place learning abilities, which correlated with self-reported frequency of wayfinding problems in everyday life (Skelton et al., 1999). Most of these studies also report a large and reliable male advantage on these tasks, and these findings are of value for understanding differences in brain function between the genders that are believed to be influenced by hormonal status (see chap. 32, this volume). Similar gender differences have been reported in a recent study comparing different levels of immersion on the transfer of spatial knowledge from a variety of training environments (no training, real world, map, VE desktop, VE immersive, and VE long immersive), where "robust gender differences in training effectiveness" in favor of males were also reported (p. 129; Waller, Hunt, & Knapp, 1998). Continuing research with clinical populations using the VE Morris Water Test is currently under way and these results are highly anticipated (K. Thomas, personal communication, June 25, 1999).

The use of flatscreen VE scenarios has also shown very promising results for training spatial orientation and navigation skills with physically disabled children (Stanton, Foreman, & Wilson, 1998). Applications in this area could be of particular value for children with physical disabilities who are limited in their ability to independently explore environments and who may consequently display impairments in cognitive mapping abilities. Foreman, Orencas, Nicholas, Morton, and Gell (1989) reported these types of impairments with a group of 10 physically disabled students having deficits in spatial awareness and cognitive mapping skills possibly due to the adoption of a "passive" navigational strategy. Other researchers have also reported similar effects due to passive navigation in unimpaired children (Hazen, 1982; McComas, Dulberg, & Latter, 1997). In a series of four studies reviewed in Stanton et al. (1998), children with physical disabilities were allowed to independently explore VEs modeled after school environments. Transfer of spatial learning was shown to generalize to the actual school that was modeled, and this learning improved with practice. Also, flexibility in the cognitive representation, or "mapping" of the environment, was inferred, as the children were able to accurately indicate the direction of objects that were not in their line of sight. Similar findings have been reported by another group that has developed a visuospatial VE scenario designed to be ultimately applied with children having motor impairments (McComas, Pivak, & Laflamme, 1998). Successful learning and transfer for object locations were found using a flat-screen "classroom" VE with unimpaired children. In this study, spatial performance equaled "real-world" training, and successful transfer to the real environment was reported. Similar improvement using a flat-screen VE training system targeting functional spatial knowledge has also been reported for teenagers with developmental disabilities in a supermarket search

and navigation scenario (Cromby, Standen, Newman, & Tasker, 1996). Further details on this and related work on spatial navigation will be discussed in the “Functional Skills” section.

Taking a more component-based approach to addressing spatial ability, we have developed a suite of ImmersaDesk-delivered (Couling, 1998) applications targeting mental rotation, depth perception, manual movement stability, 3-D field dependence (3-D rod and frame test), 3-D manual tracking, and visual field specific reaction time. These scenarios were designed to leverage the 3-D interactive assets available with this type of projection-based system in the development of a series of tasks that could serve to assess and possibly rehabilitate these more molecular components of visuospatial functioning. Our initial study targeted mental rotation (MR), a well-researched visuospatial variable, which can be described as a dynamic imagery process that involves “turning something over in one’s mind” (Shepard & Metzler, 1971).

In the VE system, MR was assessed via a manual spatial rotation task that required subjects to manipulate virtual block configurations. Subjects were presented with a target block configuration and the speed and efficiency of their movements to superimpose a replica design on the target was measured and recorded. All manner of angular disparity and axis combinations can be programmed into the system allowing for hierarchical presentation of cognitive challenges required for NA and CR purposes. Details on the relevance of this application and prior methodology applied to the study of mental rotation can be found in Rizzo et al. (1998b). Our initial feasibility study targeting MR tested 18- to 40-year-olds on self-reported side effect occurrence, performance change (learning) on the VE MR task, transfer of training from the VE to performance on a pencil and paper MR test (Vandenberg & Kuse, 1978), the relationships between VE performance and other “standard” NA tests of cognitive performance, and gender differences on all of these questions. A number of encouraging findings emerged, including minimal side effect occurrence (see chap. 30, this volume), good psychometric properties of the VE test (see chap. 35, this volume), provocative relationships with standard NA tests, a lack of gender differences compared to the pencil and paper measures, training improvement, and significant transfer of training (see chap. 19, this volume) with low initial pencil and paper performers (Larson et al., 1999; Rizzo et al., 1999).

We are now testing out the full VE system (all visuospatial scenarios cited above) with normal elderly subjects and comparisons of this data with CNS impaired populations (Alzheimer’s, TBI) will follow. Our plan is to develop a desktop system, using shutter glasses, in order to run a comparative test to determine if these scenarios can be successfully delivered on a less expensive and more accessible platform. The aim of this work is to provide a suite of VE-delivered 3-D testing and training tools that could target the NA and CR of visuospatial processes for use by researchers and clinicians.

HMD-delivered VEs have been a staple for studying spatial processes in normal subjects (see chap. 24, this volume) as seen in the work of Wraga, Creem, and Proffitt (1997), who have also investigated mental rotation ability. Other researchers are using HMD-delivered VEs to address spatial ability deficits with clinical populations. One group at the National Rehabilitation Hospital in Washington, D.C. (Trepagnier, 1999), is examining facial scanning in autistic children using an HMD with a built-in eye-tracking system. This application may allow for a more controlled analysis of the hypothesized deficits in facial eye-scanning behavior believed to occur in this population via the systematic presentation of functional 3-D stimuli. Alpini et al. (1998) have begun using an HMD-based VE to assess spatial exploratory behavior with clinical populations having vestibular dysfunction, and a lab in Denmark (Dobrzeniecki, Larsen, Andersen, & Sperling, 1999) has commenced feasibility studies for a similar application with stroke patients. These HMD systems will offer new insights into the complex factors that comprise impairments in spatial abilities. However, considerable challenges in this area remain. Reports of early work with stroke patients have shown that they have “highly disparate and constantly changing cognitive deficits, which require virtual worlds and tasks

that are adaptive to a wide range of symptoms and personality traits . . ." (A. Dobrzeniecki, personal communication, June 22, 1999). Further discussion of these types of clinical user issues appears in section 4.3.

Another promising area that has recently emerged is in the application of immersive audio VEs that can deliver 3-D spatialized sound (see chap. 4, this volume) to provide cues that are relevant to the simulated physical structure of an environment (Kyriakakis, 1999; Pair, 1999). A number of applications have been developed that provide auditory inputs to supplement environmental information for persons with visual impairments (Berka & Slavík, 1998; Cooper & Taylor, 1998). One group in particular has demonstrated the feasibility of promoting spatial–cognitive mapping using immersive audio (Lumbreñas & Sánchez, 1998). Their initial work has involved the development of a computer game (AudioDoom) designed to allow blind children to navigate and interact with a spatial environment solely through the use of 3-D sound stimuli. The dramatic effect of this application can be seen in a demonstration of this work where children were asked to reconstruct the characteristics of the explored audio gaming environment using Lego blocks. The resulting Lego constructions were strikingly similar to the structure of this "sound-delivered" VE, and this may illustrate the value of auditory cues in developing a spatial cognitive map in children who have never had any visual experience with the physical world. This system, as well as other similar immersive audio applications, may have additional usefulness for studying audiovisual integration and spatial image formation for sighted populations with other forms of CNS dysfunction, and further work in this area is anticipated. One possible application might include the use of functional magnetic resonance imaging (fMRI) brain mapping technology to directly study the underlying neural circuitry of audiospatial mapping. For example, Aguirre and D'Esposito (1997) used a flat-screen VE model of a town derived from a commercially available video game (Marathon2) to train subjects on landmark and survey spatial information of an environment. The subjects' knowledge was subsequently tested while undergoing fMRI brain imaging, and the findings indicated specific differences in brain circuitry activation for landmark and survey tasks. Practical constraints of fMRI testing on the delivery of HMD immersive visual stimuli limited the use of the actual VE during imaging, and instead, still images of the environment were presented via a mirror device. In view of this limitation for the delivery of active VE visual environments, the presentation of immersive audio environments via earphones during brain imaging studies may be of some interim value. In this way, auditory cues supporting spatial mapping could be presented, and concurrent brain imaging of the underlying brain circuitry might be explored. Until it becomes more feasible in the near future to present HMD-delivered visual stimuli within a brain scanning device such as this, auditory immersion studies could be conducted to shed insight on these types of spatial learning events in the brain.

3.5 Functional Skills/Instrumental Activities of Daily Living

Some of the VE systems targeting component cognitive processes reported on above could conceivably be reviewed here (i.e., facial scanning, virtual classroom, etc.). However, the applications reviewed in this section focus primarily on the performance of more molar behaviors required for functional activities in VEs targeting IADLs. These functional approaches emphasize the design of ecologically valid VEs to test and train more integrated behavioral repertoires in populations which are limited in their capacity for real-world independent learning. Advances in this area could be of considerable value in view of the costly and labor-intensive efforts that are required for *in vivo*, one-on-one approaches often applied with certain clinical populations. In this way, VEs can be used to assess functional behavior and deliver consistent, hierarchical, and safe training that could free the therapist's time to be spent in other more necessary and intensive one-on-one client contact, as needed.

Virtual environments that target specific functional skills in clinical populations have been developed in the areas of street crossing, wheelchair navigation, meal preparation, use of public transportation, driving, and for the analysis of obstacle avoidance with elderly persons at risk for falling. Strickland (1996) reported initial results on the feasibility of using an HMD with autistic children with the long-term goal of targeting VE training for safe street crossing. The two autistic children initially reported on adapted to the headset and were able to track moving automobile stimuli and select objects. Continued efforts with this population (Strickland, 1997) and with children having motor disabilities (Inman, Loge, & Leavens, 1997) are under way to target the functional behaviors required for safe street crossing in a virtual environment. Inman et al. (1997) have also reported success in training children with motor impairments to use motorized wheelchairs in a variety of simulated real-world conditions using an HMD-based VE system (see chap. 49, this volume). Promising initial usability (see chap. 24, this volume) has also been reported for a flat-screen VE scenario targeting this same purpose by another group of researchers in Ireland (Desbonnet, Cox, & Rahman, 1998). Related work is proposed for VE assessment of operating skills and route navigation abilities in adult rehabilitation patients (D. Rose, personal communication, March 4, 1999). This project will include real-world baseline and post-VE assessment to determine transfer of training (see chap. 19, this volume) to the targeted environment. Such work is important to determine patients' ability to use powered wheelchairs safely and effectively.

Food preparation skills within a virtual kitchen scenario have also been investigated. Christiansen et al. (1998) have developed an HMD-based VE of a kitchen in which persons with TBI have been assessed in terms of their ability to perform 30 discrete steps required to prepare a can of soup. Contingent upon success at each step, various auditory and visual cues can be presented to help prompt successful performance and learning. In the first reported pilot study with this system, 30 patients with closed-head injuries were able to successfully function using the HMD with minimal side effects. In addition, acceptable reliability coefficients were reported using a test-retest assessment. These researchers also report ongoing enhancements to the system regarding the delivery of more complex challenges and increased flexibility in the presentation of cueing stimuli. A similar approach was presented by Davies et al. (1998), targeting the steps required to brew a pot of coffee. Although the initial study tested unimpaired subjects (occupational therapists), the authors reported usability data that they conclude supports the potential for use of these types of VEs with clinical populations.

Virtual environments that target driving ability have also been tested with TBI and elderly populations. Liu, Miyazaki, and Watson (1999) reported that an HMD-based driving scenario successfully discriminated between a TBI and an unimpaired group and that age effects were also detected with this system. Virtual environments that target driving ability under a range of conditions that are impossible to measure in standard behind-the-wheel assessments could become invaluable for safely assessing this functional ability in persons with CNS impairments, as well as with aged populations (M. Schultheis, personal communication, February 12, 1999). For example, normal elderly were compared with early Alzheimer's patients using the Iowa Driving Simulator, and, as would be expected, significantly more "accidents" occurred in the Alzheimer's group (Rizzo et al., 1997). If comparable assessment were possible using a less expensive VE scenario, more widespread use of these types of realistic functional assessment tools would be possible (Mourant & Chiu, 1997). The rapidly increasing size of the aging population, coupled with age-related changes in cognitive-functional performance makes investigations into the feasibility of VE applications with elderly populations of considerable importance. For example, one area that might be of value for aging populations involves simple walking and obstacle avoidance. A VE system is currently being developed to train elderly subjects to step over obstacles (Jaffe, 1998). The relevance of this can be seen in the fact that preventable falls, and the hip damage that often accompanies them, are leading causes of loss

of functional independence with this population. This HMD-based VE application will allow at-risk elderly persons to practice stepping over moving obstacles on a treadmill while wearing an overhead safety harness. As such, an effective VE approach to address this basic skill would be of considerable value.

One particularly noteworthy and ambitious effort to address functional life skills is the work of the University of Nottingham group in the development of the Virtual City (Brown, Kerr, & Bayon, 1998; see chap. 46, this volume). This flat-screen scenario addresses independent living skills in persons with learning and developmental disabilities, and the researchers have implemented good user-centered design principles by incorporating user group input in the selection of environments targeted in the application. These settings were designed to address the use of public transport, road safety, home safety, use of public facilities within a cafe, and shopping skills in a large supermarket. An initial study tested 20 subjects with mental retardation and addressed usability, enjoyment, skill learning, and transfer of skills to the real environment using subject's self-report and behavioral observation methods (Cobb, Neale, & Reynolds, 1998). Subjects reported high enjoyment of the task and more "ease of use" with the system than anticipated in the "expected" usability ratings determined by support workers. Transfer from the VE to the real environment for some skills was noted in this initial feasibility study. This was determined by examining changes in ratings of the level of assistance provided by support workers in the real world, both before and after a 1-hour VE session. While this report was somewhat vague on presenting specific transfer data, the authors present anecdotal evidence that transfer of learning occurred in some instances and acknowledge that a longer period of training would be needed to see significant effects in this area. Work with this evolving scenario continues and results from more systematic measurement of learning and transfer are anticipated. Such results are important to support previous observations of transfer seen with these populations. For example, Cromby et al. (1996) reported evidence of positive learning transfer for another group of developmentally disabled students using a supermarket VE modeled after an actual market. Subjects were reported to be better able to navigate within, and select specific items in the real supermarket following training in the VE and these subjects outperformed those who practiced in nonspecific virtual environments. Positive results were also reported for a public transit VE training program called Train to Travel (Mowafy & Pollack, 1995). This HMD-based VE system was developed in the mid-1990s to assess and teach persons with developmental disabilities on how to use key routes on the Miami Valley Regional Transit System. However, since the VE component was part of a comprehensive training package, including video and multimedia tutorials, the specific effect of the VE on successful independent transit use was not determinable. Future studies that methodologically target the specific effects of the VE "ingredient" are necessary to determine whether these types of programs are effective for efficiently and economically targeting functional abilities with these populations. The above-cited investigations represent essential "first-steps" in determining whether VE training can foster transfer of learning to activities of daily living. For persons whose learning abilities are challenged due to CNS dysfunction, this line of research is especially important.

4. BASIC ISSUES FOR DECISION MAKING ON THE DESIGN AND USE OF VES WITH CNS CLINICAL POPULATIONS

In order for VE applications targeting NA and CR to be efficiently developed, a number of basic theoretical and pragmatic issues need to be addressed. The added issues of working with clinical user groups with CNS dysfunction also require consideration with these applications. On top of standard human factors and usability concerns (see chap. 34, this volume), unique

aspects seen with various clinical populations add another level of complexity to an already difficult set of challenges in the design and implementation of effective NA and CR virtual environments. The major questions for these types of applications are addressed in this section. A brief discussion of the basic issues as they relate to unimpaired user groups (while possibly redundant to more detailed reviews found elsewhere in this volume) is included in order to provide the necessary context for addressing the additional concerns that are specific to clinical populations.

4.1 Can the Same Objective Be Accomplished Using a Simpler Approach?

While VE technology appears to offer many advantages for neuropsychological applications, the first step for any such program is for the developer to perform a realistic cost–benefit analysis (see chap. 28, this volume). Implementation of an honest cost–benefit analysis can serve to prevent costly and misguided (though well-intentioned) system development from diverting resources from the areas where a VE approach can make a unique and useful contribution. Virtual reality has been characterized as a technology in search of an application (Wann, 1996). From this, the excitement surrounding this new technology has the potential to affect judgment of the real needs of the situation. The first question to be asked is, Does the objective that is being pursued require the expense and complexity of a VE approach, or can it be done as effectively and efficiently using simpler, less costly, and currently available methods? This “elegant simplicity” criterion requires the investigator to fully consider the objectives of the application and decide whether the development of a VE genuinely adds value beyond what already exists, or is it simply a case of technological overkill.

Virtual environments, in fact, offer immersive and interactive features (see chap. 40, this volume) that, if deemed important to a NA–CR approach, could provide valuable assets. However, if these features are not of vital importance, perhaps the use of flat-screen multimedia, “simple” video, or even already established *in vivo* tools, would be sufficient. For example, if the objective is to assess elderly persons for global cognitive functioning as an initial screening procedure for dementia (Alzheimer’s, vascular, Parkinson’s, etc.), then a very basic, standardized 30-question mental status interview/exam that measures orientation, attention, short- and long-term memory, verbal fluency, and judgment may be sufficient for this purpose. A test like this already exists, the Mini Mental State Exam (Folstein, Folstein, & McHugh, 1975), and has been shown to be of acceptable reliability and validity, inexpensive, easy to administer quickly in most settings, and provides data that can be usefully compared with norms generated over many years as a standard tool in this area. For this specific purpose, a VE approach would be redundant and inefficient. However, the same researcher may believe that probable AD could be recognized at its very earliest stage via a more systematic analysis of specific attention–memory components (perhaps iconic memory) while a person is immersed within the demands of a stimulus-rich functional virtual environment. For this purpose, a VE application may be the most efficient (and perhaps the only) method for systematically controlling the stimulus environment while precisely measuring millisecond by millisecond responses. Although the initial cost of developing such a system might be high, the earlier detection of dementing symptomatology could allow for possible treatments at an earlier stage in the disease process, leading to more informed long-term care and increased functional longevity for the client.

Following from this last point, a commonly cited advantage of VEs is the capacity to record and measure naturalistic behavior within a simulated functional scenario (Riva, 1998; Rizzo et al., 1998a; Rizzo, Wiederhold, & Buckwalter, 1998c; Rose, 1996). This asset offers the potential to collect reliable data that might have been otherwise lost using methods employing behavioral ratings from trained observers of behavior in “real-world” settings. However, behavioral

observation methods that make use of video recordings for later rating may be sufficient for certain purposes. For example, this may be the case with the assessment of “rough and tumble” play that is commonly focused on in comparisons of gender differences in children, as well as with the study of aggressive behavior (Eaton & Enns, 1986). The assessment of these behaviors within a simulated environment would require a strong tactile and physical interaction component that is not currently possible in a virtual environment. While it may be possible to design VEs with the capacity to stimulate these activities, the absence of the haptic feedback loop (see chaps. 5 and 6, this volume) from actual physical contact, as well as the practical issues of using an HMD with this level of gross motor activity, makes a real-world application a relatively simpler and more effective environment for this purpose. As well, certain types of critical thinking training approaches may be more efficiently administered to a person with a mild head injury by utilizing preserved reading comprehension skills to hierarchically teach reasoning by analogy. This is a relatively straightforward approach that the client can practice at home as well as in a treatment setting. This sort of language–logic process is viewed as less amenable to a VE approach at the current state of the technology, and this is discussed further in the next section. By contrast, if the client has impairments in areas relating to active problem solving and executive functions, then VE-delivered scenarios that allow for exploration and interaction within a dynamic simulated functional environment might offer hierarchical challenges that could not be presented efficiently and consistently using traditional methods.

In summary, the examples cited above were chosen to illustrate the “elegant simplicity” criterion applied to a range of possible applications. This first step in the VE decision-making process requires one to justify the selection of this technology in contrast to simpler, presently available tools. If the application meets this criterion and is expected to add value to already existing approaches via the assets that are available with VEs, then it is time to examine the specifics of the application in light of the following issues.

4.2 How Well Do Current VE Assets Fit the Needs of the Cognitive/Functional Approach or Target?

As can be seen in the previous section, it is recommended that value added VE applications be developed that avoid the redundant development of something that has already been proven effective in a simpler form. The selection of appropriate cognitive–functional targets is inextricably related to this, but requires an additional understanding of the match, or “good fit criterion,” between these targets and the current capabilities of VE technology. At the present time, VEs can be said to offer certain specific “attributes” (or ingredients) that would seem to be well matched for neuropsychological approaches. In general terms these include such fundamental attributes as the capacity to expose subjects to precisely administered, dynamic, 3-D, visual and auditory stimuli, as well as the capacity to involve a person within an interactive/immersive procedural activity with fuller response measurement capability. These basic attributes appear to provide the necessary ingredients for VE NA and CR applications in a number of areas and may provide “good fit” for scenarios designed to mimic real-world challenges without the loss of experimental control that often occurs in naturalistic settings. For example, as described in the attention process section, an HMD-based VE for the assessment of these processes could improve on existing methods. The attributes of an HMD-based VE appear to fit well with the need for precise stimulus control and response measurement required for attention-targeted applications. An HMD-based VE allows for the systematic simultaneous/sequential presentation of stimulus challenges and distractions within a contained setting in a manner that is not possible using traditional methods. This reasoning also holds for VEs designed to address the integrative attention control required for executive functions. The complexity of this cognitive process makes assessment and rehabilitation a questionable

process using traditional psychometric methodologies (Pugnetti et al., 1995a), and VEs offer a unique capacity to address these functions. This was seen in a case study where a VE was successful in detecting deficits that had been reported to be limiting the patient's everyday performance, yet were missed using standard NA tests (Mendoza et al., 1998).

The NA and CR of spatial ability is another area that is particularly well matched with the unique stimulus and response assets of a virtual environment. The capacity to design 3-D objects that can be presented in a specific and consistent manner and manipulated by the user contingent on a variety of task demands could be a powerful tool for these applications. The attributes of a VE appear to be well matched to these challenges, and this is reflected in the number of spatial ability applications that are currently aimed at clinical populations, as reviewed in sections 3.3, 3.4, and 3.5. On the other hand, complex reasoning abilities that have heavy requirements for language-based representation, and declarative memory may be more difficult to address at the current state of VE development, although this may well be possible in the near future. The areas addressed above are not presented as an exhaustive list of the areas where a VE might be of value. Rather, they are meant as examples of the type of analysis that we have applied to judge the fit between VE applications and NA and CR targets in this nascent field. Also, we hesitate to address target areas that do not suggest a good match with the attributes of a VE or where the technology is not in a state of readiness to add to what currently exists with traditional methodologies. Our vision of VEs may reflect gaps that others do not possess.

4.3 How Well Does a VE Approach Match the Characteristics of the Target Clinical User Group?

Awareness of the interaction between assessment and treatment strategies and patient characteristics specific to various clinical conditions has guided the development of mental health approaches for many years (Paul, 1969). The usefulness of VE applications across different clinical populations requires the same measured consideration of these issues that is found in user-centered design studies with normal groups. The unique psychological, cognitive, and functional characteristics that are commonly seen in different types of clinical conditions must be considered, along with an informed sensitivity to the vulnerabilities of these groups. Clinical user groups may differ in areas such as apprehensiveness to use an HMD, reality testing, capacity to learn to operate in a VE, susceptibility to side effects, and verbal reporting ability. Awareness and preparedness for these issues are necessary for ethical reasons (see chap. 33, this volume) as well as treatment efficacy concerns. Expected benefits of using a VE approach need to be tempered by a clinical vigilance for possible unanticipated consequences that could limit the applicability of a VE approach for certain clinical conditions. Thus far, the clinical application of VEs has appeared to be fairly thoughtful and rational, possibly owing to both the technology's limited availability and the professionalism of the innovators of these early applications. However, as the technology becomes more accessible, individuals who become enamored with virtual methods but lack sensitivity to the relevant clinical and ethical concerns may be in a position to develop VE applications. The resulting systems could be of questionable utility at best, and have the potential to do harm at the worst. Although such incidents have yet to appear in the clinical lore and literature, the possibility exists that these types of events may be selectively overlooked and/or go unreported.

When working with patient groups, an ethically based screening procedure is necessary to minimize the possibility of inducing harmful consequences on the patient via a VE approach. Persons displaying comorbid features of various psychotic, bipolar, paranoid, substance abuse, claustrophobic, or other disorders where reality testing and identity problems are evident, may be ill advised to participate in a virtual environment. It is also essential to anticipate

possible difficulties that could arise due to specific characteristics that exist for persons with CNS dysfunction and resulting neuropsychological impairments. For example, orientation and equilibrium difficulties are often sequelae of CNS dysfunction. Proper screening and ongoing monitoring guidelines are of vital importance with such individuals. Although it is the cognitive/functional impairments that are most often the focus with these groups, significant emotional, social, and identity difficulties commonly exist within the total pattern of CNS dysfunction (see chap. 33, this volume). Although a full discussion of the complex issues involved with these clinical groups is beyond the scope of this chapter, some brief discussion of age-related user issues is possible.

Issues regarding the age of the participants should be considered in decision making on the applicability of VE technology. There now appears to be a developing literature on VE applications with young populations (Cromby et al., 1996; Escamilla, Falkinstein, Chang, Schneider, & Zeltzer, 1997; Inman et al., 1997; McComas, Pivik, & Loflamme, 1998; Stanton et al., 1998; Strickland, 1996) that can allow examination of this issue. Youthful populations, having grown up during the age of computer and video games, may be more at home with VE setups. The reports to date with youthful populations mainly involve the training of functional skills that involve learning of the spatial characteristics of a target environment, sometimes requiring navigation ability. These studies have tested children and teenagers in VEs targeting wheelchair operation, spatial navigation, and supermarket shopping. Results suggesting successful assessment, training, and transfer to the real world have been published and these studies indicate that VE cognitive-functional applications can be usefully applied to these youthful clinical groups with few reports of negative complications. The occurrence of cybersickness (see chap. 30, this volume) and aftereffects (see chaps. 31 and 37–39, this volume) has not been reported to be problematic with these younger populations, although systematic assessment has not often occurred (though it should become a mandatory component of all VE investigations). The initial concerns that children might have difficulties adjusting to an HMD (see chaps. 37 and 41, this volume) did not appear to be borne out in some of these applications. For example, positive results were reported for two autistic children adapting to an HMD (Strickland, 1996). However, mixed results were observed by Inman et al. (1997) in a wheelchair navigation training VE tested with young children. In this work, it is reported that many of the users had a preference for using a large TV monitor instead of the HMD, although this was not reported to decrease performance or interest. Generally, these applications have shown the potential for positive impact on these children's chances for functional independence in the future. This is an important factor as a good number of CNS conditions that affect cognitive-functional behavior occur with children. Also, since the peak incidence for TBI is with the 15 to 24 age group, it would appear that many "youthful" persons could potentially benefit from VE cognitive-functional applications, and this age group appears to be safe to target for these purposes. However, care should be taken when there is a question about the person's capacity to verbalize their experience of discomfort due to VE exposure. In fact, this is a concern with any age group where verbal expression is suspected to be compromised.

On the other end of the age continuum, only a few studies have reported on VE applications for older populations (over 65). For example, Liu, Miyazaki, & Watson (1999) reported on the use by the elderly of an HMD driving scenario with good results, and Rose et al. (1999) tested a group of stroke patients (average age of 65) on a flat-screen system assessing spatial versus content memory following navigation within a virtual environment. Relevant issues for this age group include limiting factors such as visual difficulties, problems with mobility and balance, and susceptibility to cybersickness (see chap. 30, this volume) and/or aftereffects (see chaps. 31 and 37–39, this volume). There is also a similar dearth of research with older populations within the general simulation technology literature that could provide some direction for VE development.

Research into this age group's susceptibility for cybersickness and aftereffects (see section 4.6) would be a useful starting point for this area. If older persons are found to satisfactorily tolerate a VE application, these tools could be of particular utility to address the progressive cognitive–functional impairments seen with the increased incidence of neurodegenerative disorders observed in older populations (see chap. 18, this volume). One area of concern pertains to the observation that traditional rehabilitation approaches for progressive CNS disorders, such as AD, have met with limited success. Virtual environments designed to deliver functional training for elderly populations may fare better, and this underscores the need to determine VE feasibility for older persons. Functional training VEs, which exploit preserved procedural learning abilities in a relatively safe environment, could serve to help maintain adequate performance of IADLs needed to maximize safe living and functional independence. By contrast, procedural VE rehabilitation approaches may be of limited value for elderly persons with certain CNS disorders. Individuals with Huntington's disease often manifest difficulties with procedural learning (Butters, Salmon, Heindel, & Granholm, 1988), and these patients may not be able to benefit from a highly procedural virtual learning environment. In this case, VE applications for this group might be more usefully aimed at *assessing* the decline of this type of "hands-on" learning as a tool for measuring disease progression or for determining the efficacy of different treatment approaches.

Thus far, the few VE applications that have targeted clinical user groups appear to have been relatively benign. This may reflect either appropriate caution in the development of these applications or selective reporting. It is important that negative reactions to VE exposure be documented and shared with the VE community. In this manner, the causes of these problems can be addressed and understood, and future methods to prevent the reoccurrence of such problems can be developed. As the field continues to develop and more objective results become available, we will be in a better position to formalize the advisements and proscriptions for VE use with different clinical populations. Until that time, rational caution mixed with thoughtful sensitivity to these issues will be required in order to ethically advance these applications.

4.4 What Is the Optimal Level of Presence Needed for Clinical CNS Applications?

More detailed discussions of the human factors issues pertaining to the concept of "presence" can be found elsewhere in this volume (see chap. 40, this volume). However, issues regarding presence will be briefly addressed here, as they are seen to be relevant for the conceptualization and design of VEs for NA and CR applications. The concept of presence is often cited as one of the important features of a virtual environment (Durlach & Mavor, 1995; Slater & Usoh, 1993; Stanney, 1998). Presence can be simply described as the experience a person has when in a VE of "being there." Stated another way, *presence* is "the subjective experience of being in one place or environment, even when you are physically located in another" (p. 225, Witmer & Singer, 1998). This experience is not restricted to VEs; reading a book, watching TV, and talking on the phone can all engender some level of presence. For the purposes of the present chapter, the concept of presence and how it may relate to the design and potential effectiveness of various NA and CR VEs will be examined. An understanding of the factors involved in this relationship may be important for predicting the relative value of presence for different applications. Awareness of the nature of presence "factors" that are under a developer's control in the design of VE systems could serve to guide and inform future system development targeting clinical populations. This knowledge does not formally exist at this early stage in the study of NA and CR VE applications, but it is safe to say that different cognitive–functional targets will likely have different optimal presence requirements. Such a determination will require an analysis of presence–effectiveness relationships for a range

of different target applications. Intuitive thinking regarding VEs might suggest that a large “amount” of presence would be necessary for effective NA and CR scenarios and that this may require a high degree of realism. However, the capacity to develop veridical VE scenarios that match the characteristics of the “real-world” absolutely, and which might be expected to enhance the experience of presence, is not technically feasible at the current time and may never be. Fortunately, the experience of presence is not totally dependent on the level of realism (Welch, Blackmon, Liu, Mellers, & Stark, 1996). An extreme level of VE similarity with the real world may not be necessary for the experience of presence to occur or for VEs to be effective.

Witmer and Singer (1998) suggest that the psychological states of involvement and immersion are both necessary for the experience of presence. Involvement results when a person selectively focuses attention and energy on coherent stimuli, activities, and events, and can depend on the degree of meaning and significance that the person attaches to the activity as well as the “compelling” nature of the activity. Immersion is seen as related to one’s perception of being enveloped by, included in, and interacting with environments that provide a continuous stream of stimuli and experiences (Witmer & Singer, 1998). Involvement seems to be more a function of the user’s internal characteristics (interest, motivation, etc.) and how that relates to the “nature” of the scenario. Immersion appears more related to system attributes (for example, non-HMD vs. HMD; see chap. 40, this volume). However, these characteristics are seen to operate in an interdependent fashion, and both are believed to be necessary ingredients for the experience of presence to occur. In the process of conjecturing the value of presence for clinical VE effectiveness, it may be useful to consider the immersive and involvement components of presence and how different weightings of these factors may impact the effectiveness of various applications. The “suspension of disbelief” that occurs when one is using a VE appears, in part, due to system factors (i.e., HMD vs. non-HMD, graphic quality, computer speed, etc.) and to the individual differences of the user (i.e., degree of claustrophobic concerns, capacity for a good visual imagination, past experience with VEs, etc.; see chap. 18, this volume). The design of effective clinical VEs requires an appreciation for the complex relationship between available equipment, cognitive–functional targets, and the characteristics of the clinical population. This combination may reflect Maida’s construct of “sense of engagement,” as cited in Stanney et al. (1998), whereby unique levels of presence are optimal to support certain applications contingent on the interaction of user, system, and gaming-related motivational factors.

For example, mental health VE applications for fear reduction with phobic clients have initially been shown to be effective, even though the scenarios are often somewhat “cartoonish” and would never be mistaken for the real thing (see chap. 51, this volume). The effectiveness of these scenarios may be found to rely more on the HMD-based immersion component of presence than on an involvement component. This implies that for persons who have a long history of avoiding feared stimuli, a highly immersive HMD system may be necessary to keep their awareness directed toward the modeled stimuli (immersion promoting involvement) in order to encourage therapeutic exposure. These clients would not be expected to naturally be motivated to experience the stimuli (low involvement), and therefore a less immersive non-HMD flat-screen system for this application may fall short of the level of presence needed for effective therapeutic exposure to occur. However, an HMD may not necessarily be mandatory to achieve an optimal presence level or to be effective for targeting cognitive–functional processes. Navigation studies with clinical populations have shown successful functional skills learning using flat-screen systems for persons with severe learning or motor disorders (Cromby et al., 1996; Stanton et al., 1998). These results suggest that for certain populations and training objectives, an HMD may not always be necessary. However, HMDs may still be the most efficient tool to support the immersion-based component of presence and may be necessary for VE effectiveness with certain clinical targets. More immersion may be especially useful

for systems that target the assessment of cognitive processes, where HMD-fostered immersion would be needed to eliminate external “distractions” that would intrude on the controlled environment (Rizzo et al., 1999). Also, applications that require HMD immersion to better replicate a dynamic environment may enhance ecological validity and promote better transfer. These areas are not meant to be exhaustive, but rather illustrate examples where the immersion component of presence is emphasized.

Certain VE applications exist where the immersive component is less important, and involvement can be promoted to support a level of presence that may be necessary for effectiveness. This is obviously seen with flat-screen computer games that create a sense of presence due to their involving features (gaming, interesting graphics, sound effects, etc.). Likewise, less immersive VEs may effectively address certain NA and CR targets by leveraging the involvement component of presence. However, users in targeted clinical groups may need to possess more motivation to participate as well as have intact attentional abilities in order to stay focused and benefit from less-immersive approaches. Virtual environment applications that target visuospatial processes and more molecular motor abilities may be usefully addressed in this manner. In this regard, our lab has developed a series of visuospatial skills assessment and training tasks that utilize the ImmersaDesk system. This system is a drafting table projection-based VE device that employs stereo glasses and magnetic head and hand tracking that offers a type of VE that is semi-immersive. The size and position of the screen gives a wide-angle view of the scenario, yet the user is also able to look around and see the real physical environment. Using this system we have developed a series of visuospatial manual tasks. Unimpaired subjects that have been assessed report the tasks to be engaging (involvement), and examiners have rarely observed distraction away from the screen. Positive assessment and learning transfer effects seen thus far may suggest that for this purpose this type of presence (lower immersion and higher involvement) is acceptable for the goals of the application. However, trials with impaired populations are just beginning and the effectiveness of this system for those groups remains to be seen.

4.5 Will Clinical CNS Target Users Be Able to Navigate and Interact With the VE in an Effective Manner?

The method of navigation (see chap. 24, this volume) and requirements for interaction (see chap. 13, this volume) in a VE are important factors to consider in the design of systems for use with clinical populations. Although human-computer interaction for general computer use by persons with physical disabilities has been addressed for a number of years, VE usage by persons with cognitive-functional impairments requires additional focus. Virtual environments have been characterized as an “intuitive interface” that allows a person to interact with a computer (and data) in a naturalistic fashion (Aukstakalnis & Blatner, 1992). In this regard, Wann and Mon-Williams (1996) suggest, “The goal is to build [virtual] environments that minimize the learning required to operate within them, but maximize the information yield” (p. 845). This “interactional intuitiveness” issue becomes more relevant when designing VEs applied to persons with cognitive-functional impairments. In order for these individuals to be in a position to benefit from a VE, they often must be capable of learning how to navigate and interact within the environment.

Many modes of VE navigation (DataGloves, joysticks, space balls, etc.; see chaps. 11 and 13, this volume), while easily mastered by unimpaired participants, could present problems for those with cognitive-functional difficulties. Even if patients are capable of interacting in a VE system at a basic level, the extra nonautomatic cognitive effort required to navigate may serve as a distraction and limit targeted assessment and rehabilitation processes. In this regard, Psotka (1995) hypothesizes that facilitation of a “single egocenter” found in highly immersive

interfaces serves to reduce “cognitive overhead,” thereby enhancing potential information access and learning. Thus far, early reports on VEs with neurological patient populations using both joystick HMD-based and non-HMD systems have produced encouraging results. For example, in studies assessing executive functioning in various clinical populations (Mendozzi et al., 1998; Pugnetti et al., 1998a), teaching supermarket navigation with developmentally disabled students (Cromby et al., 1996) and teaching spatial skills to children with cognitive and motor impairments (Stanton et al., 1998), difficulties in learning to navigate in the VEs were not reported. However, navigational interface factors were not the empirical focus of these studies, and it might be expected that as VEs are designed to address more complex cognitive–functional targets, these factors may become more problematic. More naturalistic interfaces for navigation and interaction may be required to optimize performance and improve access for patients having severe cognitive or motor impairments. For example, the use of voice recognition technology may be a useful approach for some types of navigation or interaction (Middleton & Boman, 1994). This technology may also provide a more naturalistic and ecologically valid interface for some types of tasks, in addition to improving VE access for persons with motor impairments.

Another factor of critical importance is whether the means of navigation actually affects what aspects of the VE are focused on and consequently what is measured and learned in scenarios addressing cognitive processes. This was seen to be the case in a study that looked at what types of memory were enhanced during a four-room house navigation task (Attrie et al., 1996; Pugnetti et al., 1998a). As aforementioned, these studies, using a joystick interface, allowed one subject to navigate the house (active condition), whereas a yoked subject was simply exposed to the same journey but had no control (passive condition). With unimpaired subjects, differential memory performance between active versus passive groups was observed. The active group showed better spatial memory for the route, whereas the passive group displayed superior object recall and recognition memory for the items viewed along the route. Perhaps a more intuitive method of navigation may have allowed the active group to perform as well on object memory via a more equal allocation of cognitive resources. Also, this navigation method may have taxed the subjects’ divided attention capacity and thereby influenced the memory results found using this paradigm. These issues may be particularly noteworthy for the development of VEs designed to address the NA and CR of attention processing.

Increased generalization of learning to “real-world” performances might also be expected as the method of navigation and object interaction more closely resembles the requirements of the “natural” or target environment. Conversely, reduced motivation may result when a person’s first VE experience is characterized as “more work than it is worth” when confronted with an unnatural or awkward navigational interface. One obvious example of an effective match between the mode of VE navigation and the real-world objective is with the training of motorized wheelchair navigation skill in children with cerebral palsy (Inman et al., 1997). In this application, the controls for the motorized chair in the virtual application are essentially identical to the controls used in the child’s real-world environment. This would be an “ideal” match between the VE navigation mode and the demands of the actual targeted behavior. However, this sort of one-to-one correspondence is relatively rare for VEs having more complex navigational and interactional demands. It might be interesting to note any difference in effectiveness that might occur if the learning in this scenario was directed toward the operation of a standard manually operated chair. More effective transfer of this skill would be expected with the original VE application and functional target. However, if equal criterion performance was found, it might support the idea of the robustness of training with nonidentical navigational devices and would be quite interesting indeed. In essence, development of more naturalistic interfaces could be of vital importance for precise assessment and rehabilitative targeting, and could also have implications for the generalization issues discussed in section 4.7.

4.6 What Is the Potential for Side Effects Due to the Characteristics of Different CNS Clinical Groups?

In order for VEs to become safe and useful tools for NA and CR applications, the potential for adverse side effects needs to be considered and addressed. This is a significant concern as the occurrence of side effects could limit the applicability of VEs for certain clinical populations. Two general categories of VE-related side effects have been reported: cybersickness (see chap. 30, this volume) and aftereffects (see chaps. 31 and 37–39, this volume). Detailed discussion of these issues and analysis regarding normal populations is covered extensively in other chapters in this volume, so the focus here will be on reports with clinical groups.

A recent review of this area (Stanney et al., 1998) targets four primary issues in the study of VE-related side effects, which may be of particular value for guiding feasibility assessments with different clinical populations. These include: “(1) How can prolonged exposure to VE systems be obtained? (2) How can aftereffects be characterized? (3) How should they be measured and managed? (4) What is their relationship to task performance?” (p. 6). These questions are particularly relevant to developers of NA and CR VEs, as these systems are primarily designed to be used by persons with some sort of defined diagnosis or impairment. It is possible that these users may have increased vulnerability and a higher susceptibility to VE-related side effects, and ethical clinical vigilance to these issues is essential. Particular concern may be necessary for neurologically impaired populations, some of which display residual equilibrium, balance, perceptual, and orientation difficulties. It has also been suggested that subjects with unstable binocular vision (which sometimes can occur following strokes, TBI, and other CNS conditions) may be more susceptible to postexposure visual aftereffects (Wann et al., 1996; see chap. 37, this volume). Unfortunately, statistics on the occurrence of side effects with clinical populations have been inconsistently reported in the published literature to date. This is an aspect of data reporting on VEs that should be changed. Some type of assessment and reporting of VE-related side effects, whether using in-house designed ratings scales or standardized subjective and objective measures (Kennedy, Lane, Berbaum, & Lilienthal, 1993), should be standard procedure for presenting results on systems in this area.

Thus far, anecdotal reports of flat-screen scenarios used with clinical populations have not indicated problems with these less-immersive systems. However, it does not appear that much systematic assessment has occurred, or in some cases the verbal report of the patients may have been compromised. Also, most clinical applications appear to use short periods of exposure (10 to 20 minutes), and this may have served to mitigate the occurrence of side effects based on the scant reporting in this literature. In one of the first studies to present systematic data for an HMD-based system used with CNS populations, 11 neurological patients were compared with 41 non-neurological subjects regarding self-reported occurrence of side effects (Pugnetti et al., 1995b). Subjects were tested in a VE specifically designed to target executive functioning with CNS populations. The results suggest a reduced occurrence of VE related side effects relative to other studies using the same assessment questionnaire, the Simulator Sickness Questionnaire (SSQ; Kennedy et al., 1993), with an overall rate of 17% for the total sample. The authors concluded that the neurological subjects appeared to be at no greater risk for developing cybersickness than the non-neurological group. In a more recent study, Pugnetti et al. (1998c) reported side effect results comparing 36 patients having mixed neurological diagnoses, with 32 normal controls for a 30-minute VE exposure using the system described above. Using a variety of self-report questionnaires, assessments were conducted prior, during, and following VE usage, and no differences were found between the groups on any of the side effect measures. It is important to note, though, that the patient group was recruited from those with stable neurological conditions (good bilateral visual acuity, no epilepsy, preserved dominant handedness, and no psychiatric, vestibular, or severe cognitive

disorders), and this screening procedure may have contributed to the low level of side effect occurrence. The screening of patient groups, as was prudently done by these authors, may be the safest course of action until more specific and "cautiously" acquired data become available from more impaired populations, particularly regarding the objective assessment of perceptual aftereffects (see chaps. 37–39, this volume).

While these initial findings are encouraging, further work is necessary to specifically assess how the occurrence of side effects is influenced by factors, such as the type and severity of neurological trauma, specific cognitive impairments, prior VE exposure, length of time within the VE, and characteristics of the specific VE program. This is an essential step in determining the conditions where VEs would be of practical value with CNS clinical groups. A useful tool for monitoring VE-related side effects is the Simulator Sickness Questionnaire (Kennedy et al., 1993). While more involved "objective" measures may exist (see chaps. 37–39, this volume), particularly for the measurement of aftereffects, SSQ data is relatively simple to collect and may serve as a low-cost method to begin to specify and document the basic occurrence of VE side effects in clinical populations (see chap. 30, this volume). Until better data on these issues are obtained, extra caution may be needed with some applications. For example, since we cannot be confident regarding the absence of potential perceptual aftereffects occurring in our current study with an elderly group (over 65 years old) testing visuospatial abilities, we have money built into our grant to provide transportation to and from the test site. The worst thing for the user, the field, and us would be for an elderly person to have a car accident driving home after participating in an "experimental VE setting" where subjects were exposed to visuospatial manipulations. These concerns must be addressed in order to assure a positive course for developing VE applications for persons with CNS disorders.

4.7 Will VE Assessment Results and Treatment Effects Generalize or Transfer to the "Real World"?

A fundamental issue having important implications for the ultimate utility of VEs for clinical applications is the concept of generalization of measurement and treatment. In a classic review from the applied behavioral psychology literature, Stokes and Baer (1977) place strong emphasis on the need to plan and program for generalization when designing assessment and treatment interventions. This is no less important for the design and implementation of VEs for NA and CR applications. In the area of neuropsychology, improved generalization of NA and CR results is viewed as one of the primary expected benefits of using VEs (Rizzo et al., 1997). Support for this expectation can first be seen in the predecessor field of aviation simulator research. In an article on theoretical issues concerning generalization and transfer of training from aircraft simulators, Johnston (1995) cites a transfer effectiveness ratio in the aviation simulation research of .48. This ratio indicates that for every hour spent in aviation simulator training, one half hour is saved in actual aircraft training. However, while it is intuitively seductive to assume that VEs are "just another form of simulation" and that generalization will be promoted, research specific to VEs must be examined (see chap. 19, this volume). As VEs are developed to assess and treat various cognitive-functional targets, it will become increasingly important to demonstrate that the results have some relevance or functional impact on users' real-world ability. For example, initial psychological studies with VE scenarios designed to treat phobias have shown that fear reductions accrued in a VE generalize to the person's real-world functional behavior (Wiederhold & Wiederhold, 1998; see chap. 51, this volume). In these cases, clients were able to walk across real bridges, go up glass elevators, ride in aircraft, and participate in areas of everyday life in which they were limited prior to VE treatment. Such evidence of generalization of treatment from the VE to functional activities in everyday living has encouraged researchers and clinicians working in

other areas with the hope that NA and CR VEs can actually produce tangible benefits for clinical populations.

Three types of generalization or transfer have been described that have relevance to the design of systems and studies investigating VE-produced transfer (Gordon, 1987). These are: (1) transfer of gains on the same materials on separate occasions; (2) improvement on similar but not identical training tasks; (3) transfer from the training environment to day-to-day functioning. From this framework, a VE for training of some hypothetical visuospatial ability would show good generalization if improvements were seen across multiple VE sessions, on pencil-and-paper measures of the skill, and observed in a real-life task such as assembling a piece of furniture or finding one's way home. These types of generalization are of similar concern for performance measurement used for assessment purposes. The emphasis on any one of these forms of generalization will depend, of course, on the goals of the application. At this stage of VE development the primary emphasis has been on generalization from a VE environment to the actual "real-world" environment. How well suited a VE is for this purpose may be related to a variety of factors and further study with clinical populations in this area is needed. For example, one investigation with unimpaired participants reported that a short period of VE training for spatial navigation of a maze was no more effective than map training, although with longer exposure time, VE training eventually surpassed real-world training (Waller et al., 1998). This finding illustrates the importance of temporal parameters that may influence learning and generalizability in virtual environments. When designing VEs for rehabilitation purposes, this factor may be particularly relevant, especially for persons with impaired learning abilities.

While support has grown for the idea that VEs can promote generalization and transfer in unimpaired groups (see chap. 19, this volume), the research with CNS groups is limited. Evidence for generalization with clinical groups has mainly appeared in the form of positive learning transfer from non-HMD virtual training settings to the real world on various navigation training tasks (Brooks et al., 1999; Cromby et al., 1996; Stanton et al., 1998). Positive generalization of results for an HMD-based VE targeting the assessment of executive functioning has also been reported in a case study (Mendozzi et al., 1998). In this case, the patient's everyday performance was reported by family members to be impaired, yet traditional neuropsychological assessment tools suggested normal functioning. By contrast, the VE was better able to detect deficits that had been reported to be limiting this patient's everyday functioning. These findings support the idea that VEs may provide generalizable results for the testing of cognitive-functional behaviors in situations that are ecologically valid. However, these investigations represent first steps in determining whether VE-based NA and CR can foster generalization and transfer to other settings, particularly the real world. Generalization concerns have been fundamental in the evaluation of the effectiveness and value of NA and CR approaches, making it essential that intuitive expectations of positive VE results in this area be, in fact, supported with quality research. This will be vital in order for a VE approach to be taken seriously for NA and CR purposes.

5. CONCLUSIONS

The information presented in this chap. is an attempt to describe the status of the current literature and the reasoning behind the application of VE technology for NA and CR purposes with CNS clinical populations. However, the potential benefits that could be derived from VE technology are equaled by the amount of what we do not know at this time. Although a fair amount of the VE literature targeting clinical populations consists of research designs employing good methodology and statistical analysis, much of the initial work in this area is

limited by a number of factors. These include inadequate control groups, inconsistent reporting of statistics, and what appears to be a lack of a comprehensive long-term plan to address important issues. This is not meant to slight the innovative work of scientists and clinicians that have begun the difficult work of exploring the practical applications and feasibility of this emerging technology. Often with any new area of study, initial efforts consist mainly of exploratory pilot projects designed to determine potential value and serve as a springboard for future funding opportunities that will provide the support needed for more serious in-depth investigation. The current status of research on NA and CR VEs reflects this early stage of development. However, the field is at a turning point where the initial findings that hint at the potential of this technology must be further explored and developed. Awareness of the important issues and knowledge that has been uncovered thus far should support the building of more sophisticated investigations. The value of pursuing this goal is reflected in a recent National Science Foundation proposal announcement (National Science Foundation, 1998), where it is stated that, "Computer simulation has now joined theory and experimentation as a third path to scientific knowledge. Simulation plays an increasingly critical role in all areas of science and engineering . . ." (p. 1). In order translate this hopeful view into useful application, systematic research is needed to provide answers to the basic issues and questions that were discussed throughout this chapter.

It is recommended that future clinical VE studies include some recording and reporting of side effects. This can, at a minimum, be attempted by using variously available questionnaires (see chap. 30, this volume). The same recommendation can be made for the measurement of presence factors via the use of available rating scales (see chap. 40, this volume). Information regarding both side effects and presence acquired with these basic tools might provide the field with useful information that could aid in understanding the strengths and limitations of a VE approach for certain populations and for specific targets. A primary area that warrants in-depth exploration involves the issue of generalization or transfer of training (see chap. 19, this volume). This issue is at the crux of the presumed value of VE applications and requires considerable forethought when developing an experimental design for any type of assessment and treatment study, and is no less important in the study of VE approaches. There is a good number of excellent transfer studies that are coming out of the human factors literature on VEs, and these need to be carefully examined for the insight and tools that they can provide in the construction of better designs for specific NA and CR applications with clinical populations. Consideration of the specific characteristics commonly observed with different clinical populations and how they could be addressed in the design of navigation and interaction methods within a VE is also required (see chaps. 13 and 24, this volume). Finally, an assessment of the match between the assets found in a VE and the requirements of the specific cognitive-functional targets needs to be continually addressed.

The brief sampling of methodological, conceptual, and pragmatic issues presented in this chapter suggests some very basic considerations for the development and application of NA/CR VEs for use with clinical CNS populations. Virtual environment technology is at the very beginning stages of development in terms of our understanding on how to scientifically maximize its potential usefulness and value for clinical applications. As a larger body of VE-related literature develops, we will be in a better position to consider the standards that should be applied to research-based and clinically oriented NA and CR applications. Future integration of physiological monitoring, brain imaging, and eye-tracking technologies within VEs guarantee new application domains waiting to be explored once more basic parameters are addressed. The research conducted thus far applying VE technology to clinical CNS populations, while still in its infancy, has produced initial results that are encouraging. As the technical capabilities for producing these systems continue to improve, it will be necessary that our conceptual and methodological understanding of VE technology keep pace. If this concurrent progress takes

place, the remaining challenges will exist only in the limits of our ethics, clinical sensitivity, and powers of imagination.

1. INTRODUCTION

Virtual environment (VE) technology is currently being used to treat phobias and other psychological disorders. This chapter reports a brief collection of pioneering and current research activities that introduce an innovative paradigm in psychotherapy that is termed virtual reality therapy (VRT).

Behavioral therapy techniques for treating phobias and other psychological disorders include exposing the patient to anxiety-producing stimuli on a graded scale, known as systematic desensitization. These stimuli can be generated either through the patient's imagination or in actual real-life situations. In using systematic desensitization techniques, many patients appear to have difficulty imagining the prescribed anxiety-evoking scenes. They also seek to avoid experiencing real-life situations that trigger their fears. As a learned behavior, this avoidance lowers their anxiety, reducing public embarrassment but it does nothing to relieve them of their fears.

VRT can overcome some of the difficulties inherent in the traditional treatment of phobias. VRT, like current imaginal and in vivo modalities, can generate stimuli that are useful in desensitization therapy. VRT can provide stimuli for patients who have difficulty imagining fear-producing triggers and/or are too phobic to undergo real-life experiences in public. Unlike in vivo systematic desensitization, VRT can be performed within the privacy of a room, thus avoiding public embarrassment and violation of patient confidentiality. VRT can generate stimuli of much greater magnitude than standard in vivo techniques. Since VRT is under the control of the patients, it may appear safer to them and, at the same time, more realistic than imaginal desensitization. VRT also has the advantage of greater efficiency and economy in delivering the equivalent of in vivo systematic desensitization in the therapist's office.

The idea of using VE technology to combat psychological disorders was conceived within the Human-Computer Interaction Group at Clark Atlanta University in November 1992. Since then we have successfully conducted pilot experiments in the use of VE technologies for the treatment of specific phobias: fear of flying (North & North, 1994; North, North, & Coble, 1996b, 1996a, 1997); fear of heights (North & North, 1996; North et al., Coble, 1996b; Rothbaum et al., 1995); fear of being in certain situations (such as a dark barn, an enclosed bridge over a river, and in the presence of an animal [e.g., a black cat] in a dark room, North et al., 1995b, 1995a, 1995a, 1996c); fear of public speaking (North et al., 1996b, 1997); and obsessive-compulsive disorder.

2. APPLICATIONS OF VRT

2.1 Fear of Flying

Two case studies show the effectiveness of VRT in treating the fear of flying. The first experiment, conducted in late November 1992, had to do with a 32-year-old married woman, a human-computer interaction group researcher. She was diagnosed and treated for fear of flying using an existing virtual scene. The virtual scene was a simulated city running on a Silicon Graphics computer. This scene originally was created for research on an innovative navigational technique for virtual environments. The subject participated in eight sessions, each lasting about 30 minutes. She reported a high level of anxiety at the beginning of each session, gradually reporting lower anxiety levels after remaining in the virtual situation for a few minutes, and eventually reported an anxiety level of zero. To investigate the transfer effect of VRT to the real world she was flown, in the company of the therapist, in a helicopter for approximately 10 minutes at low altitude over a beach on the Gulf of Mexico. As with the VRT sessions, she reported some anxiety at the beginning but rapidly grew more comfortable. Now the subject comfortably flies for long distances and experiences much less anxiety (North & North, 1994; North et al., 1996b, 1996a, 1997).

In September 1995, a 42-year-old married man who conducts research at Clark Atlanta University sought treatment for his fear of flying. The subject's anxiety and avoidance behaviors were interfering with normal vocational and personal activities. For example, he was unable to travel to professional conferences, visit relatives, or take a vacation by air. The subject, accompanied by a virtual therapist, was placed in the cockpit of a VE helicopter and flown over a simulated city for five sessions. The modified 11-point (0 for complete calm and 10 for complete panic) Subjective Units of Discomfort (SUD) scale was used to measure the degree to which the subject was affected by VRT. In VRT treatment, the subject's anxiety usually increased as he was exposed to more challenging situations and decreased as the time in those new situations was increased. The subject experienced a number of physical and emotional anxiety-related symptoms during the VRT sessions, including sweaty palms, loss of balance, and weakness in the knees. The VRT resulted in both a significant reduction in anxiety symptoms and the ability to face the phobic situation in the real world. The subject at this time is able to fly with reasonable comfort (North et al., 1996a, 1996b, 1997).

Virtual environment software developed for treatment of fear of flying was used in two additional case studies. Hodges et al. (1999) and Wiederhold, Gevirtz, and Wiederhold (1998) reported the successful treatment of two female patients suffering from this phobia. During 20 minutes of VRT, the patients wore a head-mounted display (HMD) and viewed three-dimensional (3-D) computer-generated images of several flying scenes, including sitting in a plane with the engines off, sitting in a plane with the engines on, pushing back to taxi, taxiing

down the runway, taking off, flying in good weather, flying in turbulent weather, and landing. Self-report scores on questionnaires relating to fear of flying and attitudes toward flying were positively changed after the VRT session.

2.2 Agoraphobia

We conducted a controlled comprehensive study on the effectiveness of VE technology in the treatment of psychological disorders, beginning in 1993. Specifically, we assessed the effectiveness of VEs in the treatment of agoraphobia, the fear of being in places or situations from which escape may be difficult or embarrassing. Sixty participants were selected for this study. Thirty were placed in the experimental group and 30 were placed in the control group.

The VE system for this study consisted of a stereoscopic HMD (CyberEye, General Reality Company), an electromagnetic head-tracker (Flock of Birds, Ascension Technology), and a DataGlove (Power Glove) worn by the participant to allow interaction with objects in the virtual environment. Interactive imagery was generated by software developed at the Human-Computer Interaction Group and Virtual Reality Technology Laboratory at Clark Atlanta University, executed on a Silicon Graphics Workstation and Pentium Personal Computer (VREAM Virtual Reality Development Software). Several VE scenes were created for use in the therapy sessions, including these:

- A series of Balcony Scenes, consisting of four balconies attached to a tall building. The balconies were at ground level, second-floor level (6 meters), 10-floor level (30 meters), and 20-floor level (60 meters).
- Empty Room Scene, consisting of four walls, ceiling, and floor. The room was 4 by 6 meters in size, with only one door (entrance and exit). There were no windows or furniture in this room.
- Dark Barn Scene, consisting of a barn in an open field. The interior of the barn was black (simulating darkness). The barn had a wide door so participants could exit as quickly as they wished. There were several dark-colored objects inside the barn.
- Dark Barn with a Black Cat Scene. A black cat was simulated within the dark barn. The black cat was placed on top of an object but was not visible from outside the barn. In order to see the black cat, the participant had to enter the barn and look to the right.
- Covered Bridge Scene, containing a bridge (10 meters high) that ran across a river, had walls on each side and a ceiling. There were two windows on each of the walls. Dark colors were used to simulate a closed environment.
- Elevator Scene, consisting of an open elevator (no walls or ceiling) located in the atrium of a 49-story hotel.
- Canyon with Bridges Scene, containing three bridges of different heights spanning the canyon from one side to the other. A river ran through the bottom of the canyon. The bridges varied not only in height but also in apparent steadiness. The lowest two bridges (7 and 50 meters) appeared safe and solid. The highest bridge (80 meters) was a rope bridge with widely spaced wooden slats as the flooring.
- Balloons Scene, consisting of three hot-air balloons at different heights. The first balloon was 20 meters high, the second balloon 30 meters high, and the third balloon 40 meters high. A one-floor building and a four-floor building were in the scene.

Only participants in the experimental group were exposed to the VRT treatment. In the initial laboratory session, which lasted approximately 20 minutes per participant, the VRT

participants were familiarized with the VE equipment. During this session, VRT participants also eliminated any of the eight scenes described above which did not cause anxiety and ranked the remaining scenes from least to most threatening. For the VRT participants' subsequent eight sessions, which were 15 minutes each for 8 weeks (one session per week), individual VE desensitization was conducted in a standard format. The first session began with the least threatening level of the participants' least threatening scene. The SUD was administered every 5 minutes. Participants progressed systematically through each level of a scene, and then moved to their next most threatening scene. This progress was totally under the control of the participant, with the exception that if a participant's SUD score was two or less, the experimenter urged the participant to move up to the next level or next scene. Each session after the first began at the scene and level at which the participant's previous session ended. After eight weeks, a posttest of all participants in the experimental and control groups was conducted to obtain Attitude Towards Agoraphobia Questionnaire (ATAQ) and SUD scores.

VRT appeared to be effective in the treatment of individuals with agoraphobia. Negative attitudes toward agoraphobic situations decreased significantly for the VRT group but not for the control group. The average SUD scores decreased steadily across sessions, indicating habituation.

For a complete and detailed report of this study, readers may refer to the publications in the *Virtual Reality Therapy Book* (North & North, 1996), *CyberEdge Journal* (North, North, & Cobb, 1995b), *International Journal of Virtual Reality* (North, North, & Cobb, 1995a), or *Presence: Teleoperators and Virtual Environments* (North, North, & Cobb, 1996c).

2.3 Acrophobia (Fear of Heights)

Twenty college students took part in the first acrophobia study, conducted in collaboration with others (Rothbaum, Hodges, Kooper, et al., 1995a; Rothbaum, Hodges, Opdyke, et al., 1995b). The goal of this study was to investigate the efficacy of VE graded exposure in the treatment of acrophobia. Twenty college students who had reported fear of heights were randomly assigned to VE-graded exposure treatment or to a waiting-list comparison group. Sessions were conducted individually over 8 weeks. Outcome was assessed by using measures of anxiety, avoidance, attitudes, and distress associated with exposure to heights before and after treatment. Significant differences between the participants who completed the VE treatment and those in the waiting list were found on all measures.

Another case study also demonstrated the effectiveness of VRT in the treatment of acrophobia. After obtaining informed consent, the subject was asked to rank order a list of acrophobic situations according to the degree of anxiety arousal. During the subject's first session he was familiarized with VE technology through several demonstrations. For the subject's subsequent eight sessions, which were between 15 and 28 minutes each, individual VRT treatment was conducted in a standard format. The first session began with the least threatening level, which was at ground level near a bridge crossing a river in the middle of a simulated town. The SUD was administered periodically every 2 to 5 minutes. The progress was totally under the control of the subject, with the exception that if the subject's SUD score was zero the experimenter urged the subject to move up to the next level of the scene. At one month after treatment, the subject was asked to complete a 10-point scale (including degrees for worsening symptoms) rating the degree to which his acrophobia symptoms had changed since a pretreatment test (SUD). The results indicated significant habituation of the subject with respect to both anxiety symptoms and avoidance of anxiety-producing situations. Thus, we concluded that VRT treatment was successful in reducing fear of heights (North & North, 1996; North, 1996b).

2.4 Fear of Public Speaking

The fear of public speaking, sometimes referred to as social phobia, is a common disorder that affects many people in the world. Research into this widespread phobia was conducted through the collaboration of Clark Atlanta University (CAU), the U.S. Army Research Laboratory, and Boeing Computer Services, with special technical assistance from the Speech Improvement Company, Inc. The research may have far reaching benefits. With the assistance of the Speech Improvement Company, it may have a positive impact on clinical sessions of individuals suffering from the fear of public speaking. Additionally, the general population may benefit from this research because new technology could provide greater access to a safe, confidential, and economical approach to the treatment of psychological disorders.

Participants in the research were recruited from CAU Introductory Psychology classes. After an extensive two-stage screening process, 16 participants were selected from the pool. They were assigned to two treatment components: virtual reality therapy and a comparison group. Selected participants reported experiencing anxiety and avoidance behavior that was interfering with their normal activities. They were unable to participate in social gatherings, classes, or professional conferences.

Apparatus for this study consisted of a Pentium-based computer and an HMD with head-tracker (Virtual-I/O). Modeling was done by VREAM Company under the direction of the researchers. A model of an auditorium located in the CAU Research Science Building was created. The virtual auditorium is 48 feet wide, 100 feet long, and 55 feet high. The seating area has three sections of chairs and can accommodate over 100 people. Specialized features created for the facility include a virtual wooden podium with a speaker's stand. An amplifier with direct connection to the VE software and hardware were used in the therapy sessions. This enabled participants to hear the echo of their voices. Simulation of the real echo in the auditorium was created by a headphone attached to the HMD. The treatment schedule consisted of five weekly sessions. The sessions lasted 10 to 15 minutes.

Two assessment measures were used in this study. The first measure was the Attitude Towards Public Speaking (ATPS) questionnaire, which contains six items for assessment that range from 0 to 10 on a semantic differential scale. The second measure used was the SUD scale.

Symptoms experienced by participants during VRT included an increase in heart rate, feeling a lump in the throat, dry mouth, sweaty palms, loss of balance, weakness in the knees, and other symptoms. These symptoms also appeared in the studies that dealt with the treatment given for acrophobia, agoraphobia, and fear of flying.

Virtual reality therapy appears to be very effective in reducing self-reported anxiety. The VRT treatment resulted in both a significant reduction of anxiety symptoms (SUD and ATPS measurements) and the ability to face phobic situations in the real world. At this time several of the participants can comfortably speak in front of a crowd with improved confidence.

2.5 Posttraumatic Stress Disorder (PTSD)

Posttraumatic stress disorder (PTSD) is one of the most disabling psychopathological conditions affecting military veterans. An estimated 830,000 U.S. veterans currently have symptoms of chronic combat-related PTSD. Hodges et al. (1996) report an experiment in which virtual reality exposure (VRE) is used as an alternative to typical imaginal exposure treatment for Vietnam combat veterans with PTSD. A patient was exposed to two virtual environments, a virtual Huey helicopter flying over a virtual Vietnam countryside and a clearing surrounded by jungle. The patient was encouraged to approach the landed aircraft and fly over jungle, river, and rice paddies. The fly-through included sounds of the rotary blades, combat noises, jungle

noises, explosions, and men's voices. The pretreatment and posttreatment assessment technique was used for this case study. The patient experienced a 34% decrease on clinician-rated PTSD and a 45% decrease on self-rated PTSD after VRE treatment.

2.6 Claustrophobia

Claustrophobia is a cousin to agoraphobia but has its own peculiar characteristics. Botella et al. (1998) report VE to be effective the treatment of patients suffering from claustrophobia. The selection of claustrophobia for study was based on its unique characteristics. Clinically, claustrophobia is the functional equivalent of agoraphobia; however, there are fewer avoidance situations (Barlow, 1988; Booth & Rachman, 1992). Moreover, by itself claustrophobia may place many limits on its victims and severely impair the quality of their life. This is particularly evident in that closed places are a part of daily life. People commonly encounter elevators, planes, tunnels, cabins, tests for medical diagnosis and therapy such as computed tomography scan and magnetic resonance imaging and the like.

To increase the levels of difficulty in the "claustrophobic" environment, two different settings were created. The first was a house and the second an elevator. In each setting, several different environments existed that permitted researchers to construct performance hierarchies, with degrees of increasing difficulty.

These were the settings for VE scenes in this experiment:

1. A 4×5 meter room that has a door that exits to an external terrace and 2×4 meter garden. There is also a large window with blinds in the room. When and window are open, a blue sky can be seen and the sound of birds can be heard. The door, window, and blinds can be opened and closed in three stages. Another door in the room opens to a second room or second claustrophobic setting.

2. A 3×3 meter room in which there is no furniture or windows. The ceiling and floor are darker with a wood texture that gives the sensation of greater closure. In the center of the room there is as lectern with several buttons that permit the patient to interact with the virtual environment. The patient can also close the door of the room in three stages. Once it is closed, the patient can block it by pushing one of the buttons on the lectern. Additionally, a wall in the room can be displaced at the will of the patient by making a loud noise. The wall can also be moved by manipulating buttons on the lectern and by keeping the patient enclosed in a 1-meter-wide space.

3. A wide entry with a large window in which the large window cannot be opened; however, the window permits one to see plants growing outside. From this entry, the patient has access to the elevator by pressing a button.

4. The elevator is designed to offer different claustrophobic possibilities and threats. These threats take into account various parameters (i.e., size, placing, and the possibility of blocking the elevator). All of the possibilities created by the big elevator may be realized through the use of a small elevator.

At first, the hardware used in the experiment was a Silicon Graphics Indigo High Impact computer graphics workstation. To extend the commercial use of this technology, the VE system used in clinical psychology was adapted and used with a less-expensive personal computer. Currently, work is being conducted on a PC Pentium Pro with 128 Mg of RAM and a graphic card AccelEclipse of 32 Mg, which is being used as a hardware platform. The software used are Windows NT and World Up (Sense8).

This research has demonstrated the effectiveness of the software. It can be stated, with confidence, that the claustrophobic context can activate a high degree of anxiety in patients and

through virtual exposure victims of claustrophobia can be threatened and helped to overcome this debilitating phobia.

These results were achieved by using virtual exposure as a unique technique. This therapy was not used in conjunction with any other psychological treatment techniques. Therefore, VE appears to be very useful as a therapeutic treatment strategy.

2.7 Obsessive–Compulsive Disorders

Approximately five million people suffer from obsessive–compulsive disorder (OCD) in the United States alone. One in 50 Americans suffers from OCD, and because of the disorder they are forced to alter the normal activities in their lives. Men, women, and children of all races and socioeconomic backgrounds are affected by OCD.

Fear of contamination, fear of making mistakes, and fear of harm to another person are the most common obsessions. Common compulsions include cleaning and washing, arranging and organizing, collecting, counting, and repeating. The most common treatments for OCD are medication and behavior therapy.

Most victims of the disorder are ashamed of their uncontrollable repetitive behavior and are very concerned about what other people, who have seen their obsessive behavior, think of them. VRT has the potential to reduce a patient's embarrassment by providing privacy. VRT also offers the patient a chance to concentrate on the problem. This process may help the patient reduce information overload. It also assists the patient in releasing cognitive resources to seek an alternative to the obsessive–compulsive behavior.

North and North (2000) combined their VRT technical advancements with a program developed by Marc Degroot of Immersive Company in California to create a treatment for individuals suffering from OCD. This treatment was evaluated in a case study. Following an extensive two-stage screening process, a subject was recruited from a Clark Atlanta University Introductory Information Technology class for the study. The subject was placed in a virtual room that contained several books, pencils, and other school equipment. The treatment was administered over eight weekly sessions. The sessions lasted 10 to 15 minutes apiece. The subject was asked to pick items from the virtual room that she needed for a day at school and place them in a virtual book bag. She was asked to repeat this process until she no longer had doubts about what she had collected for her classes. She was asked to leave the virtual room and go outside the virtual house. She was then asked if she was sure about the collected items in her book bag. If she had a doubt and her anxiety level was high, she was given a chance to repeat the process until her anxiety level reached zero (no anxiety). The symptoms experienced by the subject during VRT mirrored those that most OCD patients experience during a real situation. They included obsessive and compulsive thoughts and behavior, an increase in heart rate, sweaty palms, loss of balance, and weak knees.

This OCD study indicated that VRT is very effective in reducing self-reported anxiety. The VRT treatment resulted in both a significant reduction of anxiety symptoms (SUD and ATOCD measurements) and the ability to face phobic situations in the real world. The treated subject now reports the ability to comfortably go about her daily schooling without excessive thoughts about the items she needs to have for each class.

2.8 Attention Deficit Disorders

Attention deficit disorder (ADD) is common among children. Current research indicates that between 5% and 10% of children suffer from this disorder. Many of these children are highly intelligent and creative despite wandering attention and impulsiveness. Because they have problems with short-term memory and short attention spans, they have a hard time completing

tasks. They have trouble concentrating, being easily distracted, mostly by sights and sounds. They especially exhibit problems in a group situation (Hunsucker, 1988). In general, ADD patients' problems are physical, academic, behavioral, emotional, and social.

Traditional treatment for ADD includes medications such as Methylphenidate (Ritalin), D-Amphetamine (Dexedrine), and Pemoline (Cylert). Behavioral management also includes punishment and reward techniques.

Several research studies reported in this chapter have shown that VRT provides specific stimuli that can be used in removing distractions and providing environments that get the subjects' attention and increases their concentration. Virtual environments technology can hold a patient's attention for a longer period of time than other methods can. Virtual scenes may enhance the patient's short-term memory and increase attention span. Researchers at CAU's Virtual Reality Technology Laboratory are developing several classroom situation scenes to extensively test these hypotheses. An informal pilot study conducted in this lab showed that a patient's mild ADD symptoms decreased while under VRT. Although we have used only visual stimuli, the preliminary observations are very encouraging. There is good evidence from our previous research that this kind of experience may be easily transferred to everyday activities. The ongoing ADD research will be extended to include other stimuli such as auditory and tactile. A scenario for social interaction is also under development to test the effects of VRT in teaching patients interactions needed to improve their social skills.

2.9 Autism

Virtual reality therapy has the potential of helping children with autism. This is a disorder that involves an internal distortion of the external world. Unfortunately, there are few if any effective treatment methods for children with the kind of serious learning problems that autism produces. Experiments with VRT indicate it may offer some progress toward an effective treatment. Virtual reality therapy allows controlled distortion of the environment in a way that almost matches the perception of an individual. Two intensive case studies were conducted to determine if children with autism could respond to VRT and to investigate if they might benefit from environments that such therapy can provide. Both cases showed that VRT can provide a sense of presence (see chap. 40, this volume), which in turn allows a safe and controlled learning environment for individuals afflicted by autism (Strickland, 1996).

2.10 Body Image Experience

How one views his or her own body can have an effect on one's health. Eating disorders, one of the most common pathological concerns of Western society, have long been associated with alterations in perceptual–cognitive representations of the body. Many studies have shown that the perception of one's body and the experiences associated with it represent one of the key problems of anorexic, bulimic, and obese people. These perceptions also have a strong influence on therapy. Unfortunately, the treatment of body experience problems is not well defined. Both cognitive and behavioral approaches have an influence on the level of body awareness. Virtual Environment for Body Image Modification (VEBIM) treatment consists of a set of tasks aimed at altering a patient's body image. It attempts to integrate both cognitive and behavioral therapeutic approaches within an immersive virtual environment. A study on a preliminary sample of sixty normal subjects was conducted to test the efficacy of this approach. The study showed that even a short-term application of VEBIM can partially reduce the level of body dissatisfaction without any major side effects. Nevertheless, an alteration of one's body image toward a more realistic perception might be decisive for the long-term outcome (Riva, 1997a, 1997b).

2.11 More Research on Virtual Reality Graded Exposure Therapy

Wiederhold and her associates have established the Center for Advanced Multimedia Psychotherapy (CAMP) in San Diego, California. The Center assists patients who suffer from phobias by using state-of-the-art VRT systems to combat a variety of phobias (Wiederhold & Wiederhold, 1998).

At CAMP they have investigated the use of virtual reality graded exposure therapy (VRGET) for the treatment of fear of flying (Wiederhold, Gevirtz, & Wiederhold, 1998). In one of the first studies, three groups were compared. One group received traditional imaginal exposure therapy (IET). The participants in this group, with the therapist's assistance, constructed an individualized fear hierarchy and progressed through the hierarchy based on SUDSs levels. One group, who received VRGET, also progressed through the virtual world based on SUDs levels. The other group, which received virtual reality exposure therapy plus physiological feedback (VRETpm), was progressed through the virtual world based on skin resistance levels. Heart rate, respiration rate, skin resistance, peripheral skin temperature, and brain wave activity were monitored and measured for all three groups. However, the pm group received information on physiology (biofeedback). Prior to beginning exposure therapy, all three groups were given two sessions of relaxation and breathing retraining to use as a coping mechanism while performing the exposure therapies and to use later while actually taking a real airplane flight. All three groups completed questionnaires relating to fear of flying, attitudes toward flying, and state and trait anxiety prior to beginning relaxation training, after two sessions of relaxation training, and after six sessions of exposure therapy. A 3-month posttreatment follow-up was done with all participants to see if flying behavior had changed following treatment. The study was completed in February 1999. The group receiving VRETpm was 100% successful (with success measured as ability to fly with no medication and no alcohol when contacted at 3 month posttreatment follow-up). The VRGET group receiving no physiological feedback was 80% successful, and the IET group was 20% successful.

A study that began in October 1998 is looking at the efficacy of using VRGET to treat the fear of driving. The same protocol used in the fear of flying study is being utilized in the fear of driving study. Two sessions of relaxation training are followed by six sessions of exposure therapy. This study does not, however, include an imaginal group.

A third study that began in February 1999 is investigating the use of VRGET in patients with neurovestibular disorders (see chap. 7, this volume). It is hoped that VRGET will help desensitize these patients to complex visual stimuli, which often provoke dizziness and vertigo.

3. VRT ISSUES

3.1 Assertions Concerning VRT

We can now make these assertions concerning virtual reality therapy based on the data collected and subjects' verbal reports concerning the VRT experiments.

- A person's experience of a situation in a virtual environment may evoke the same reactions and emotions as the experience of a similar real-world situation.

People who are agoraphobic in the real world are also agoraphobic in the virtual world. This assertion is based on results of our research studies on psychological treatment categories. When subjected to virtual phobic-invoking situations, participants exhibited the same types of responses as would be exhibited in real-world situations. These responses included anxiety, avoidance, and physical symptoms.

Subjects were repeatedly asked to rate their current level of anxiety on a SUD scale. The relatively high SUD scores at the beginning of each treatment session indicated that the subjects' fear structures were invoked, and SUD scores (and thus fear levels) gradually decreased as subjects remained in the virtual scene.

Actual behavior and verbalization were a second measure of anxiety. Examples of common subject behavior included subjects tightly gripping support rails and displaying reluctance to let go of the rails. Verbal expressions included such comments as these: "The higher I get, the more worried I get," "I am really there!" "It feels like being in a real helicopter," "I am afraid to fall down!" "I do not like this at all!" "I am scared!" and "I feel like I am actually on the fiftieth floor!"

Physical symptoms reported by subjects included shakiness in the knees, heart palpitations, tenseness, sweaty palms, and dizziness.

- A person may experience a sense of virtual presence similar to the real world even when the VE does not accurately or completely represent the real-world situation.

Remarkably, subject reactions consistent with phobic stimuli were experienced in spite of the fact that their virtual experience did not correspond to the real-world experience in several ways. All environments were visually extremely less detailed than a real scene, and some environments included much simpler auditory and tactile cues, such as engine sound and vibration of the Apache AH64 helicopter in the fear of flying study.

As stated previously, the subjects reported a number of physical and emotional anxiety-related symptoms, such as dizziness, sweaty palms, heart palpitations, etc. Subjects would likely not have reported these feelings if they did not perceive that they were experiencing a realistic situation, even though the VEs were not exact copies of real world scenes.

- Each person brings his or her own background into a VE experience.

Perception is in many ways just as much a product of previous experiences as of current stimulation. Each subject is a unique, specific individual, with independent experiences of reality, which are unique and different from the objective world, or so-called world of reality. The implication for VE is that the sense of virtual presence (see chap. 40, this volume) is dependent not only on the physical qualities (resolution, realism, interactivity, lag time) of the experience provided by the virtual environment, but also on what the participant psychologically brings to the environment. The very nature of the act of perception causes each person to react differently to the same real or virtual experience.

This was evidenced by SUD, ATAQ, and ATPS scores and verbal comments of subjects. Just as different individuals may react differently to a real world experience, subjects exhibited different reactions to the same virtual world experience. This point was clearly demonstrated by the variety of responses among subjects to the same phobic stimuli of the virtual scene. Several subjects went through several levels of the phobic situations without reporting any significant anxiety. On the other hand, many subjects reported differing amounts of anxiety in different levels of the virtual scene. There was major variation in the amount of time spent in each level of the virtual scenes by different subjects.

- Experience with a VE increases a participant's sense of virtual presence.

The idea that a sense of presence may increase with experience has been suggested by several researchers (Held & Durlach, 1992; Loomis, 1992; 1993; Naiman, 1992; see chap. 40, this volume). Our experiments verified this hypothesis in that the longer subjects stayed in the

virtual scene the deeper they were pulled into the virtual world and the greater their sense of virtual presence.

Based on subjects' SUD, ATAQ, and ATPS scores and verbal comments during the experiments, subjects initially felt some level of virtual presence in the phobic situation, and their sense of virtual presence increased over time or at worst was maintained during all the sessions.

- The sense of presence in virtual and physical environments is constant and subjects have to give up the sense of presence in one environment (e.g., physical environment) to achieve a stronger sense of presence in the other one (e.g., virtual world).

This assertion is based on the data (SPSVP—Sense of Presence Scale in the Virtual and the Physical environments questionnaire—and SUD) collected from subjects. Specifically, the SPSVP was designed to assess one's sense of presence of the VE and physical environment, sense of interactivity with the VE system, and one's perception of the real world in comparison to the virtual environment. The subjective measures of sense of presence in the VE increased gradually during each session. The subjective measures of sense of presence of the physical environment while attending the VE decreased gradually within and between sessions. These results led to the conclusion that the longer subjects remained in the VE, the higher was the subject's sense of presence in the VE (even when using very minimal stimuli), while the sense of presence of the physical environment decreased. This supports a theory that the total sense of presence is constant, and subjects have to divide their overall sense of presence between the virtual and real worlds.

- Subject concentration increases significantly in the virtual world as compared to the physical world, when the subject has enough interaction to develop a strong sense of virtual presence.

Each subject's interest level in the learning study was determined by a 10-point scale instrument administered at the end of each experiment. The scores ranged from very weak to very strong. The interest level and sense of control level in the virtual world were always higher than the scores in the physical world.

It was obvious that each subject was excited, enthusiastic, and eager to be in the virtual environment, rather than the physical environment. The main conclusion of this research was that memory span increased significantly in the VE as compared to the span in the physical environment, and that learner's motivation and interest levels may be maintained longer in the virtual environment. We hypothesize that at least a part of this effect may be due to the simplicity of the virtual environment, which provides less distraction to the learner.

- A person's perceptions of real-world situations and behavior may be modified based on his experiences within a virtual world.

The use of virtual environments is intended to augment human intelligence by either increasing or modifying a person's intellectual understanding of the structure or nature of objects or tasks (Bajura, Fuchs, & Ohbuchi, 1992). A VE can also modify users' perceptions of real-world situations and thus behavior in those situations.

This could readily be seen in the reports of subjects who exposed themselves to real-world phobic situations after receiving VRT treatment. In these cases, what was learned and experienced in the VE was transferred to real-world perception and behavior.

3.2 Safety

There are risks associated with virtual reality technology, as pointed out by Stanney (1995; see chap. 29 and 36, this volume), and definite steps must be taken in treatment to minimize these risks. According to Stanney, subjects at risk for psychological harm are primarily those who suffer from panic attacks, those with serious medical problems such as heart disease or epilepsy, and those who are (or have recently been) taking drugs with major physiological or psychological effects. Questions regarding these situations must be asked as a part of the screening process, and persons with these characteristics must be excluded from VRT experiences. Also, some people experience symptoms ranging from headache to epileptic seizure when exposed to visual stimuli that flickers at 5 to 30 Hz (see chap. 29, this volume). In VRT, no frame update rates in this range must be used. Furthermore, patients have to be closely observed by therapists at all times, and if there is evidence of any significant physical or psychological distress, both the patient and the therapist must have the ability to quickly terminate the virtual reality session.

Therapists are urged to ask patients to sit on a chair rather than stand up; use a modified HMD so patients can see their physical body partially; choose HMDs with a narrower field of view; and most importantly keep sessions brief (between 15 and 20 minutes long). This configuration reduces the degree of immersion (see chap. 40, this volume) but increases the physical and psychological safety of the patients (see chaps. 29–32 and 36–39, this volume). There is still a great need for research in this area, and we strongly recommend that researchers take appropriate steps in minimizing patient risks.

It must also be noted that symptoms of anxiety while under VRT are often distinctly different but may overlap with those of cybersickness (see chap. 30, this volume). The anxiety symptoms evoked under VRT are the same as the real-world experience of the patient and include shortness of breath, heart palpitations (irregular or rapid heartbeat), trembling or shaking, choking, numbness, sweating, dizziness or loss of balance, feeling of detachment, being out of touch with self, hot flashes or chills, loss of control, abdominal distress, and nausea. It is thus important that therapists distinguish between the two syndromes.

3.3 Complexity of VRT

The differences between VRT and simple desensitization and exposure therapy are important. VRT appears to be oriented more toward neurophysiological information processing theory and the accelerated integrative information processing paradigm presented by Frances Shapiro. Thus far, research indicates that VRT works very well with subjects who suffer from various kinds of phobias. Intuitive observation has also led to the belief that more than desensitization is at work during VRT treatment. Patients who were immersed in the virtual world typically would not communicate with therapists residing in the physical world. They appeared to be reliving their previous disturbing or anxiety-provoking experiences even though the virtual world did not accurately match their existential world. They would usually look repeatedly at the same simple object or objects within the virtual world. In general, VRT appears to provide a link between the reality of the client and the objective world. However, at this time there is no concrete or empirically based evidence to explain why and how VRT works. Thus, there is a great need for researchers to investigate the psychological mechanics of VRT.

4. DISCUSSION AND CONCLUSIONS

Results of the experiments reported herein indicate that VRT might be effective in reducing self-reported anxiety of subjects with a variety of psychological disorders. It should also be

noted that these studies do not speak to the relative effectiveness of VRT as compared to conventional treatments (e.g., imaginal systematic desensitization) as the control group used in most of these studies was simply a no-treatment group.

Although results of the research projects covered in this chapter are impressive, additional research is needed to more thoroughly explore the effectiveness of VRT and extend it to other psychological disorders. These studies must allow for both objective and subjective measurement of anxiety to ensure the validity of research outcomes.

The groundbreaking efforts reported herein only scratch the surface of a vast uncharted area. It will take many more innovations, and many more trials and errors to arrive at the point of fully utilizing VE in the treatment of a majority of psychological disorders. Perhaps it will take even longer to develop VRT systems that can be used by patients as self-healing machines.

5. ACKNOWLEDGMENTS

The research projects described in this chapter were sponsored by several grants from Boeing Computer Services (virtual systems department), U.S. Army Research Laboratory under contract DAAL03-92-6-0377, and supported by the Emory University and Georgia Institute of Technology Biomedical Technology Research Center (for the collaborative research of the fear of heights). The views contained in this document are those of the authors and should not be interpreted as representing the official policies of the U.S. government, either expressed or implied.

1. INTRODUCTION

How can virtual environment (VE) technology be used for design? Many designers are beginning to realize the potential of VE for design, some have been using the tool for many years. However, there are still many people and companies who could benefit from this technology but do not know where to begin. In many cases, people are even unsure as to which questions they must find answers to. This chapter addresses these issues and provides a number of key questions to consider in the procurement of a VE based design solution. A classification scheme of VE solutions for design is put forward and is illustrated by examples from current design situations. These examples serve also to provide the reader with a starting point for their own solution.

Design can be described as the process of taking a number of often conflicting criteria for the creation of an object such as form, function, cost, and manufacturability and marrying these together to form a whole (can one say that any man-made object is not designed?). A system is a complex entity involving many parts that have to function together. *Systems design*, therefore, involves putting together a complex entity with conflicting requirements to function harmoniously. This can naturally be a time consuming process, involving many people, physical prototypes, and much expense.

Computerized design and visualization based on VE technology is being increasingly used to simplify this process and at the same time reduce costs, wastage, and product development time. This chapter is aimed at people interested in learning where VE technology can be applied to systems design and includes examples from real design situations.

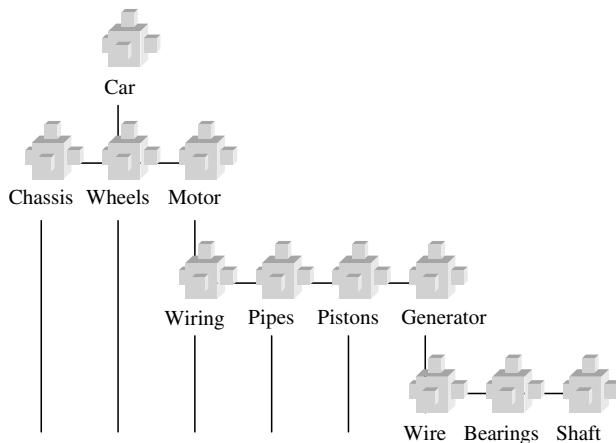

FIG. 52.1. Part of the system hierarchy of a car.

1.1 What Is a System?

System is an overused word. In essence, any collection of parts put together into a larger functional whole can be considered a system, such as an artwork, a car, computer, factory, or refinery. A system may be composed of a hierarchy of subsystems, which in turn may themselves be composed of subsystems and individual parts. So, for example, a car is composed of wheels, motor, chassis etc, with the motor being comprised of pistons, generator, wiring, pipes etc, with the generator containing wire, bearings, a shaft etc (see Fig. 52.1).

When designing such a system, a subsystem may be used ready made or designed anew. So, a new model of car may, in fact, be based on the same chassis as a previous model with a motor from a completely different vehicle. Reusing subsystems like this saves both development time and money.

1.2 Design

According to Rheinfrank, Evenson, and Wulff (1994, p. 78), design can be used for “facilitating meaningful innovation” and plays an important role in providing “useful tools and meaningful cultural artifacts” from a combination of “understanding what people do and think” and “innovative technology.” In this sense, design is considered part of the entire production process, from ideas to final product, and is not just an aesthetic afterthought. A system evolves, ideally, through an iterative process of prototypes, involving actual users, designers, and other experts until a satisfactory result has been achieved (Norman, 1988). In many cases, constraints are imposed that contradict optimal user design (such as cost and manufacturability), which must become part of the total design.

Furthermore, experts from diverse fields may be responsible for parts of the system, and they need to be able to communicate their ideas to the other people in the design team. An architect needs to be able to communicate their ideas to the builders and a common language is sought—in this case, plans and diagrams. The design process can, in itself, become a common artifact, around which communication takes place.

One major distinguishing factor between design processes is the level of end users participation. The end users are those people who will be using the final product, such as driving the car, living in the house, or wearing the shoes. In a few cases, they may also be the people using the VE tool, for example, to plan a building or to experience a concept design or artwork.

In some situations, such as the design of a new concept car, experts answer for the needs of end users using experience from previous designs and knowledge about the intended market. In other situations, such as the design of a new rehabilitation aid (see chaps. 49 and 50, this volume), end-user involvement is critical if the final result is to match the user's needs and be accepted. In this case, the design process must help to bridge the gap between the design experts and end users in such a way as to ensure that the end users are able to express their desires and can communicate these to the experts.

At what stage can design enter into the system development process? One can argue that design is present at all stages, so perhaps it is more useful to define the stages of a system conceptualization and manufacture in terms of design terminology.

A concept design is often formed before the physical system. Such designs push the barriers of conservatism in order to try new ideas. This process begins in the minds of the designers and expresses itself in rough sketches, drawings, and other informal material, later becoming more concrete, and in some cases resulting in concept sculptures or even working models. If practical considerations as to cost and manufacturability have been taken into account, these are only loosely bound, because the point of a concept design is to give the imagination free reign.

Product design is the purposeful design of an object for a particular market and must not only take into consideration form and function, but also cost, manufacturability, intended market, and so forth. Some design situations may concentrate on a particular criterion of the design, such as usability (see chap. 34, this volume), ergonomics (see chap. 41, this volume), or accessibility for disabled people (see chap. 49, this volume).

The object being designed also affects the design process. Small simple objects require few resources and minimal time to design. Combining many components into an interconnected system, on the other hand, often requires repeated prototypes, even partial manufacturing and testing for compatibility, consuming greater time and resources.

1.3 Virtual Environments and Computer-aided Design

Computer-aided design (CAD) can be considered the forerunner and heavyweight cousin of today's active design VE systems. Typical CAD programs are aimed at the single expert user, whereas VE design tools allow novices (end users, for example) to design in a more intuitive and natural way and interdisciplinary design teams to communicate ideas using the tool as the medium. Large libraries of objects can be made available without the need for expensive storage spaces. Objects can be reused and new designs can be created from the components of a previous design.

Alternatively, the term *computer-aided design* can also imply a tool that aids in the design of a system through automated procedures. For example, a tool may allow one to design a factory by positioning prefabricated and functioning elements such as conveyor belts and machinery. Or the form of a car may be interactively sculptured by hand.

Virtual environments can be used for everything from visualization (see chap. 53, this volume) and presentation of ideas to interactive design and brainstorming, from concept design to final product specification. Objects can possess all the attributes associated with a real object such as form, color, material, movement, weight, and sound. Furthermore, a virtual object can be "superreal," with extra attributes such as textual annotations, manufacturing instructions, multiplicity (alternative designs for different situations), history (playback of the design process), antigravity, and physically impossible form changes. Changes can be made interactively and more easily than if the object was physical and more prototypes can be tested than financially possible otherwise. Design alternatives and their consequences can be immediately visualized with the computer providing feedback about structural problems such as stress distribution (Vance, 1998) and object fit. Ergonomic testing can occur, with

either people models (virtual humans) being placed in the environment or end users interacting with the virtual model. Once a product design is complete further processing can take place, with the tool finally passing specifications on to the manufacturer, such as which and how much material to use, as well as design alternatives given available resources. If the object being designed is going to remain immaterial, as in the case of futuristic concept designs or computerized art, then connections to reality can be completely severed, allowing designs to break the laws of physics and achieve greater freedom of expression.

Interaction with the model can take advantage of the user-friendly input devices usually associated with VEs such as DataGloves, head-mounted displays (HMDs; see chap. 3, this volume), stereo audio (see chap. 4, this volume), and haptic feedback (see chaps. 5 and 6, this volume). Designers can interact directly with the model, perhaps moving large objects with a single movement or making shape changes by waving a hand. It must be noted, however, that current VE systems promise a higher degree of usability than can be delivered—this is still an area of active research (see chap. 34, this volume). Moreover, a VE system can be programmed to take an active part in the design process, such as:

- Performing background analyses and presenting the results within a virtual environment (for instance, finite element analysis, structural strength calculation, loading on a human body, and field of view)
- Making suggestions on issues such as form, manufacturability, color, and lighting
- Providing tools for the testing of ergonomic considerations
- Connecting parts in such a way as to minimize material usage (such as pipe and cable drawing)
- Automatically generating designs based on specifications

Networking VEs allows designers in distant locations to collaborate, coming together in the same virtual environment. Alternatively, if the design is a sequential process from one person to the next, the computer can aid by providing a track through the design sequence and annotations from one designer to subsequent ones.

However, despite the potential of VEs to support interactive design and to have a truly three-dimensional (3-D) interface, the standard tried-and-true process is still very common. One typically begins by modeling in a CAD package, importing the models into a VE package, adding movements, sound, and other features not possible in the CAD program, then allowing end users to use or view the resulting virtual environment.

1.4 Classification of Virtual Environments Design Tools

Ten characteristics of VE design tools are described below for the classification of the form and usage of VEs in a given design situation. These characteristics have been chosen to be as independent from each other as possible, though other classification schemes are equally possible. The choice of a VE design tool depends on the desired design situation, budget, and project goals. Through the example situations described later, the reader can work backward, classifying his or her own design situation to allow the definition of the system most appropriate to their needs. Each characteristic is headed by a number of questions to aid in the decision process.

1.4.1 Task

What do you want to do? What are your objectives?

It is important that a detailed task analysis is performed, with particular regard to the expected role of the VE system. Many questions must be answered to provide the basis for

further analysis, such as: What is the actual design task? Is the purpose to design a product or concept? Or is the task to document a design process in the real world? Is the intention to compare and contrast a number of prototypes? Or to test aspects such as ergonomics and manufacturability? Is the user to be allowed into the design process? In what way? Is the intention to sell an idea or product that needs to be viewed in the right context?

1.4.2 Concreteness

Do you want to design a concept or something concrete?

Is the design of an object a product that is to be finally manufactured, or is the design for conceptualization around a theme? The former requires a greater attendance to practical details such as manufacturability, structural strength, and space overlap, whereas the latter allows such considerations to be ignored. The form of the tool also varies; product design requires a certain amount of “intelligent” programming and support tools, whereas the concept design tool must allow free-form design and not hamper the designer.

1.4.3 End-User Participation

Will you involve end users in the design team?

Level of end-user participation defines, to some extent, the ease of use that a VE design tool will have. Expert designers have time to learn a complex tool, whereas end users may have to use the tool without any former training. On the one end of the scale is participatory design, in which the end users themselves have a key role in the design team with experts providing support and backup. At the other end of the scale, knowledge of the needs of end users is invested in the expert designers themselves, and end user input is restricted to perhaps a predesign survey or a postdesign evaluation. Both methods are equally valid in appropriate situations.

Participatory design is advantageous when the tacit knowledge invested in the people who work day-to-day in a particular situation must be captured. So, for example, in the redesign of a factory in a process industry, involving the factory-floor workers ensures that knowledge about how one can sense a smoothly running machine (a combination of sound, vibration, smell, and visual cues) is incorporated into the VE design of the centralized control room. Furthermore, when large changes are to take place in a work situation, involving the people who are to work in the new environment in the design process increases the acceptance of these changes. User involvement can take a variety of forms, from appraisal of an expert modeled and animated 3-D virtual model with ensuing discussion to active design using a VE design tool. Moreover, designs can be worked on over a long period of time and discussed among a larger group than is possible in traditional design situations. In all cases, the situation must always be controlled by design experts to help reach the desired goal, though the designer's role becomes that of a facilitator, with their own ideas taking no more weight than any others in the design team. Using VEs for participatory design is often justified by considering it a medium that supports discussion across diverse backgrounds and work competencies using a common, visual language.

In situations where designers regard the end user as a collection of typical characteristics such as a size, arm length, wrist torque, and so forth, expert-driven design works well. In this case, typical end users may be called on for evaluation, but the bulk of the work progresses in a team of experts. Even so, VEs aid in the discussion across backgrounds and work competencies, allowing engineers, designers, and administrators to communicate using a common visual language.

A variant on the participatory design situation is where the tool itself is expert driven, but the design group consists primarily of end users who instruct the expert on what to do or build. This situation can alleviate the problems with having a large group simultaneously trying to

use a VE design tool or when the end users lack competence to use the tool directly, and thus must spend too much time simply learning the tool rather than concentrating on the design task.

1.4.4 *Level of Expertise*

What is the level of expertise of the members of your design team? In which areas?

Related to the above scale is that of intended user group of the design tool. This defines how complex the tool can be, the format of the user interface, and the tasks that it can support (such as level of detailed design, coloring, and interactivity). Some tools may even be equipped with two modes, novice and expert—the former supporting the standard, easy-to-understand functions (such as moving, rotating and resizing objects), the latter allowing an expert greater modeling freedom. Generally, if the tool is to be used for participatory design, the user group must be considered novice, whereas expert designers will require greater functionality. This, in turn, defines the types of design that can be achieved, with end-user designs often being less realistic, but with a high level of description, and expert designs being precise to the millimeter and realistic.

1.4.5 *Simultaneity*

How long is the design process? Are the members of your design team in the same geographical location?

Cooperative design is supported using VEs to allow separation of the participants in both time and space:

- *Same time and place*: The designers are in the same place at the same time, each with their own computer or sharing a display and control device. Communication is direct through normal speech with the virtual design acting as a point of commonality.
- *Same time, different place*: The designers are separated by distance but able to participate at the same time. In this case, cooperation may be between individuals or groups working together with the VE acting as the communication medium transmitting speech and body movements.
- *Different time, same place*: Design is often a long process, with several people taking part at different times using the same equipment. The VE can function as the communication medium, recording changes and annotations from the designers and keeping track of who has made which changes.
- *Different time and space*: Similarly, if the virtual design is made available on a network, a combination of the above two can occur with people meeting in the VE from distant locations and also able to see other's changes made previously with annotations.

1.4.6 *Degree of Immersion*

Do you require a fully immersive VE system, or is a desktop system adequate? What is your budget? What resources do you currently have available?

Virtual environment hardware can range from purely desktop (standard personal computer screen, keyboard, and mouse) to fully immersive systems with sight, sound, touch, and even smell information supplied by the computer (see chaps. 11–13, this volume). In these environments one can either be alone or interact with others. Desktop systems and projector systems intended for an audience are best suited for design groups working together, particularly if coupled to human-friendly input devices. Single-person immersive systems tend to exclude the potential for cooperative design unless each person has their own hardware. Ease of use varies, with many tools requiring the design process to be on a desktop system and final visualization in a more immersive environment.

1.4.7 Interactivity

Do you intend use the VE as part of a presentation? Do you want the audience to sit passively or take an active role? Will the VE tool be a stand-alone application to be shipped to customers? What should they be able to do?

A VE can be viewed passively with automated fly or walk-throughs, perhaps even presented as a video; can allow simple interaction such as viewpoint maneuvering and object manipulation; can permit structural changes, say the repositioning of furniture; or be a fully interactive design tool with the ability to create new objects and alter existing ones (see chap. 13, this volume). Most current VE tools require prior modeling of objects in a traditional CAD package but then allow all positional changes to be made interactively (see chap. 12, this volume).

1.4.8 Realism

What are the important aspects of your design? Which of these need to be “real”? In what way?

Many designers strive for picture-perfect realism in their models, both physical and virtual (see chap. 40, this volume). This is appropriate for the visualization of, say, a concept car or a new building (seen chap. 42, this volume). In other situations, realistic behaviors of objects are more appropriate, such as in the design of a functioning factory or the testing of a driver’s controls. Realistic objects can help the user overcome some of the hardware limitations causing problems in the perception of scale and space in desktop VE systems. However, too much realism too early in the design phase can be a distraction, causing designers to focus on irrelevant detail and detracting from the high-level design task. Similarly, end users may not have the competence or time to design the smallest details and thus need either vast libraries of detailed objects or a small library of representative simple objects (Davies, 2000).

1.4.9 System Control

Do you want the computer to take an active role in the design process? If so, how?

The computer managing the VE can also be programmed to perform other tasks such as structural analysis, fluid flow, object collision and overlap, calculating distances between points, or reach envelopes for virtual humans. These can be represented graphically for the user, thereby supporting the design process. Such tools do not take control away from the designer, but rather enhance his or her abilities. Powerful tools also exist for terraforming, realistic cloud control, and others to enhance the realism of the environment and to decrease nonproductive work of designers, allowing them to concentrate on the design task.

Alternatively, designers may have produced a VE to be tested by end users in which some alterations can be made to allow contrasting of a variety of designs. These alterations are usually limited within the boundaries set out by the designers. Similarly, the computer may control the entire design, allowing the user only limited direction choices, such as is the case of some art design programs.

1.4.10 Object Library

Will your VE be constructed from scratch, or can objects be taken from a library? What do want your end users, audience, or customers to be able to do?

One of the powers of a VE-based design tool is the ability to access vast libraries of objects. These can either be static objects classified according to some scheme such as function (office furniture, factory fittings) or form (tables, chairs) or be more dynamic in nature with generic objects being modifiable. For example, one can choose to place a table, specifying the number of legs, size and shape of the top, and the finish.

Alternatively, the system can require that some objects be created from scratch. This is often the case with unusual shapes or where a new form is necessary. The normal procedure is then to design the object in a CAD package and import it into the design environment, thus being suitable only for expert designers.

However, if the purpose of the design is for concept formation, simple objects may suffice as substitutes for more complex ones. Indeed, complex objects may detract from the design task as the users tend to focus on irrelevant detail (Davies, 2000).

2. APPLICATIONS

The potential for VEs to support the design process is great; however, there has been a certain reluctance among companies to invest in this technology due to cost and doubtful returns on their investment (Wilson, Cobb, D'Cruz, & Eastgate, 1996; see chap. 28, this volume). This initial sluggishness is, however, beginning to subside due to the successes of pioneer companies and decreasing costs of VE systems (see chap. 42, this volume). Instead, companies are now faced with the challenge of selecting the correct VE tool and obtaining the competence to use it effectively.

Many VE-based design tools begin with university research, gradually expanding into the marketplace as the usability level becomes acceptable and a need is recognized. The majority of standard VE programs have begun this way, with resulting continuous improvement. All support the expert designer in building realistic and functional environments; some even allow interactive design in immersive environments by nonexpert users, though this is less usual.

This section describes a cross section of design applications using virtual environments. Reference to specific hardware and software platforms has been avoided to ensure generality. Furthermore, each application area is analyzed and important features are highlighted with reference to the above classifications.

2.1 Design of Land Vehicles and Aircraft

2.1.1 *Background*

Virtual environments are well suited for the design of large and complex systems that constitute a vehicle. In such designs, many people with diverse areas of expertise are involved over a long period of time (Östman, 1998). Companies using VEs for vehicle design are Volvo, John Deere, Ford, Chrysler, General Motors, British Aerospace, Aerospatiale, and Boeing, to name a few.

Design in this area includes concept formulation, perhaps looking at the outer form of a car (Is it pleasing to the eye? What is the wind drag coefficient?, etc.), planning the actual construction sequence of the final product, and testing issues such as order of assembly and part fit. Furthermore, people may also be considered within the design (see Fig. 52.2), perhaps as drivers or machinery controllers, determining whether there is enough standing room or if controls can be reached and activated. In some cases, reaching a control, perhaps a lever, can result in a body position that does not allow enough torque to be applied to actually perform required actions. In other situations, the factor of interest is more obscure, such as sitting comfort over a long period of time or reachability of driver controls for people of varying body dimensions.

Another problem is assembling parts into small areas, such as in the engine bay. Wires and pipes have to be drawn in a way that is physically possible, keeps the amount of material used to a minimum, allows mounting in the first place and fixing at later stages, and, in many cases, the mounting must not be in the way, or indeed, completely hidden.

FIG. 52.2. Vehicle design using VE technology. Image Courtesy of Opticore.

Sometimes, the usage of a vehicle within a certain environment is of interest, in which case not only is the vehicle modeled but also a suitable place for it to be driven in. This allows ergonomic testing in an ecologically valid situation. Combining with physical artifacts can further heighten the sense of realism (see chap. 40, this volume), particularly if the physical controls are coupled to the computer system.

2.1.2 The User Group

Most companies do not have the resources or expertise to develop their own VE systems, though some in the vehicle industry are large enough to affect the development of VE software with their requirements. The majority of design is by experts, usually experienced CAD and 3-D modelers. Desired behaviors may be programmed into the VE model (see chap. 12, this volume), for example, to give controls some functionality or to allow the dynamic alteration of seat colors. Virtual humans are frequently used to test reachability, field of view, and other characteristics. People other than designers may then interact with the model in a limited way, activating predefined behaviors or visualizing the environment and providing comments to help in the prototype evaluation. Often the virtual model is used to sell an idea to customers or management, or to try out a variety of alternatives.

2.1.3 Rationale for Using Virtual Environments

The main reason for using VEs instead of physical mock-ups is cost saving, reduced development time, and improved quality (Östman, 1998). A greater number of more realistic prototypes can be assessed in quicker time using less material (thus reducing time to market). Some parts of an environment may still need to be built, such as the driver's seat, to test ergonomic considerations not possible in a VE due to lack of tangibility of the virtual models. These physical models can be combined with a VE to provide a realistic setting. Concept vehicles can easily be created and outfitted with standard fittings from a library. Designs can be contrasted side by side to compare the relative merits and demerits of each. The design process can be retraced and a person's input reassessed to determine whether the design could progress in a different direction.

Designs can also be easily worked on by multidisciplinary teams of people located in remote parts of the company when kept virtual. As in any distance work, this reduces the need for travel and allows expertise to be spread more effectively.

2.1.4 Classification

Generally, due to the broad nature of the different companies using VEs for vehicle design, all possible variations exist, depending on need and the design task:

Task: The task is usually to design a manufacturable and working vehicle or aircraft that fulfils design criteria such as safety, functionality, and appearance, and sometimes involves testing with end users. Alternatively, the task may be to develop a new idea, a concept vehicle to show to the public or to provide inspiration within the company.

Concreteness: Vehicle design can range from concept to production. Concepts can be produced that may not necessarily be possible in reality. Aircraft can now be totally designed and tested in a VE, resulting in plans (and 3-D models) from which the real aircraft is then built.

End-User Participation: End-user participation is uncommon in the actual design of vehicles, though they may be called in to test a selection of half-ready alternative designs. In some situations, such as the testing of driver controls, end users may be asked to test functionality. The value of bringing end users early into the design process is slowly being realized.

Level of Expertise: Design teams are typically composed of experts with the tool being used to aid communication, speed up the design process, and reduce prototyping costs. For these reasons, the tools tend to be a combination of intuitive interfacing using advanced VE hardware (typically a large multiprojector system with stereo and DataGlove) and complex design tools.

Simultaneity: The design of vehicles can cover the entire scale of simultaneity. Typically, several designers work on the same model over a period of time. The most common method is to work on a shared design, with an individual's changes and comments being tracked by the system. Some work has also been performed in allowing several designers to participate in the same environment at the same time, though this is less common.

Degree of Immersion: This can range from desktop systems, where designers view a VE in a window on the screen and ordinary graphical user interfaces (GUIs), to fully immersive 3-D systems (see chaps. 11–13, this volume). The former is typically used for the actual design and testing, whereas the latter is more common for visualization and presentation of the resulting design.

Interactivity: Depending on the level of immersion and the users of the system, interactivity can range from full control over the design for experts in a typically nonimmersive environment to control of only the programmed behaviors for testers in a fully immersive environment (see chap. 13, this volume). Full control is provided by standard VE software packages and allows all object attributes to be modified.

Realism: The standard means of managing realism and detail level is to include only those details relevant to the design. For example, in testing of different fabrics on the seats in an airplane, none of the objects are given realistic movements, nor are objects outside the cabin modeled. However, the seats are able to show the fabric patterns in a realistic and convincing manner. In the design of a new car shape, only the outer form is modeled, but this must be in a fluid and natural way, without any jagged lines or flat patches usually associated with 3-D graphics.

System Control: Ordinary VE packages do not provide many automated tools, though features such as collision detection and point-to-point measurement are usually standard (see chap. 12, this volume). Tracking of changes and annotations are also common; however, extra features such as automatic connection of, say, engine components needs to be programmed. Virtual humans are frequently used to test field of view and reachability of controls, thus taking the place of end-user testing.

Object Library: For designers of vehicles and aircraft, a specific object library consisting of parts from previous designs is beneficial. Standard parts can be included in the library,

allowing a new vehicle to use as many of the standard fittings as possible, thus reducing the need for new production lines or orders. New objects are usually modeled in a CAD package and imported into the design.

2.1.5 Summary

Current VE systems for vehicle design have shown great benefits in increasing the competitive edge. Advantages are a reduction in production time, quicker time to market, less costly prototypes, and a greater distribution of expertise. High-end graphics computers are used, the cost of which is offset by the savings over previous techniques. However, designers are let down by the intangibility of virtual models and the complexity of software programs. These will improve, however, as work on tactile and haptic feedback (see chaps. 5 and 6, this volume) progresses and interaction becomes more intuitive and moves from two-dimensional (2-D) to 3-D GUI (see chap. 13, this volume). A problem may be that as more companies use virtual design, the competitive edge may be lost.

2.2 Architectural and Interior Design

2.2.1 Background

Interior and exterior design—the design of person-size spaces, such as workplaces and the buildings they are housed in, is one of the most common applications for VE technology. At its simplest form, interiors can be modeled by experts—architects, designers and VE technicians—and shown to potential customers or users. The intention may be to entice people into buying a particular product by showing it in a realistic and immersive way (see Fig. 52.3) or to perform an evaluation for further refinement of the design. In this case, visualization is the key task and the system being designed is usually a personal space, say the interior of an aircraft or a house, or the exterior view of a building as it will look in current settings. A VE allows one

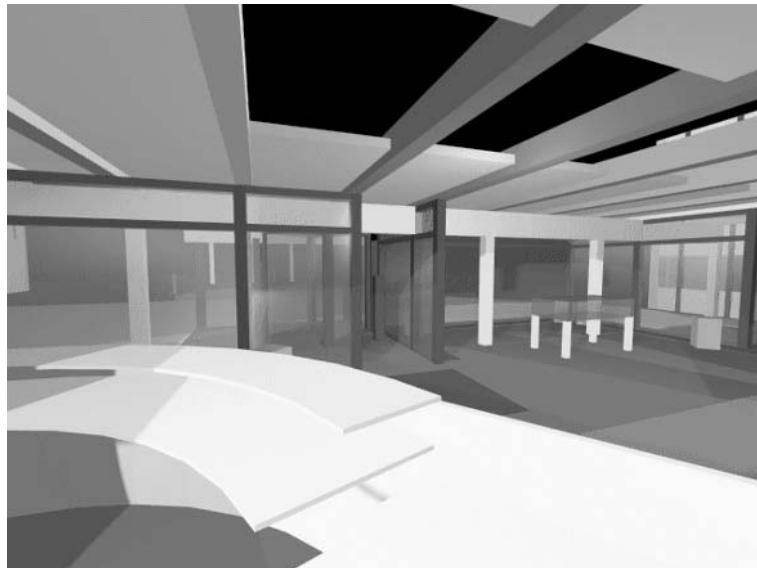

FIG. 52.4. Visualization of the view from a reception area. Courtesy of Design@Work, University of Lund, Sweden.

to see how the environment will look for people untrained in reading plans (see Fig. 52.4) and allows comparison of alternative designs and modification of details, such as color and wallpaper design.

At the other end of the scale, VEs are used to aid end users in the design of their own environments (Davies, 2000; Ehn et al., 1996; Wilson, 1999). Three-dimensional visualization has been used for many years, often with models presented as static pictures or animation sequences (Akselsson et al., 1994) that users are asked to evaluate. Similarly, 3-D visualization is used to aid in the discussion between parties involved in the design of environmental adaptations for disabled people (Eriksson, 1998; Eriksson & Johansson, 1996). Both of these have allowed end users to participate in the design process and produced results that are functional and well received. Virtual environments for active design by end users themselves, however, is a less well-solved problem and still the area of much research (Davies, 2000; Wilson, 1999). In all these cases, the goals are to give end users, designers, architects, and others a common language in the communication about the design of an environment and to bring out the user's tacit knowledge of their environment (see Fig. 52.5). One of the main problems is finding a tool that can be used by nonexperts without hours of training. Previously, noncomputerized design tools have been employed, such as full-scale modeling, advanced meeting techniques, and role-play to activate end users' tacit knowledge and as a communication medium (Ehn et al., 1996). These allow direct participation in the design process and are hands-on. However, the full-scale laboratory imposes the following limitations: difficulty in changing color and lighting; ease of alteration (considerable physical effort is required to dismantle and rebuild rooms and to model an object); difficulty in documenting and reproducing visualizations; building very large environments; portability; and showing results after the laboratory has been emptied again. Additionally, all participants must come together in the same time and place—not always possible for a company or process industry (Davies, 2000). This is where a VE solution can be of help, with its user-friendly interface devices and time and space independence. The important considerations are how people will have to use the environment and the actions they will have to perform. Furthermore, using a VE allows a projection of oneself into the

FIG. 52.5. Pausing for a break during the participatory design of a workplace. Courtesy of Design@Work, University of Lund, Sweden.

intended environment and the enacting of scenarios, either through immersive technology or by placement of life-size virtual humans.

2.2.2 The User Group

The primary users are VE designers themselves, using the standard CAD and VE design tools. Visualization may take place in an immersive setting, involving end users, either as an audience, being shown the highlights of a particular design, or actively in control of the viewpoint, being allowed to explore the space and form their own impressions.

Active design with users in control is more problematic since a careful balance must be struck between the capabilities of the tool and its corresponding complexity. If the tool is too complex, users feel disinclined to use it and tend to opt for less cognitively loading discussion aids such as pen and paper (Davies, 2000).

2.2.3 Rationale for Using Virtual Environments

Virtual environment technology has proven useful as an aid in visualization—many companies make money by architectural design using this, often with adjustable parameters such as decoration, furniture layouts, exterior cladding, and building size. The main advantage over traditional plan drawings and mock-ups is the heightened feeling of presence (see chap. 40, this volume)—of being able to see the environment from all angles and being able to unambiguously communicate with end users or customers.

The people who will have to live with an environment are more likely to understand and accept the architect's limitations if these can be shown graphically and if they have a chance of affecting the design before construction. Furthermore, getting the design right the first time reduces the need for expensive rebuilding, as in the case of adaptations for disabled people (Eriksson & Johansson, 1996).

Architecture is very often about feeling. Plan drawings just do not create a feeling for the size and scale of a room—it is not possible, particularly for an ordinary person, to get a feel for the space. However, when immersive VEs are used, observers are able to get inside the

environment, feel the place in relation to their own body space, and even try out an environment themselves, perhaps looking to see what the view from a window is or trying to squeeze into a kitchen. When a virtual building is placed in a picture of the real environment it becomes possible to assess the impact on the surroundings.

As with all design situations, one can also try many more designs using a VE than with mock-ups, build very large environments, and even try out scenarios in the environments to see whether, for example, the room layout is optimal or what would happen in an evacuation situation.

2.2.4 Classification

Task: The task in interior design is usually to build and visualize a planned real environment. In some cases, the place may already exist and is being redesigned, but more often the intention is to visualize a new idea or design in a more realistic way than plan drawings and to aid in communication among the interested parties.

Concreteness: The design is usually of an actual environment and is thus not merely a concept. On the other hand, an architectural office may use VE technology to sell their design or win a contract. Thus, the VE begins as a concept, but may become a truly “concrete” design. In the case of participatory design, end users manipulate objects in the VE that symbolize real objects. In many cases these objects represent more complex forms, such as a cube for a machine, and the design progresses at a high conceptual level.

End-User Participation: End users—people who are going to live or work in an environment—are often included at the final design phase, choosing among a selection of prototypes. In some cases their comments are fed back into a new round of designs, resulting in new prototypes to be tested, or their suggestions are taken into consideration during the actual drawing up of architectural plans. Fully participatory design, where the end user is essentially given *carte blanche*, is becoming more common, particularly in Scandinavia (Davies, 2000; Ehn et al., 1996) and England (Wilson, 1999; see chap. 17, this volume). Halfway houses are common, where the end user is able to manipulate some features of the design, perhaps altering the layout of a shop or the fabric on a chair.

Level of Expertise: In most cases the worlds are designed by experts, which are then shown to novice end users. Very few situations allow end users to design the desired environment themselves completely from scratch.

Simultaneity: Architectural design is often a group activity, with people sharing the same view of the VE and using it as a discussion starting point. In some cases, a design may be placed on the Internet for others to see and comment on.

Degree of Immersion: Immersive environments that allow several people to participate at once are best for group discussions. Either projection walls or surround projection are often used, but HMDs are unlikely due to the closed-in nature and discouragement of group discussion.

Interactivity: For designers, standard VE tools are used with standard 2-D interfaces, giving total control over the environment, but not necessarily from within. If end users are involved, the level of interactivity regularly allows the ability to walk around and interact with the environment, such as opening doors, and operating taps. In some cases, the repositioning of objects or changing of appearance from within is allowed.

Realism: Level of realism has to be carefully controlled if end users are participating in the actual design. If there is too much detail, people will focus on the wrong aspects. If there are misleading details, then their perception of the environment may be incorrect. A careful balance must be struck between speed of rendering and which details to include. Objects of

prime interest may need to be highly detailed, whereas others can simply be boxes, perhaps with a digital photo from the real environment pasted on its side.

System Control: The computer is usually not required to do much more above the visualization of an environment, though some care may need to be taken with large environments to remove all parts that are not currently visible from calculation (such as above and below floors) to speed up computer processing. Realistic movement of objects is often desirable, not just that objects look right; they need to work as in reality too. For example, it should be possible to open doors and objects should be affected by gravity and have momentum. The viewpoint should move in a natural way, perhaps with a selectable eye-height, being fixed to the ground, and able to climb stairs.

Object Library: If the environment is being created by expert designers, a library of favorite objects is beneficial, tuned to the type of environment being built (such as a home or office). If end users are to design the environment, one can either incorporate a large comprehensive library that includes all possible objects (Eriksson & Johansson, 1996) or use representative objects and require participants to fill in the details from imagination and through a shared history (Davies, 2000).

2.2.5 Summary

Many visualizations of residential buildings or offices are successfully performed around the world every year by architectural firms and housing agencies. However, there are still many interface problems to be solved before such organizations can buy off-the-shelf VE packages that allow end users an active role in the design process. There is also a certain reluctance to give away the design to end users before architectural plans are finished—a fear, perhaps of losing control over the design and involving people who are not experts in architectural design. This is one of the greatest misunderstandings—VE technology is a tool that can be used by all people involved in the design process—architect, builders, and end users to aid communication. However, the process needs to become more democratic rather than autocratic.

Another problem is that VEs do not allow the feeling of recreating an environment completely. Missing are tactile (see chaps. 5 and 6, this volume) and audible (see chap. 4, this volume) feedback. Everything appears ghostly and can be passed through, and realistic sound effects such as echo of footsteps and background noises that help create a feeling of space are generally not modeled. Furthermore, participatory design using VEs will be improved when several people can act at once—current systems require that people must take turns or see each other as avatars (see chap. 15, this volume) in the VE and cannot easily converse and cooperate. These will change as the technology advances. Interaction with the VE tool can also be problematic, and improvements are continuously being sought to make immersive design easier for end users.

2.3 Planning and Monitoring of Construction Projects

2.3.1 Background

Working paper drawings are typically used to communicate a building design to a contractor. The contractor's planners then have the task of taking these drawings and creating schedules and plans for the construction process—a process requiring much intuition, imagination, and judgment (Adjei-Kumi & Retik, 1997). The planners use software that aids project management by supporting formulation and evaluation of project schedules in a symbolic and abstract manner. The output is hard to interpret and does not realistically support the visualization of schedules, thus requiring great experience and knowledge of perceived characteristics

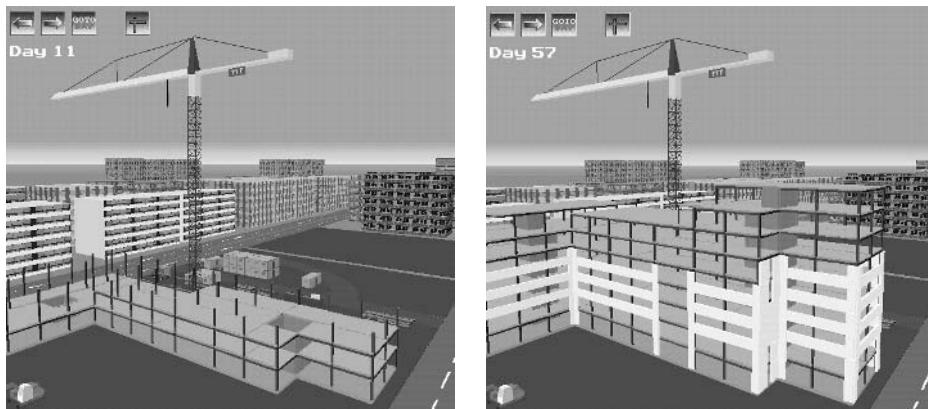

FIG. 52.6. Visualization of stages in a construction process. Courtesy of the Department of Civil Engineering, University of Strathclyde, Glasgow.

and spatial relationships between various components. Furthermore, communication between planners and other parties involved becomes prone to misunderstandings, leading to potentially dangerous errors in the construction process.

Current visualization techniques for building construction concentrate on the final product (see section 2.2), not the process, whereas construction planning tasks deal with the entire project from beginning to end. Current computer tools cannot capture or display the construction process, hence there is a need for a tool that supports both visualization of schedules for planners and communication between planners and others during the construction process.

Recent research in England (Adjei-Kumi & Retik, 1997; Retik, 1997) has concentrated on producing computerized tools for visual planning of the construction process using VE techniques to allow realistic visual presentation of construction project information (see Fig. 52.6). These tools allow planners to both assemble a building in stages from a library of ready-made objects and to replay the construction process to facilitate visualization, show others, and allow checking against the actual progress of the real building. Within the framework of the drawings given to the contractor, planners are more or less free to design the construction process as they see fit—in this case, the design takes the form of construction schedules rather than the building form itself.

2.3.2 *The User Group*

The primary users are planners, with experience using planning and construction tools and an expected high level of computer competence.

2.3.3 *Rationale for Using Virtual Environments*

Due to the programming capabilities of VEs, a tool can be made that fulfills the above criteria and that can be used on the construction site or at the contractor's offices. Simulation of time steps can be programmed, and the building can be viewed from all angles, including inside. As a communication medium, 3-D visualization is less ambiguous than plans, drawings, and schematics, though it must currently remain a complementary tool.

Reduced misunderstanding is expected to lead to fewer errors in the construction process, reducing the need for redesign or partial deconstruction in extreme cases, thus saving time and materials and shortening the entire construction time.

2.3.4 Classification

Task: The task is to construct a building virtually, record the schedule of the construction process over time, and be able to review this process for both discussion of the construction process and monitoring of subsequent construction.

Concreteness: The building itself is a concrete object; however, planners do not determine its form. Rather, planners focus on the process of construction, which, in this case, is the object of design. This is a more abstract entity than usually built using a VE, as it is essentially the passage of time that is to be modeled. Nevertheless, there is a definite process, resulting in a concrete object, not a concept design.

End-User Participation: End users, those who are to populate the building, are not considered in this stage, though in the initial design of the building, architects may have brought them in. However, the people using the tool itself are different from the tool designers, thus are end users of a different nature.

Level of Expertise: The users of the VE tool are experienced in planning construction and are hopefully motivated to learn a new tool, especially if it is expected to facilitate their job and reduce the chance of mistakes.

Simultaneity: The tool may be used by several people at one time as a discussion focus for the construction of a building, but it is not intended to be used by planners in different locations, nor necessarily by different people at different times in the design process—though the tool does not exclude these possibilities.

Degree of Immersion: For greater portability and reduced cost, such a tool is not intended to be immersive. Nor does an immersive system facilitate group work and discussion.

Interactivity: In the design of the construction process, the tool allows full control of the placement of objects representing the parts of a building and the manipulation of time. For visualization, navigation around the building site and the ability to step through time are provided.

Realism: The detail required for this tool must concentrate on the parts of the building. To be useful to planners, it must be able to accurately depict shapes of building parts (such as girders, fasteners, wall segments, etc.) so that it can accurately portray problems that may occur due to assembly in the wrong order. On the other hand, realism of the graphics is not so important. Lighting and shadowing are irrelevant, as are sound effects, realistic detail, and picture perfect textures on objects. Thus, a simple PC-based VE system is adequate.

System Control: The system is required to understand concepts such as linkages of components, gravitation (or rather that objects must sit on other objects), and a breakdown of working areas to trace the intended progress of the work. It is also required to link to other modules, such as commercially available construction scheduling software to display schedules, resources, costs, and other features in the traditional way (bar charts, networks, etc).

Object Library: The crux of this tool is the existence of a large object library from which planners can select the parts they require and the ability to import other elements that may already exist in CAD format. The library, in this case consists of two types of elements—process-based and product-based. Product-based elements include cranes, mixers, scaffolding, fences, huts, among others, and can be directly placed into the environment as 3-D models. Process-based elements describe activities. These are automatically connected by the system and require the integration of technical knowledge and experience. These can also be placed interactively during the planning process.

2.3.5 Summary

The work to date has highlighted a major weakness, that VE design tools are only as good as their virtual library and that this must be large in order to be useful. Similar problems have been found in other design tools using VEs, such as in the adaptation of environments for

disabled people (Eriksson & Johansson, 1996; see chap. 49, this volume). Nevertheless, such a planning and monitoring tool has been successfully designed and tested, and further work is in progress to incorporate greater automation and design aids, such as an expert system to advise on rectification of deviations from the planned schedule.

A further point to note is the success in using PC-based desktop VE technology; immersion is not necessary, making such a tool affordable to construction companies. Careful concentration on only essential features to support the design process has allowed the peeling away of unnecessary complexity and spurious detail.

2.4 Industrial Plant Design

2.4.1 Background

Design of industrial plants requires not only knowledge of chemical and mechanical processes, but also how the various parts can be linked together. Such a plant is a highly complex and sophisticated entity, with a multitude of parts interconnected by pipes and wires and requiring access by operators and service personnel.

Previously, physical models of industrial plants were built and used as discussion pieces for design teams, with the design process being primarily performed using 2-D CAD drawings. All object placements and connections were done by hand, a complex task prone to errors and nonoptimal solutions. Furthermore, going between the schematics and plans and the physical model was a difficult process of identification and location. Model adjustment was, of course, time-consuming and expensive.

A tool for the design of industrial plants based on VE technology has been successfully used in a variety of industries, including offshore oil and gas, chemical and pharmaceutical production, power generation, and paper milling (see Fig. 52.7). This is a highly sophisticated and complex tool designed for experts to use and provides many automated features.

2.4.2 The User Group

The primary users are plant designers with training and experience in chemical and mechanical processes pertinent to the type of plant being designed. Secondary users may be others that the design is shown to, potential investors or politicians, for example. An interactive design

(b) Using live design data, Cadcentre's REVIEW Reality photorealistic plant visualization software gives engineers and nonengineering staff alike a unique impression of what the finished plant will look like, in this case, a pharmaceutical plant in North America.

can also be used for later identification of faults and for coupling the plan drawings with the locations of elements in the real model.

2.4.3 Rationale for Using Virtual Environments

As an interactive medium, a VE-based tools offers a significant improvement over prior techniques of plant design. Entire factories can be assembled by selecting components from a library of objects and placing them within a designated space. Cable and pipe drawing are automatic, thus reducing the chance of error due to misconnection or unnecessarily crooked pipes to fit around cables and pipes already placed. Adjustments can be performed in real time with the results immediately visible in the factory design and on the automatically generated schematics. Furthermore, components can be coupled to a database and thus interactively interrogated for information. Likewise, individual components can be isolated, viewed, and shown within the context of the entire system.

2.4.4 Classification

Task: This tool is used primarily to design working industrial plants and secondarily to provide information throughout the lifetime of an installation for maintenance and modification purposes. Components can be placed and connected into a (theoretically) working system. These can then be interactively interrogated to provide information for designers, builders, and maintenance personnel.

Concreteness: The design task is very concrete and usually results in a functioning factory or plant. In some cases a plant may be designed to show others, with the VE tool acting as a high-technology viewer of the proposed plant, perhaps to convince investors of the benefits and safety of the proposed system.

End-User Participation: There is almost no end-user (e.g., plant operator) participation. The design is driven mainly by experts with knowledge of how and where people must be able to fit into the design (e.g., gangways, room for turning valves, etc).

Level of Expertise: A high level of expertise is required of users. Not only does one need to know about the plant and process being designed, but the tool also requires a certain degree of modeling experience. On the other hand, many tasks are automated, which significantly increases the ease-of-use and reduces the complexity of the tool. Additionally, VE technology has been used to extensively improve the interactivity of the system.

Simultaneity: Many people can participate, both across time and space.

Degree of Immersion: The hardware used ranges from ordinary desktop PCs, or even portable systems, to fully immersive multiprojector studios and is usually determined by the budget and complexity of the system to be designed. As with most design tools, however, it is unusual for HMDs to be used due to the closed-in nature and loss of contact with others on the design team.

Interactivity: Plant design is highly interactive. The key is a tight coupling between direct manipulation in 3-D of the entire plant, individual objects, and other information such as part specifications and schematics. This can be automatically linked from the 3-D interface to 2-D windows on the computer screen to Web pages showing 3-D images.

Realism: Models are static, with no actions associated with them. The aim is to design, not simulate a process.

System Control: As previously described, there is a high degree of automation. Indeed, this is necessary if such a tool is to be of any advantage over existing techniques.

Object Library: There is a large object library, which can be complemented by CAD models. Building a plant becomes a simple process of dragging and placing system components on a “concrete” base.

2.4.5 Summary

Using VEs for plant design is a good example of a commercial application based on standard, albeit advanced technology, which has shown consistent advantages for its users. Nevertheless, improvements are continuously being made as new hardware and software become available.

2.5 Others

This section contains descriptions of some other applications of VE technology to design. These are kept short, because they are similar to previously described applications, are on the fringe of systems design, or there has been very little work performed in the area.

2.5.1 Artistic Design

Within the artistic community, VEs are commonly used to create virtual art galleries to display ordinary static art. However, in some cases it is used as the actual medium for the artwork itself (Shaw, 1995), for designing physical artworks, or for exploring other facets of artistic interconnectedness, such as between art, design, and architecture (Kiechle, 1996).

Artwork usually intends to produce a pleasing, controversial, or perhaps thought-provoking experience for the observer. There is not necessarily a product to be developed, nor limitations of space and time to be adhered to. In fact, many interactive artworks deliberately break these barriers (e.g., Sommerer & Mignonneau, 2000). Virtual environment technology is used both for construction and interaction with virtual artworks, perhaps with many participants, and as a tool in the design and documentation of real, physical art (Kiechle, 1996). Artworks can be considered a system in that they are composed of many interacting parts built using a hierarchical structure.

Virtual environment tools, CAD packages, and other 3-D design programs are used by artists to assemble the system or for the construction of physical artworks. The primary users are artists—expert users—with the audience being able to perhaps navigate through the constructions or make predefined alterations within the boundaries of the experience. Ordinary VE technology is used for the construction phase; however, the potential for immersive systems to create experiences far beyond those of, say, an ordinary sculpture are well recognized by art designers (e.g., Shaw, 2000) but are seldom realized due to the cost of such systems. It is expected that more interactive art will be constructed in the future, perhaps for perusal over the Internet or available in art galleries, with maybe even the ability to share the experience with people at other locations around the world.

2.5.2 Small Things

Many small devices such as telephones and video players can be designed using VE tools. Prototype interfaces can be constructed and tested with end users for comprehension and ease of use; parallel prototypes can be contrasted and the optimal design chosen. Typically, ordinary CAD and VE packages are used to construct the devices, with output being via an ordinary screen, or even a stereoscopic display. When this is combined with tactile feedback (see chaps. 5 and 6, this volume), highly realistic interaction can occur, giving the testing a high degree of ecological validity.

2.5.3 Ergonomic Design

Improvement of VE design tools for architectural and interior design is occurring due to the gradual unification of virtual human modeling programs and VE technology. This is

increasing the ability to put people into the environment being designed, try different body sizes according to race, gender and disability, and run routines to automatically test factors such as turning space, angle of lift and the corresponding stress on the body, glare, and so forth. The next step will be to allow real people to interact with virtual humans in a realistic manner, using them as role-players in a scenario being played out in the VE (see chap. 15, this volume).

3 CONCLUSION

This chapter has shown the potential of VE for systems design and allowed the reader to see where it can fit within his or her own design process. A number of common features and useful rules of thumb have been identified; however, a few further comments are necessary.

It is essential to have a clear idea of how VE technology can help in the design of your system. What is the task to be performed? And can one buy a ready-made solution or reuse a solution from another field? Many general-purpose VE systems can be purchased, but these require significant work to create a useful tool for a specific design situation. This cost must be added to that of hardware and software. Alternatively, one can often buy an entire package from a VE consultancy company, which will deliver a ready-made solution of hardware and (programmed) software as well as support and service. However, in either situation, be aware that there are many technical limitations and compatibility issues to be resolved, small conversion programs can be surprisingly expensive, and current practices may have to be severely modified (or even discarded) to incorporate VE design.

Next, one must consider who is to use the tool. If end users are to be involved in some way: Will they be required to interact directly with the tool, or will they be chaperoned by a design expert? This significantly affects the degree of ease of use and selection of display methods and input devices. Even if end users are not to be directly involved, what is the CAD and 3-D modeling expertise of those who will use the system? End-user participation seems to be beneficial where the clients are those who will be expected to live or work in the environment being designed. Increased involvement appears to improve acceptance of the results, providing a feeling of ownership for the design, and allows for the capture of tacit knowledge not necessarily available to the designer.

The level of immersion, interactivity, and realism are closely bound to the design task. Tasks where attention to detail is essential, developing a feeling for the form of an object (say a car) or being able to get a feel for a space, require often-expensive immersive technology, a high degree of interactivity, and realism. If, however, such attention to pictorial detail nor immersion is required, excellent results are obtained by small systems, often based on ordinary PC technology. This is indeed borne out by work in other areas such as VEs for rehabilitation (see chap. 49, this volume), where expensive immersive technology is beyond the budget of most medical institutions and positive results have been obtained with smaller systems. Furthermore, the so-called ordinary PC technology of today is equivalent to the high-end graphics workstations of a couple of years ago—and this trend shows no sign of flattening off, implying that only extreme cases require a large investment.

Finally, a good recommendation is to see how one's competitors are using VE technology. If they are not—why not? Do they lack vision, or are the predicted financial gains too uncertain (Wilson et al., 1996)? If they merely lack vision, then maybe it is time to be a pioneer—VEs are here to stay, with some developers now reaching over a decade of experience and many companies reporting substantial savings in time and resources, as well as a significant competitive advantage.

1. INTRODUCTION

Virtual environments provide a natural setting for a wide range of information visualization applications, particularly when the information to be visualized is defined on a three-dimensional (3-D) domain (Bryson, 1996). This chapter provides an overview of the issues that arise when designing and implementing an information visualization application in a virtual environment. Many design issues that arise (e.g., issues of display or user tracking) are common to any application of virtual environments. In this chapter, the focus is on those issues that are special to information visualization applications, as application issues of wider concern are addressed elsewhere (see chaps. 42–55, this volume).

1.1 What Is the Problem?

In this chapter, information visualization is considered to be the visual investigation of numeric data. This data may represent real-world observations or the result of simulation. The data may express tangible, real-world quantities, such as water temperature, or may represent abstract quantities, such as stock market prices. Data is herein restricted to “information” rather than “objects” in order to avoid having to discuss representation of conventional real-world objects. Using this restriction allows the current discussion to concentrate on those aspects of information visualization that are unique to nonrealistic, abstract representations of information. Of course there is considerable overlap between “information” and “object” (e.g., representation of topographic data). If that representation is abstract in order to bring out some feature of the topography, the discussion in this chapter is relevant. If the topography is to be represented realistically, then the discussion here may not apply.

Virtual environments (VEs) provide unique opportunities for information visualization (Bryson, 1996; Cruz-Neira et al., 1993; Lin, Loftin, & Nelson, 2000). The inherent

three-dimensional (3-D) nature of VEs makes them a natural choice for investigation of multi-dimensional data domains. The natural, anthropomorphic interface suggested in VEs inspires natural, intuitive interfaces for the investigation of data. This intuitive interface may be particularly suitable for visualizing highly complex data sets, where phenomena in the data cannot be effectively displayed all at once. In such situation an intuitive 3-D interface may allow for rapid investigation of data employing a What's happening here? paradigm.

This chapter explores how VEs can be effectively used for information visualization. After characterizing the information visualization process, an examination of how information visualization environments differ from other, more "real-world"-oriented applications is provided. Using these observations, implementation strategies tailored for information visualization in VEs are provided, including issues of run-time software architectures, distribution, and control of time flow. These implementation strategies will be driven by consideration of the human factors of interaction. The chapter closes with a discussion of the challenging aspects of information visualization in virtual environments.

1.2 The Data Analysis Pipeline

In order to describe special issues that arise in the implementation of VE information visualization systems, a conceptual model of an information visualization system is required. There are many ways to conceptualize information visualization, and we make no claim to the most complete or optimal conceptualization. The following, however, has been found very informative when considering implementation issues.

The information visualization process is considered as a pipeline, which in its most generic form starts with the data to be visualized. From this data visualization primitives are extracted. These primitives may consist of vertices in a polygonal representation, text for a numerical display, or a bitmap resulting from, for example, a direct volume representation. Primitive extraction typically involves many queries for data values. The extracted primitives are then rendered to a display. This pipeline allows user control of all functions, from data selection through primitive extraction to rendering. This pipeline is shown in Fig. 53.1.

As an example of this pipeline in operation, consider streamlines of a vector field (see, e.g., Bryson, 1998). Given a starting point of a streamline, data (the vectors at that point) are accessed by the streamline algorithm. The vector value is then added (sometimes with a complex high-accuracy algorithm) to the starting point, creating a line primitive. This process is iterated to build up a (typically curved) line with many vertices. These vertices are the streamline's extracted representation. These vertices are then rendered in the visualization scene. The extraction of these primitives may involve significant computation even though the data may exist as a precomputed file. Computations like those in this example will turn out to be a significant issue in the implementation of information visualization in virtual environments.

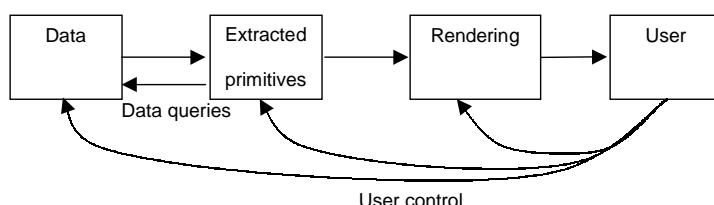

FIG. 53.1. The data analysis pipeline.

1.3 Why Perform Information Visualization in a Virtual Environment?

Virtual environments offer several advantages for many classes of information visualization (Bryson, 1996; Cruz-Neira et al., 1993; Lin et al., 2000; Song & Norman, 1993). The inherent 3-D interface makes VEs a natural setting for information that exists on a 3-D domain. Examples of such data include 3-D scientific simulations, such as fluid flow, electromagnetic fields, or statistical data indexed by location in 3-D space. Three-dimensional interaction techniques common in VEs (see chap. 13, this volume) provide natural ways to control such features as visualization selection and data manipulation. In addition, experience has shown that one of the greatest advantages of information visualization in VEs is the inherent “near-real-time” responsiveness required by head-tracked direct-manipulation virtual environments (see chap. 8, this volume). This responsiveness allows rapid queries of data in regions of interest. Maintaining this responsiveness in an information visualization environment is the most challenging aspect of such an application and will be one of the primary foci of this chapter. When designed well, the combination of 3-D display, 3-D interaction, and rapid response creates an intuitive environment for exploration and demonstration.

Figures 53.2 and 53.3 show examples of VEs for the visualization of information arising from scientific computation. Figure 53.2 shows a system developed at the University of Houston for the exploration of geophysical flows (Lin et al., 2000). Figure 53.3 shows the Virtual Windtunnel, developed at NASA Ames Research Center, which is used to investigate results of simulations in computational fluid dynamics (Bryson & Levit, 1991; Bryson, Johan, & Schlect, 1997). Both examples exhibit the use of multiple visualization extracts in a single environment. All of these extracts are interactive and can be changed under user control.

Multimodal interfaces, using sound (see chap. 4, this volume), touch, and force (see chaps. 5 and 6, this volume) displays for VEs have been explored for information visualization in virtual

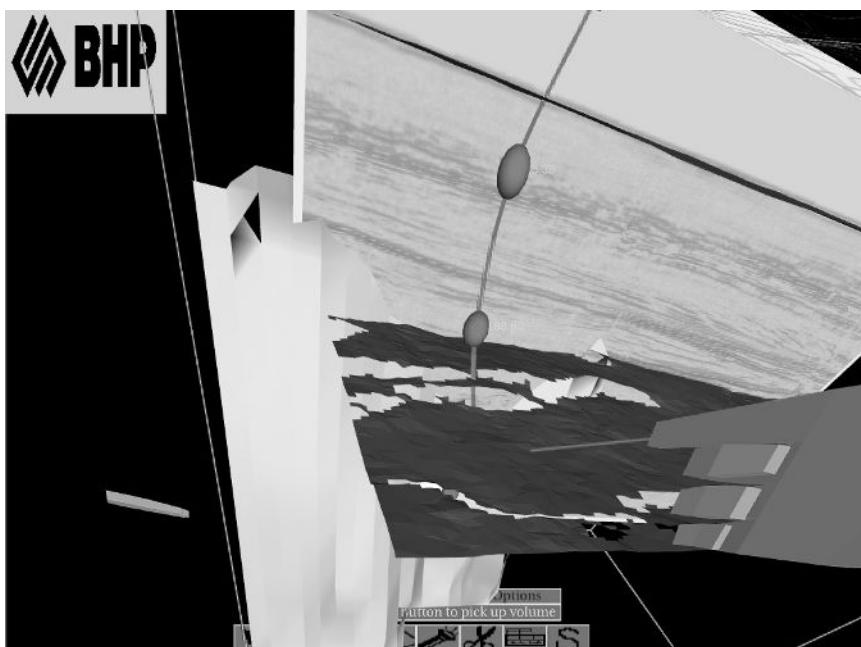

FIG. 53.2. An information visualization VE for exploration of geological data sets. Courtesy of the University of Houston/Bowen Loftin.

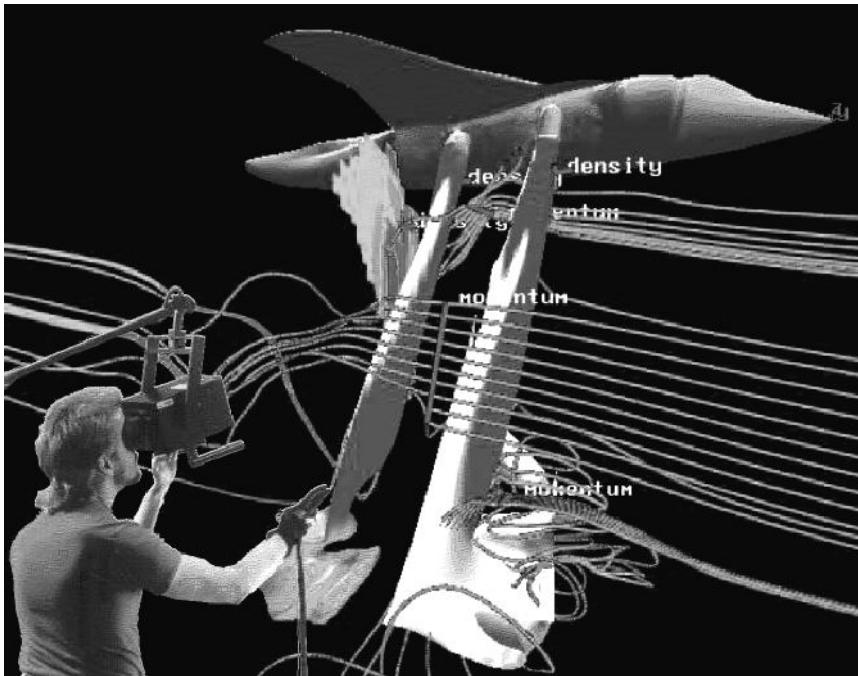

FIG. 53.3. The Virtual Windtunnel, a VE for visualization of Computational Fluid Dynamics simulation results.

environments (e.g., Taylor, Robinett, Chi, Brooks, & Wright, 1993). With the possible exception of force displays, however, the efficacy of such interfaces has not been demonstrated.

1.4 How Information Visualization Differs from Other VE Applications

The design and development of an information visualization application within a VE is different from most VE application development (see chaps. 42–55, this volume). Information visualization environments are often abstract and involve large amounts of data access and computation in response to a query. For time-varying data, different senses of time arise, in which the data may evolve more slowly or even backward relative to user time. Such differences between information visualization environments, and more conventional VE applications can be generalized into the following areas:

- **Greater flexibility in graphical representation:** The inherently abstract nature of information implies opportunities for simpler, faster graphics, such as representing a streamline as a simple polyline. Conventional applications, such as training (see chaps. 43 and 44, this volume) or entertainment (see chap. 55, this volume), are typically more concerned with realistic graphical environments and so may have less flexibility in the selection of graphical representation. Of course this is not a universally applicable rule, as some representations of information, such as direct volume rendering, can be very graphically intensive.

- **A large amount of numerical computation may be required:** Although information visualization typically addresses pre-existing data, visualization extracts may themselves require considerable computation. Streamlines or isosurfaces in the visualization of continuous vector and scalar fields are well-known examples that require large amounts of computation. Statistical or data mining techniques for abstract data may also require computation. As more

sophisticated data analysis techniques are used in VEs more computational demands can be expected.

- **A large amount of data access may be required:** Visualization extracts require access to data, and some extracts require more data access than others. Complete isosurfaces, for example, require traversing an entire data set (at a particular time step for time-varying data) for the computation of the data set. Time-varying data sets can be extremely large, requiring access to hundreds of gigabytes of data in a single analysis session, albeit a single time step at a time.

- **There may be various senses of time:** Several senses of time can arise in an information visualization system, particularly when addressing time-varying data sets. While some of these senses of time correspond to conventional time in other VE applications, completely new ways of thinking of time arise from the fact that a user may wish to manipulate time flow in a time varying environment. This issue and its impact are discussed in much more detail in section 4.

These differences between an information visualization VE and other applications have major impacts on the design of the VE system.

2. SYSTEM ARCHITECTURE ISSUES SPECIFIC TO INFORMATION VISUALIZATION IN VIRTUAL ENVIRONMENTS

There are several issues that arise in the design and implementation of VEs for information visualization. In this section, some of these issues are examined in detail. First, however, a classification of the types of interaction that may occur, which in turn depends on the time flow of the data, is provided.

2.1 Classification of Interaction and Time Flow

There are two design questions that must be answered before considering an appropriate implementation of an information visualization application in virtual environments:

1. **Is the user allowed to interactively query data at run time, generating new visualization extracts?** If so, the system will likely have user-driven data accesses and computation to support extraction of new visualization geometry.
2. **Is the data time-varying?** If so, there will be at least two senses of time in the virtual environment: user time and data time. The flow of data time may be put under user control so that it may be slowed, stopped, reversed, or at times randomly accessed.

These questions are independent, and both must be answered in order to determine which kind of implementation strategy will be appropriate. There are four combinations that arise from the answers to these two questions:

- **Noninteractive, non-time-varying data:** This is the simplest information visualization environment, where the visualization geometry can be extracted ahead of time and displayed as static geometry in a head-tracked virtual environment. No data access or computation issues occur in this case. The user may be able to rotate or move the static geometry. The design issues that arise in this case are common to all VE applications and so will not be considered further in this chapter.

- **Noninteractive, time-varying data:** In this case the visualization extract geometry can be precomputed as a time series, which may be displayed as a 3-D animation in the virtual

environment. The user may be given control over the flow of the animation, to slow it down, stop it, or reverse direction. Such user-controlled time flow implies a special interface, which may include rate controls to determine the speed and direction of the data time or a time step control for random access of the extracted geometry at a particular data time. When the extracts are defined for discrete time steps, interpolation in time may be desirable to allow for a smooth flow between time steps. What kind of interpolation is appropriate will be highly domain and application dependent. Except for these considerations, however, the issues that arise in this case are common to most VE applications and so will not be considered further in this chapter.

- **Interactive, non-time-varying data:** In this case the data does not change in time, but the user specifies the visualization extracts at runtime. In a VE, such extracts may be specified via a direct-manipulation interface where the user either specifies a point or manipulates an object in 3-D space. The visualization extract may require significant computation, which will have an impact on the responsiveness of the system. This impact is discussed at length in section 2.2. When visualization extracts do not change they are typically not recomputed.

- **Interactive, time-varying data:** For this type of environment, the data itself is changing with time, so any existing visualization extracts must be recomputed whenever the data time changes. This can result in a large amount of computation for each data time step, the implications of which are discussed below in section 2.3. In addition, the user may be given control over the flow of data time, allowing data time to run more quickly or slowly, or in reverse. The user may wish to stop time and explore a particular time step. When time is stopped the system should act like an interactive, non-time-varying data environment, allowing visualization extracts to be computed in response to user commands.

2.2 Interaction Versus Data Time Scales

Responsive interaction plays two important roles in virtual environments:

- **Fast graphics** is required to permit the head-tracked display required for a strong sense of object presence and immersion (see chap. 40, this volume).
- **Fast response** to user commands are required for a direct manipulation interface paradigm, where the user is allowed to directly “pick up and move” objects in the virtual environment.

In information visualization environments, there is the added requirement that the user be able to move a data probe displaying a visualization extract and see that extract update in near real time as appropriate to its new position. If the data probe’s extract updates sufficiently quickly, the user will have a sense of exploring the data in real time.

How fast the graphics and interaction response must be turns out to be both application and domain dependent. A VE for training manual tasks, such as a flight simulator, requires response times of less than $\frac{1}{30}$ of a second. Longer response times have been observed to train users to expect delays that may not exist in the real world and lead to incorrect operation (Sheridan & Ferrill, 1974). Information visualization, however, does not typically require fidelity to any real-world time scales. In fact it is often desirable that the information being visualized be presented with very different time scales from the real world, with data time being either slowed down or sped up depending on the user’s needs.

While fidelity to real-world time scales is not a guide to the required responsiveness of an information visualization environment, human factors considerations will set performance requirements. Three human factors issues turn out to be important for information visualization in virtual environments:

- **Graphics update rate:** How fast must the graphical display update rate (graphical animation rate) be to preserve a sense of object presence and/or immersion? By graphical update rate we mean the rate at which frames are drawn to the frame buffer(s), not the display device's refresh rate.
- **Interaction responsiveness:** How quickly must objects in the environment respond to user actions in order to maintain a sense of presence and direct manipulation? This requirement applies to the overall head-tracked display as well as ability to interact with objects.
- **Data display responsiveness:** How fast must interactive data display devices, such as a data probe, update to give the user a sense of exploring the data?

The relationships and differences between these time scales are subtle. Graphics update rate will limit interaction and data display responsiveness because the interactive displays cannot be presented faster than the graphics update rate. Update rate and responsiveness, however, are very different kinds of measures: Update rate is measured in frames/second, while responsiveness is the *latency*, measured in seconds—the time interval between a user action and when the system's response is displayed. This latency is determined by all processes triggered by the user's actions, from reading the user tracking devices through processing the user's commands through possible subsequent computation to the display of the result. Experience has shown that the limits on these time scales are as described below (see Bryson, 1996; Sheridan & Ferrill, 1974):

- **The graphics update rate must be greater than 10 frames/second.** While faster update rates are desirable, 10 frames/second is sufficient to maintain a sense of object presence even though the discrete frames of the display are easily perceptible. Slower update rates result in a failure of the sense of object presence, eliminating the enhanced 3-D perception advantages of a virtual environment.

- **Interaction responsiveness must be less than 0.1 seconds.** While lower latencies and faster responsiveness is desirable, a latency of 0.1 seconds is fast enough to give the user a good sense of control of objects in the virtual environment. Longer latencies typically cause the user to experience unacceptable difficulty in selecting and manipulating objects in 3-D space.

- **Data display responsiveness must be less than about one third of a second.** While faster responsiveness is desirable, a data display latency of one third of a second maintains a sense of “exploring” the environment, though the user may use slow movements to adapt to this relatively long latency. Longer latencies in data display require such slow movements on the part of the user as to lose usability (see chap. 34, this volume).

The graphics update rate and interaction responsiveness requirements are similar: One graphics frame of latency is allowed for to maintain good responsiveness for user interaction. The data display responsiveness requirement, however, is less restrictive. The difference in latency requirement between interactivity and data displays is due to the fact that user interaction (selecting, acquiring, and moving objects) is a manual task driven by the human factors of manual control, whereas observing data display during movement is an intellectual task in which the user observes what happens as a data probe is moved through space.

Interactive time-varying environments potentially present a difficult challenge in meeting the above requirements: All nonprecomputed visualization extracts must be computed whenever the time step changes. Furthermore, when the time step changes, all computations must take place before any of the extracts can be displayed so that extracts from different data time steps are not displayed at the same time. Experience has shown that it is acceptable for the data time

step to change quite slowly, so long as the 10 frames/second graphical update rate and the one third of a second data responsiveness requirements are met.

These observations suggest that graphical display and user interaction be treated independently of the visualization. For example, interaction and visualization display may be treated independently by having simple graphical tools in the VE that respond to the user without waiting for data to be displayed (Bryson et al., 1997; Herndon & Meyer, 1994). These tools may trigger associated data displays, but these data displays should occur asynchronously from the display of the tool, allowing the tool to respond to the user's input as quickly as possible.

A simple crosshair in 3-D space, with an associated streamline of a vector field, is an example of such a tool. In this example, the user can "pick up and move" the crosshair, which will be very responsive (within the limits of the graphical update rate) due to its simple graphical nature. When this crosshair is moved it will trigger the computation of a streamline at its current location. This streamline may take much longer to compute and display, after which time the tool will trigger a new streamline from its new location. If the process computing the streamline runs asynchronously from the process handling user interaction and graphical display, interaction responsiveness will be only slightly impacted by the computation of the streamline (assuming a preemptive multitasking operating system). This example shows that the difference in time scales between interaction responsiveness and data display responsiveness has strong implications for the run-time architecture of the information visualization system. These implications for the overall system architecture are discussed in section 2.3. The method of triggering computations outlined in this simplified scenario will be discussed in more depth in section 4.

2.3 System Architecture

The observations in the previous section imply that any implementation of an interactive information visualization VE in which computation of visualization extracts takes place should contain at least two asynchronous processes: a graphics and interaction process and a visualization extract computation process. More generally, the graphics and interaction task may be performed by a group of processes we shall call the interaction (process) group, one or more processes for graphics display and possibly separate processes for reading and processing user tracking data. Similarly, the visualization extraction task may be performed by several processes, called the computation (process) group, possibly operating on multiple processors in parallel. These groupings are chosen because processes in the interaction group all have the same 10 frames/second and 0.1 second latency requirements, whereas the computation group has the one third of a second latency requirement. This process structure decouples display and computation so that a slow computation does not slow down the display process and the speed requirements of the display process do not limit the computation.

The interaction process group passes user commands to the computation process group, which triggers the computation of visualization extracts. These resulting extracts are passed back to the interaction process group for display. This basic architecture is outlined in Fig. 53.4.

3. DISTRIBUTED IMPLEMENTATION

Distributed data analysis can be highly desirable, particularly in one or more of the following circumstances:

- Data exists on a remote system, and it is inconvenient to move the data to the local visualization system.

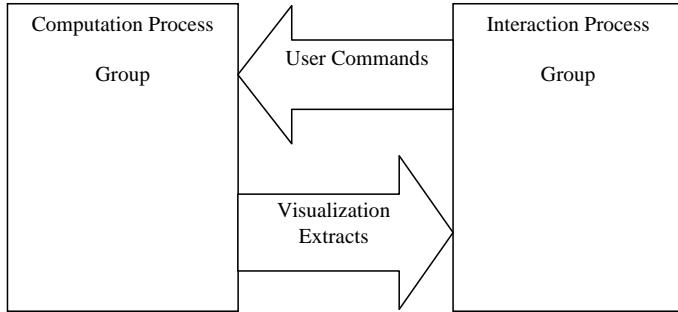

FIG. 53.4. Run-time process architecture of an information visualization system for interactive and/or time-varying data.

- Desired visualization extracts require more computation than the local visualization system can easily deliver.
- Data is the result of a concurrently running computation on a separate high-performance computational system.
- Remote collaboration is desired, where several clients have (effective) access to the same data.

The use of separate, asynchronous computation and interaction process groups communicating via buffers as described in section 2.3 facilitates a distributed implementation, where the process groups exist on separate, possibly remote machines communicating over a network.

3.1 Distribution Strategies

There are several strategies for the distribution of data analysis. These strategies are determined by selection of where to place which operations in the data analysis pipeline of Fig. 53.1. These strategies and their advantages and disadvantages are as follows:

- **Remote data, local extraction, and rendering:** In this option data exists on a remote system, and individual data values are obtained over a network as required by the local visualization extraction algorithm. This strategy has the advantage of architectural simplicity, with all visualization activities taking place on the local system, as if the data were local. This strategy has the disadvantage that it requires a network access each time data is required, which can be time-consuming. There are techniques to overcome this disadvantage, such as clever prefetching, where data is delivered in groupings that anticipate expected future queries. For some information types the remote data distribution strategy may be too slow for a VE interface, for example, when analyzing continuous fields that arise in computational fluid dynamics, where large visualization extracts may require many data accesses for their computation. For other applications, however, where data accesses are relatively few, remote data distribution may be a viable strategy.

- **Remote data and extraction, local rendering:** With this strategy visualization extraction occurs on a remote system, typically the same system that contains the data. In an interactive system the extraction computations are in response to user commands passed from the user's local system. The results of the extraction, typically geometrical descriptions of 3-D visualization objects, are transmitted to the user's local system for rendering. Architecturally, this strategy maps closely to the run time architecture illustrated in Fig. 53.4, with the computation process group on (one or more) remote machines and the display and

interaction process on the local system. This strategy has the advantage that the extractions algorithms are “close to the data,” so data access is not a bottleneck. It also has the advantage of local rendering, which allows head-tracking display for each participant as required in virtual environments (see chap. 8, this volume). The disadvantages of this strategy include the fact that response to user commands requires a round trip over the network, and the requirement that the user’s local system be capable of rendering the extract’s geometry.

- **Remote data and extraction, distributed rendering:** This strategy is a variation of the above remote data and extraction, local rendering strategy. In this case the rendering commands occur on the remote system and are passed as distributed rendering calls to the user’s local system for actual rendering. A local client program is still required to read the user’s trackers and process and send user commands. This strategy has advantages and disadvantages similar to the remote data and extraction, local rendering strategy, except that the network round-trip time is now part of the graphics display loop. This may introduce unacceptable delays into head-tracking responsiveness.

- **Remote data, extraction and rendering:** This strategy places all the operations of the data analysis pipeline on the remote system(s), with the final rendered frames returned to the user’s local system over the network. This strategy has the advantage that very powerful remote systems can be used when the user has a very low-power local system. The disadvantage is that the rendered frames can be large, for example, for a $1,024 \times 1,024$ 24-bit RGB-alpha display requires a four-megabyte frame buffer, and two such frame buffers are required for stereo display. This implies an 80-megabyte transfer every second in this example to maintain the frame rate of 10 frames per second. This bandwidth requirement is beyond most available large-area networks. There are also serious issues of latency control in this strategy because the network time is part of the display responsiveness loop. There are, however, situations where the local system is incapable of the kinds of rendering desired and this strategy may be the only viable option. Direct volume rendering is an example when this strategy may provide the optimal choice.

The above strategies are not exclusive: one may have remote visualization extraction taking place on one remote system while the data resides on a third system.

3.2 Remote Collaboration Strategies

Once a system is distributed, the opportunity arises for remote collaboration, where two or more noncolocated users examine the same data together. Strategies for remote collaboration are related to, but different from, distribution strategies. Next, common remote collaboration strategies are briefly summarized:

- **Distributed data:** This collaboration strategy places copies of the data to be examined on all participants’ client systems. Collaboration is implemented by passing either user commands or computed visualization extract results between each of the participants’ systems. The primary advantage of this strategy is that the software used is similar to stand-alone versions of the same systems. The main disadvantages include the difficulty of ensuring synchronization among the participants, and the requirement that each participant’s system be capable of storing data and computing (at least locally generated) visualization extracts. Many distributed collaborative VE systems, such as military training systems (see chap. 43, this volume), utilize the distributed data collaboration strategy.

- **Data server:** This collaboration strategy builds on the remote data distribution strategy. The data typically resides on a single remote system and is accessed by the participant’s local system as needed. The visualization extracts are computed locally and are communicated in the same manner as in the distributed data collaboration strategy above.

- **Visualization extract server:** This collaboration strategy builds on the remote extraction distribution strategy, in which visualization extracts are computed on a remote system, which is typically where the data being examined is stored. The extracts are sent to each participant's system for local rendering. The advantages of this strategy include:

- As there is only one set of extracts associated with each set of data, synchronization is greatly simplified.
- Local rendering allows each participant to render the visualization extracts from a local point of view, as required for head-tracked displays.
- The extract server system can arbitrate conflicting user commands.

The visualization extract server collaboration strategy has the disadvantage of poor scaling to large numbers of users, though this problem will be alleviated when reliable multicast technologies become available. The other disadvantages of this strategy are the same as those for the remote extraction distribution strategy.

- **Scene replication:** This collaboration strategy has a privileged user whose view is presented to the other participants. This collaboration strategy is similar to the remote rendering distribution strategy. This strategy has the same advantages and disadvantages as the remote data, extraction and rendering distribution strategy, with the added disadvantage that all participants will see the same view thereby precluding the use of head tracking for all participants.

4. TIME FLOW AND CONTROL

When visualizing time-varying data, a user may desire to control the flow of time, for example, make time speed up, slow down, or reverse. Furthermore, to view a particular phenomenon in more detail at a specific point in time, the user may stop the time flow. These non-real-world manipulations of the flow of time require several new ways of describing time in a virtual environment. The discussion in this section closely follows Bryson and Johan (1996), where more details can be found.

4.1 Requirements of Time-Varying Interactive Visualization

There are several design principles that must be considered before developing time-varying interactive visualization applications:

- **Correct simultaneity:** All visualization extracts displayed at the same time should have been computed for the same data time, unless explicitly directed otherwise by the user.
- **Completeness:** All visualization extracts requested for a particular data time should be displayed unless the user directs otherwise.
- **Time flow control:** The user should be able to change the rate and direction of the flow of data time steps.
- **Interactive exploration:** If the user slows or stops the flow of time, interactive exploration should still be allowed. This implies that new visualization extracts may be computed even if the data time step does not change.
- **Minimize delay:** The system should display the most recently computed visualization extracts unless otherwise explicitly directed by the user.

4.2 Types of Time

In time-varying information visualization environments, time assumes an unusual and subtle meaning. There are several senses of time that arise in such environments.

- **User time:** The time that the user experiences, the “wall clock” time.
- **Data display time:** The displayed time step, defined as the time step of the data from which currently visible visualization objects were extracted.
- **Data time:** The time step from which visualization extracts have been computed. Data time may or may not be equal to data display time.
- **Frame time:** The number of times a set of visualization extracts have been computed for a given time step. Frame time is measured by counting the number of times the computation process has been called for a given data time.

One should distinguish between data display time and data time so that when data time is moving forward visualization extracts can be computed from the next data time while the current data display time is presented to the user. The next data time may not be related to the current data display time; for example, the user may choose a particular data time for the next display frame unrelated to the current data display time.

The purpose of the frame time counter is to support the scenario in which the advance of data time is stopped and the user wishes to interactively explore the current time step’s data. By stamping the visualization extracts with their frame time in addition to their data time the most recently computed extract may be displayed, maximizing interaction responsiveness. The use of frame time is discussed in the next section on buffering strategies.

4.3 Buffering Strategies

In the run-time architecture described in section 2.3, the computation process group produces visualization extracts that are displayed to the user by the interaction process group. The method of communication between these groups is driven by the principles outlined in section 4.1 and is implemented using the time parameters defined in section 4.2.

The most difficult case is when the information visualization system supports several independent visualization objects, such as streamlines and isosurfaces, which can be independently specified and displayed. This shall therefore be assumed the case in the current discussion. It is further assumed that the graphics process keeps a list of visualization extracts to be displayed. It is desirable that visualization extracts that do not change be displayed without recomputation. The buffers that pass the visualization extracts from the computation process to the graphics process should be capable of passing only those extracts that are newly computed without destroying those older extracts that should continue to be displayed. This requirement is most easily met if buffering takes place at the visualization object level, where each visualization object manages its own buffer.

There are two approaches to buffering, *local time* and *time-cached buffering*. Local-time buffering does not retain visualization extracts over time, while time-cached buffering saves visualization extracts for possible reuse when appropriate.

4.3.1 Local-Time Buffering

In local-time buffering, only the most recently computed visualization extracts are displayed and there is no attempt to cache visualization objects from previous time steps. This approach to buffering is appropriate to non-time-varying data because new visualization techniques are generated only in response to user commands. Local-time buffering should be implemented so that: (1) the most recently computed extracts are available, and (2) the computation process does not have to wait while a visualization extract is displayed. Conventional double-buffering techniques, where one has a *write buffer* into which computed visualization extracts are stored and a *read buffer* out of which previously computed extracts are displayed, only partially

meet these requirements. Consider the case where the computation process is faster than the graphics process. This will often happen in non-time-varying environments where perhaps one visualization extract is being computed in response to a user command, whereas all current visualization extracts need to be displayed. When using a double-buffer approach and the computation process is faster than the graphics process, the write buffer will be filled before the graphics process's read buffer has been used and released for writing. This will cause the computation process to wait until the read buffer has been released. Such waiting will result in a delay if the user is “sweeping” a visualization object in space, producing a continuous stream of visualization extracts to be computed.

A better approach is to use a triple-buffer strategy, where three buffers are available. During typical operation, the computation process will fill one or more of these buffers, so (after the buffers have been filled) there may be two or more buffers marked “read.” Each of these buffers will be marked with the time frame number defined in section 4.2, as well as the data time number if the data is time varying. In order to minimize delay the graphics process will choose the buffer with the highest time frame number, which will be the visualization extract most recently computed. In the meantime, if the computation process wants to proceed it can compute the response to the most recent user commands, overwriting the older of the two available read buffers, thus minimizing latency. In this way a triple-buffer strategy allows local-time buffering to meet the requirement to minimize delay.

In a time-varying data environment, the buffers will also be stamped with the time step in which the extract was computed. The graphics process then selects buffers from the time step being currently displayed in addition to selection of the highest data frame time. This assures that the requirement of “correct simultaneity” of section 4.1 is met.

4.3.2 Time-Cached Buffering

In a time-varying data environment one may wish to cache previously computed visualization extracts. When this is done, if the time step from which those visualization extracts were computed is encountered again, those extracts can be displayed without recomputation.

Time-cached buffering requires local-time buffering within each time step. When the time step advances the most recent visualization extracts for that time step can be stored. Then, when that time step is reselected, either by user command or because the time flow is periodic, those extracts can be displayed without recomputation if their specifying data (e.g., seed positions for streamlines or values for isosurfaces) are still valid.

5. TIME-CRITICAL TECHNIQUES

One of the prime requirements of VEs is responsiveness. In section 2.2, the performance requirements for various aspects of an information visualization application within a VE were discussed. These requirements can be difficult to meet in light of the possibly complex graphics and extensive computation required for computation of visualization extractions. One is often faced with a conflict between the requirements of a complete or accurate visualization and the requirements for responsiveness and fast graphical display rates. Although accuracy is often critical in an information visualization environment, users often prefer fast response with a known degradation in accuracy for purposes of exploration. When a phenomenon of interest is found in the more responsive but less accurate mode, the user can request that this phenomenon be recomputed and displayed more slowly with higher accuracy. The automatic resolution of the conflict between accuracy and responsiveness, finding the appropriate balance, is known as *time-critical design*, the topic of this section.

5.1 The Time-Critical Philosophy

Time-critical design attempts to automate the process of finding a balance between required accuracy and responsiveness. This approach is very different from real-time programming, which guarantees a particular result in a specified time. Real-time programming typically operates in a fixed, highly constrained environment, whereas time-critical programs are typically highly variable. This variability is particularly evident in an information visualization environment, where the data and extracts computed and displayed may vary widely within a single user session. Time-critical design does not guarantee a particular result, instead it delivers the “best” result possible within a given time constraint. A successfully designed time-critical system will provide a graceful degradation of quality or accuracy as the time constraint becomes more difficult to meet.

Time-critical design for a particular aspect of a program begins with defining a cost and benefit metric for the task to be completed. The task is then parameterized in a way that controls both costs and benefits. When the cost and benefit of a task are known as a function of the task’s parameters before that task is performed, the appropriate choice of parameters is selected to maximize the cost–benefit ratio. There are often many tasks to be performed in an environment, and the benefit of a particular task can be a function of the state of that environment. The solution of this problem is often approached as a high-dimensional constrained optimization problem, maximizing the total cost–benefit ratio for the sum of the tasks to be performed given the constraint of the total time allowed for all tasks.

As discussed below, however, it is often very difficult to know the benefit and cost of a task before that task is performed. In such situations, hints provided by the user or simple principles, such as assuming equal benefit within a set of tasks, are often used.

5.2 Time-Critical Graphics

Time-critical techniques were pioneered in computer graphics (Funkhouser & Sequin, 1993), where objects were drawn with higher or lower quality depending on such benefit metrics as position in the field of view and distance from the user. Such implementations often used multiple representations of an object at varying levels of detail. In information visualization, however, many visualization extracts are already in a minimal form, such as streamlines defined as a set of points. There are opportunities for graphical simplification in information visualization, however. For example, it may be the case that many more primitive elements are used to define a surface than is necessary for its display. An isosurface may have regions that are close to flat but the algorithm used to derive the isosurface may create many surface elements in that flat region. Display of that surface would be faster if the flat region were represented by fewer surface elements (see, e.g., Chen et al., 1999, and subsequent papers in that volume). A surface may also be represented in simplified form until it became the focus of attention, where small variations from flatness may be important. Unfortunately, algorithms that identify such opportunities for surface simplification are computationally intensive and may therefore be unsuited to recomputation in every frame.

From similar considerations, it may be concluded that unlike general computer graphics based on precomputed polygonal models, the use of time-critical graphics in information visualization will be highly dependent on the domain-dependent specifics of the visualization extracts. It may be very difficult, for example, to assign a benefit to a particular extract, especially when that extract may extend to many regions of the user’s view. Although simple benefit metrics, such as the location of the extract on the screen, may be helpful, one should keep in mind that the user’s head may be pointed in one direction while the user’s eyes may be scanning the entire view. Such scanning is to be expected in an information visualization environment where the scene may contain many related, extended objects.

From these considerations there are few generalizations that can be drawn about the use of time-critical graphics techniques in information visualization. Opportunities do arise, however. Simple examples of time-critical graphics techniques that may be useful in information visualization include:

- Simplified representations, such as wireframe rather than polygonal rendering
- Surfaces represented as 2-D arrays, where simplified versions of the surface may be obtained by rendering every n point in the array
- Techniques that have been developed for time-critical direct volume rendering (e.g., Wan, Kaufman, & Bryson, 1999).

A more general approach to time-critical graphics is to use multiresolution representations of data or resulting visualization extracts. This is a new area of research, however, with relatively few results at the time of this writing.

5.3 Time-Critical Computation

Computation of visualization extracts can provide several opportunities for time-critical design (Bryson & Johan, 1996) because such computation is often the most time-consuming aspect of a visualization system. As in the case of time-critical graphics, the specifics of time-critical computational design will be highly dependent on the nature of the extract computed. Several general observations, however, can be made.

- Both the cost and benefit of a visualization extract can be very difficult to estimate a priori based on its specification and control parameters, especially since the extent of an extract is difficult to predict based on its specification alone.
 - The cost of an extract can be roughly defined as the time required for its computation. Experience has shown that this cost does not vary widely between successive computations.
 - Parameterizing the extent or resolution of the computation may most easily control the cost of a visualization extract. Techniques that begin their computation at a particular location in space, such as a streamline emanating from a point in space, lend themselves well to controlling their extent in space, which controls the time required by their computation. The cost of visualization techniques that rely on abstract or indirect specification is more effectively controlled by varying resolution.
 - Other ways to control the cost of the visualization extract include choice of computational algorithm and error metrics for adaptive algorithms. These control parameters have a more discrete nature and may be set by the user or set automatically via specific trigger criteria.

Given that the benefit of a visualization extract is hard to predict, one may treat all extracts as having equal benefit unless specified by the user. In combination with the observation that costs do not change dramatically in successive computations, this allows the following simple solution to the problem of choosing the control parameters. For simplicity, the situation in which all visualization extract's costs are controlled by limiting their extent is considered. Here, each extract computation is assigned a time budget, and each extract's computation proceeds until its time budget is used up. Then the time taken to compute all extracts is compared to the overall time constraint. Each extract's time budget is divided by a scale factor determined by the total actual time divided by the total time constraint. This scale factor may have to take into account any parallel execution of the extract computations. If the time required to compute all extracts is greater than the time constraint, this will result in smaller visualization extracts that will take less time to compute. If the extracts become too small, a faster but less accurate computational algorithm may be chosen. If the time required to compute all extracts

is smaller than the time constraint, the time budget of each extract is increased, resulting in larger visualization extracts. A similar approach may be used to choose the resolution with which visualization extracts may be computed.

It may be evident from this discussion that the types of control parameters one may use in time critical design will be highly dependent on the nature of the extract and how it is computed. Clever approaches can significantly enhance the time-critical aspects of a visualization technique. As an example, consider isosurfaces of a 3-D scalar field. Such isosurfaces are traditionally specified by selecting a value, resulting in a surface showing where that value is attained in the scalar field. Controlling the cost of a traditional isosurface by limiting the time of the computation will have unpredictable results. In the conventional marching cubes algorithm for computing isosurfaces the entire data set is traversed. If the marching cubes algorithm is stopped before completion and before regions of the field where the isovalue is attained are traversed, no isosurface will appear at all. Controlling the cost of the marching cubes algorithm by controlling the resolution with which the data set is traversed is possible, but this strategy does not provide fine control and may result in a significant degradation in quality. A different approach to isosurfaces, *local isosurfaces* (Meyer & Globus, 1993), directly addresses this problem. Rather than choosing an isovalue, for a local isosurface the user chooses a point in the dataset, from which the isovalue is determined as the value of the scalar field at that point. The isosurface is then computed (via a variation on the marching cubes algorithm) so that it emanates from that point in space and is spatially local to the user's selection. The cost of a local isosurface is controlled by computing the isosurface until that isosurface's time budget has been used up. Two examples of local isosurfaces can be seen in Fig. 53.3.

6. CASE STUDY: THE VIRTUAL WINDTUNNEL

The Virtual Windtunnel (VWT, Bryson & Levit 1991; Bryson et al. 1997) is a VE for the analysis of time-varying fluid-flow data sets that are the results of computational fluid dynamics computations. VWT supports distributed collaborative operation as well as several types of data analysis (see Fig. 53.3). In this section the implementation strategy of VWT is outlined.

VWT is designed to address the case of interactive, time-varying data from section 2.1 and therefore uses the system architecture described in section 2.3. There are several processes in the display and interaction process group, including a graphics process and multiple processes to read user tracking. The computation process group uses multiple processes to perform computations in parallel when multiple processors are available. VWT represents the visualizations as object classes and maintains lists of object instantiations for both computation and display. For distributed operation, the remote data and extraction, local rendering strategy of section 3.1 is used in combination with the visualization extract server collaboration strategy of section 3.2.

Time-flow control fully implements the discussion in section 4, using time-local buffering with the triple-buffering technique (Bryson & Johan, 1996). Each visualization object contains the triple buffer structure in the object definition, and each object manages its own buffer. Time-critical computation is implemented for several of the visualization techniques using the simple scaling strategy described in section 5.3. When the data is not time varying, the computation of streamlines and local isosurface extracts is reentrant, so in subsequent time frames these extracts may be enlarged if their defining data have not changed. Time-critical computation of the streamline extracts implements a choice of several computational algorithms, listed here in order of increasing accuracy and decreasing speed: one-step Euler integration; second-order Runge Kutta; and adaptive fourth-order Runge-Kutta. Which algorithm is used is automatically chosen based on the size of the streamline relative to a user-controlled *preferred*

size. When the streamline falls significantly below the preferred size, a faster but less accurate streamline computation algorithm is chosen. Details can be found in Bryson (1998).

VWT has been tested in distributed collaborative mode with as many as four participants, two in Washington, D.C., and two in California (a distance of approximately 2,400 miles), with the data and visualization extract server in California. Communications in this test were over a conventional network. When examining a non-time-varying data set, the performance requirements of 0.1 second latency were maintained. Time-varying data sets also maintained the latency performance requirement for a small number of visualization extracts, however, as more and larger extracts were used (e.g., large isosurfaces) network bandwidth constraints became significant.

7. CHALLENGES

While several information visualization systems have been implemented in a VE setting, there are several challenges that have been encountered, which at the time of this writing do not have satisfactory solutions.

- **Large data sets:** Many information visualization applications involve very large data sets. Examples from computational fluid dynamics include time-varying data sets hundreds of gigabytes in size. Examples from the NASA Earth Observing System are expected to generate a terabyte of data a day. Accessing this data within the performance constraints of VE is beyond the reach of current technology as of 2000. Higher bandwidth and lower latency access to mass storage devices will help, but the tendency in the data-generating community is to use higher computational power to generate higher resolution and therefore larger data sets. Techniques to preextract interesting features from such data sets hold the greatest promise as a solution to this problem.

- **Representation of abstract data:** Most information visualization systems that have been successfully implemented in VEs are in domains that map closely to the real world, such as fluid flows or geophysics. Other domains involve the use of more abstract data. Appropriate mappings of abstract data into a 3-D VE is an area of ongoing research.

- **High-dimensional data:** Most information visualization systems that have been successfully implemented in VEs have data that is defined in 3-D space. Many information domains have data defined on a higher dimensional domain. Visualizing this data in two dimensions has been an ongoing area of research. We expect that visualizing this data in the inherently 3-D environment of VEs would be of benefit. Mapping these higher dimensions into the three dimensions of VEs is a problem that has yet to be thoroughly explored.

- **Time-critical distributed design for distributed environments:** Time-critical design for distributed VEs, where network traffic and latency times must be considered, is an unexplored area (see chap. 16, this volume). This challenge becomes more complex in the context of distributed computation, where different extracts are computed on separate systems.

8. CONCLUSIONS

Information visualization is an active and fruitful area of VE research and development. The advantages of information visualization in VEs include:

- 3-D display
- 3-D user interaction
- An intuitive interface that facilitates the exploration of complex data

In order to implement an effective information visualization application in a virtual environment, however, issues of responsiveness and fast updates must be addressed. These issues may be resolved via use of appropriate system architectures, design based on human factors issues, appropriate time control for time-varying data, implementation of time-critical techniques whenever possible, and appropriate choices for distributed implementations. The details of how these solutions are implemented will be highly dependent on the target domain and the specifics of the visualization techniques used.

1. INTRODUCTION

By considering both the sensory and cognitive capabilities and limitations of humans, significant advances can be made in applying virtual environment (VE) technology to manufacturing systems. An integrated approach, which includes feasibility analysis, iterative design, and systematic evaluation, is needed to realize this potential. In order to provide appropriate information support, activity analysis needs to be conducted. A three-step manufacturing activity analysis procedure is presented to evaluate feasibility, determine potential benefits, and to establish the costs and benefits of using VE technology. A limited number of demonstrations and applications of VE technology using visualization (see chap. 53, this volume), simulation, information provision, and telerobotics (see chap. 48, this volume) have been made in manufacturing. These applications relate to tasks including the design of manufacturing activities, design of manufacturing facilities, training, execution of control and monitoring activities, execution of planning activities, and execution of physical processing activities. Only approximately 10% of these applications, however, have been evaluated empirically. The most promising areas for future application and research include manufacturing facilities and product design (see chap. 52, this volume), training (see chaps. 43 and 44, this volume), and execution of physical processing activities.

Applications of VE technology to manufacturing are just beginning to emerge. These applications are directed toward using VE technology as a means of improving performance for a wide variety of manufacturing tasks involving humans. The goal of this chapter is to review recent VE applications in this domain in order to isolate areas where additional applications and research have the potential for improving modern manufacturing.

1.1 Manufacturing Systems

Manufacturing is the process by which raw materials and purchased items are transformed into finished goods of greater value. Every type of tangible good available to society, from consumer durable goods to electronics, computers, and automobiles, results from manufacturing. The importance of manufacturing to the economic well-being of a nation cannot be underestimated. Higher levels of manufacturing activity lead to higher standards of living, as evidenced by such nations as the United States, Canada, Great Britain, France, Germany, Switzerland, and Japan. Manufacturing accounts for about 20% of the gross national product (GNP) in the United States, whereas primary industries (agriculture, forestry, mining, etc.) account for less than 5% of the GNP (Groover, 1996).

In order to manufacture items, manufacturing systems are required. A *manufacturing system* is an organized collection of machines, equipment, and humans that function in a predetermined manner to convert inputs into finished goods in response to actual or anticipated demand. Various types of manufacturing systems are found in different industries, depending on the nature of the products to be made and the demand for them. Fixed-position systems are those where the facilities required for manufacturing (machines, tools, etc.) are brought to the item for each operation. This approach is used for very large items, such as aircraft and ships. Product-oriented systems (flow shops) are those where the processing equipment is arranged in a line (or similar configuration) and items flow down the line one after another with finished items coming off the end of the line. These are the easiest systems to operate and control, and are used when product variety is low and demand is high (mass production). Process-oriented systems (job shops) are those where similar machines are grouped together into different departments (machining department, inspection department, etc.) and items travel from department to department as required for processing. Such systems are able to accommodate the largest possible variety of different products, but items take the longest to produce. Job shops are used when product variety is high and demand is low. Group technology systems are those where similar products are grouped together into part families, equipment is formed into one or more groups (or cells), and each part family is assigned to a specific machine group for production. This approach is a compromise between product-oriented and process-oriented systems and is used when product variety and demand are both medium. Finally, flexible manufacturing systems consist of multiprocess, numerically controlled machines that are linked together via an automated material handling system and are under hierarchical computer control. These systems have a large range of processing capabilities and can change from one product to another quickly and easily. Flexible manufacturing systems are best suited for mid-volume, mid-variety production where different products may be required in random order and in small order quantities.

1.2 Framework for Investigating Virtual Environments in Manufacturing

In order to discuss applications of VEs in manufacturing, some type of framework is needed. All manufacturing systems are comprised of three basic components, each of which can be considered a system. The *physical processing system* is responsible for the actual physical conversion of inputs into finished goods. The *planning system* is responsible for the generation of plans establishing how to employ the physical processing system. These plans consist of what products to make as well as when, how, and in what quantities. Finally, the *control and monitoring system* is responsible for ensuring that the plans generated by the planning system are properly executed in the physical processing system. This often requires real-time decision making to be performed and feedback to be sent back to the planning system.

Williams (1992) stated that a manufacturing system could be viewed in two fundamentally different ways. The first is the *functional view*, where one is concerned with what activities have to be performed and under what conditions they are performed. Though there are many different activities in manufacturing, one finds that every activity involves either a transformation of information or a transformation of matter and/or energy. Activities of the former type are known as informational activities, whereas the latter are known as physical activities. One can differentiate between three different types of informational activities: decisional, information acquisition, and information support. Decisional activities are those that result in the creation of new information (e.g., designs, plans) from existing information. Information acquisition activities are those in which new information is acquired. Such information can come from outside the system or from within the system via data acquisition (e.g., temperature sensors, position sensors) or data input (e.g., keypad, touch screen). Information support activities are those that provide information as required for execution of other activities. Information communications, storage, and presentation are all necessary for providing information support.

The second way to view manufacturing systems is the *implementation view*, where one is concerned with which resources (machines, equipment, computers, people, etc.) are used to implement the various manufacturing activities specified in the functional view. There are two main categories of resources in manufacturing systems: humans and mechanisms. When a human is involved in activity execution, the activity is done manually. If no human is involved, the activity is automated. Note that humans usually require one or more mechanisms to assist in activity execution. For example, a planner may need a calculator to execute a decisional activity, whereas a shop-floor worker may need a screwdriver to assemble two items together or a cart to move heavy items.

The functional and implementation views, as well as the basic components of manufacturing systems, can be combined into a classification of components, resources, and activities for manufacturing systems, as shown in Table 54.1. For simplicity, only the most fundamental planning activities are considered. The planning activities and control and monitoring activities are all decisional in nature; any information needed for executing these activities must be obtained via information support and information acquisition activities. The physical processing activities are all physical in nature, and in a similar manner rely on information support and information acquisition activities to provide any information needed.

Williams (1992) also discusses the concept of a manufacturing system life cycle. The three stages of his manufacturing system life cycle that are most relevant to VE applications are system design, system manifestation, and system operation. During the *design stage*, each component of the manufacturing system must be designed, both in terms of activities (functional view) and resources (implementation view). In the *manifestation stage*, the manufacturing system design becomes reality: resources are purchased, installed, and tested, and human operators are trained to perform the various manufacturing activities for which they are responsible. Following the manifestation stage is the *operation stage*, where the various manufacturing activities are executed, with the given resources, in order to obtain finished items of various types in response to demand. All of the activities shown in Table 54.1 occur during the operation stage.

Putting these three elements—functional and implementation views, basic components, and life-cycle stages—together results in the specification of the different tasks involved in manufacturing over the life cycle of a system, as shown in Table 54.2. For the purpose of investigating VEs in manufacturing, six major tasks involved in manufacturing can be considered over the life cycle of a system. Note that planning, control and monitoring, and physical processing under the operation stage of manufacturing are not combined into one task in Table 54.2 because applications of VE technology can vary greatly across these three tasks. We use the term *task* rather than activity to distinguish between those activities that are executed during the operational stage and those that are executed at different stages of the life cycle of manufacturing systems, as summarized in Table 54.2.

TABLE 54.1
Resources Employed and Activities Performed in Manufacturing Systems

<i>Manufacturing System Component</i>	<i>Manufacturing Resources (Implementation View)</i>	<i>Manufacturing Activities (Functional View)</i>
<i>Planning</i>	Planning Facility Buildings, rooms, areas Computers Data communications/ storage devices Data acquisition/input devices	Planning Activities Product design: products to be made. Process planning: operations required to make the products. Production planning: when to make the various products, in what quantities, and with which resources. Shop-floor scheduling: how the various items are scheduled for production in the physical processing facility.
<i>Control and Monitoring</i>	Control and Monitoring Facility Buildings, rooms, areas Computers Data communications/ storage devices Data acquisition/input devices	Control and Monitoring Activities Manufacturing activity control: control of all physical activities in the manufacturing facility to ensure that plans are realized. Quality control and inspection: activities performed to ensure items are produced to specification. Testing: activities performed to ensure that items function as intended. Inventory control: control of inventories (raw materials, work-in-process, and finished items).
<i>Physical Processing</i>	Physical Processing Facility Buildings, rooms areas Processing machines, equipment, tools, fixtures Material handling equipment Material storage equipment Data communications/ storage devices Data acquisition/input devices	Physical Processing Activities Fabrication: activities that change the dimensions, geometry, and/or one or more properties of an item directly (e.g., machining). Assembly/disassembly: activities that change the dimensions, geometry, and/or one or more properties of an item indirectly, i.e., by combining the item with other items (e.g., welding). Material handling: activities that transform physical items in space (e.g., moving items from one machine to another, shipping). Material storage: activities that transform physical items in time (e.g., storage of items between operations). Maintenance: activities that keep the manufacturing process functioning.

TABLE 54.2
Manufacturing Tasks Over the Life Cycle of a Manufacturing System

<i>Life-Cycle Stage</i>	<i>Manufacturing System View</i>	<i>Manufacturing System Component</i>	<i>Manufacturing Task</i>
Design	Functional	Planning, control and monitoring, physical processing	Design of manufacturing activities
	Implementation	Planning, control and monitoring, physical processing	Design of manufacturing facilities
Manifestation	Functional	Planning, control and monitoring, physical processing	Training for manufacturing activity execution
Operation	Functional	Planning Control and monitoring	Execution of planning activities Execution of control and monitoring activities
		Physical processing	Execution of physical processing activities

1.3 Role of Humans in Manufacturing

Humans are always present in manufacturing systems. The manner and extent to which humans are involved in executing the various manufacturing tasks may vary greatly from one manufacturing system to another. The role of humans in manufacturing is dependent on several parameters. Both the type of manufacturing system and nature of the products being made must be considered. For example, flow shop operation requires relatively few decisional activities but many physical activities per unit time, whereas job shop operation is the opposite. Certain decisional and/or physical activities are present in some manufacturing systems but not others.

In addition, Williams (1992) defines the *automatability*, *humanizability*, and *extent of automation* limits as additional parameters for determining the role of humans in manufacturing. The automatability limit defines the absolute extent to which tasks can be executed by automated means. This limit results from the fact that certain tasks may require capabilities beyond those found in currently available technology. For example, humans must handle decisional tasks requiring thought, creativity, and other cognitive activities, as well as physical tasks that require human capabilities (e.g., intricate assembly operations). The humanizability limit defines the absolute extent to which humans can execute tasks. This limit results from the fact that certain tasks may require computational capabilities, speed of response, physical strength, endurance, and so forth, beyond human capabilities. The difference between the automatability and humanizability limits defines the extent to which choice exists in using humans to execute manufacturing tasks. If the difference is large, much choice exists, and execution could range from highly automated (closer to automatability limit) to highly manual (closer to humanizability limit). If the difference is small, there is little choice: whether or not tasks are executed by humans or by automated means is largely predetermined. The actual allocation of tasks to humans and mechanisms, where choice exists, determines the extent of automation for the task set.

Once the manufacturing tasks to be done by humans are established, one must establish how. Two distinct problems must be tackled: task assignment and task design. Task assignment establishes what tasks are to be done by which workers. Multitasking is common in manufacturing where human operators are routinely called on to perform a variety of time-sharing

tasks, such as job scheduling, inventory management, machine setup, and inspection. Pesante, Woldstad, and Williges (1997) investigated characteristics of an inspection task that could facilitate multitasking. The ability to employ multitasking depends on the tasks involved. Task design, on the other hand, establishes exactly how the human operator is to perform the required task(s). This, in turn, will depend on the task requirements and human capabilities and limitations.

1.4 Virtual Environments

Virtual environments, in the broadest sense, are tools used to assist humans in task execution by providing information and feedback. They can be viewed as a means of executing information support activities. Milgram and Drasic (1997) describe a reality–virtuality continuum for characterizing VE representations. The four major components of this continuum include: reality, augmented reality, augmented virtuality, and virtuality. This classification might provide some intuition to determine potential applications of VE by linking a given application domain to a VE class along this continuum.

The “reality” class defines the environment as consisting solely of real objects observed via a video display. Telepresence using video cameras (see chap. 48, this volume) are included in this level of virtuality to improve an operator’s perception and to provide a natural interface.

Augmented reality (AR) is an enhanced, or augmented, environment where computer-generated images are added to the real environment. Most AR systems are coupled with see-through head-mounted displays (HMDs) and head trackers. Task-related information or graphics are provided from the computer to support the operators who are executing tasks in the real environment. The success of AR applications depends mainly on the way information is transmitted to the operators rather than the immersive feeling or fidelity within the virtual environment (see chap. 40, this volume). This class of applications can support tasks requiring physical manipulation of real objects.

Augmented virtuality is almost the same as AR, except the primary VE is enhanced through some additional real-world image. Augmented virtuality provides a partially immersive environment where real physical objects interact in a virtual world. An example of augmented virtuality is where a user reaches forward in the virtual world and grasps a virtual object on a VE workbench that provides a large projection screen, or in a Cave Automatic Virtual Environment (CAVE) that provides a VE room.

Virtuality is a completely immersed environment and is commonly referred to as “virtual reality.” Many applications are implemented using an HMD to provide complete immersion. The main uses of virtuality are training and applications requiring simulation that do not allow the operator to interact with real objects. The success of these applications depends on the level of immersive feeling and the degree of fidelity of the VE system. For the purpose of this chapter, a distinction is made between four different methods by which VEs can provide information support:

- *Visualization:* A VE visualization occurs when the user interacts with three-dimensional (3-D) objects in a VE and the interaction is in terms of navigation only (see chap. 24, this volume). In other words, the user can move through the VE world as desired, scrutinizing virtual objects from different positions, angles, and orientations. The virtual scene is continuously updated according to the user’s viewpoint; therefore, the user can feel and experience the VE to a greater level than possible for a passive observer. This capability results in an ideal workspace for various engineering applications. Although visualization requires 3-D representation of objects in the VE, the difference between visualization and traditional 3-D computer-aided design (CAD) is that visualization concentrates on the high degree of perception rather than on

the pure quality of the graphics (Wilson, Cobb, D'Cruz, & Eastgate, 1996). In VE visualizations, the world may be either static or dynamic (see chap. 53, this volume). In the latter case, system behavior in the VE is presented according to some predefined script, as the user has no control over the objects. This is essentially equivalent to simulation animation via a VE, where the term *simulation* is used in the operations-research sense of the word (i.e., objects interacting with one another, as part of a system or process, in a scripted manner established by specified input parameters).

- *Simulation:* In a VE simulation, the user interacts with virtual objects in a virtual or augmented world, and the virtual objects act like the real ones in response to unscripted user actions. Users can be immersed in the VE, where they interact directly with the elements of the simulated VE world. This allows users to experience simulated situations directly, they can touch virtual objects and change their state in the same way as they do in the real world. This results in an ideal environment for evaluating the design of equipment, systems, and tasks that either do not exist in the real world or for which actual usage would be impractical or cost-prohibitive (see chap. 52, this volume). The critical component is the interaction between users and the VE (i.e., feedback from the VE to the user's physical world). Simulation via VEs requires more than realistic visualization; it also requires realistic physical behavior on the part of the virtual objects. Therefore, most VE simulations employ visual (see chap. 3, this volume), auditory (see chap. 4, this volume), and/or haptic (see chaps. 5 and 6, this volume) displays to support realistic interaction between users and the VE system.

- *Information Provision:* Virtual environment technology can be used to guide and support workers to complete their work more efficiently by means of information provision. Task-related information, such as instructions and data, can be conveyed to workers both when and where needed via VE technology. Augmented-reality displays are a promising approach for providing information for execution of real-world tasks because they allow users to see both virtual and real objects together. In this approach, virtual objects are used to present required task-related information to the user directly.

- *Telerobotics:* Telerobotics involves remote control of robots (see chap. 48, this volume) and is used when the user interacts with virtual or real objects in an unscripted manner. This interaction causes certain activities to occur in the real world via a robot or some other electromechanical device. These activities, in turn, affect virtual objects via feedback and provide a sense of telepresence. The fundamental purpose of telepresence is to extend an operator's sensory-motor facilities and problem solving abilities to a remote environment (Rosenberg, 1993). Telerobotics is typically used to remove an operator from a hazardous environment. However, the current generation of telerobotics does not convey the necessary level of perception and awareness to an operator for accurate control and decision making. To overcome this limitation, a VE display can reconstruct the remote environment so that the operator can control robots in the real environment via a virtual interface.

The ability to use a given VE method for a particular information support activity depends on the informational requirements of the activity. Thus, in order to employ VEs to aid in activity execution, it is necessary to examine both the informational requirements and ability of the VE method to satisfy these requirements. Two important attributes, from the VE perspective, are the information modality and the volume of information per transaction. The information modality is the principle factor in establishing the VE technology and hardware required, but a certain VE method may be cost-prohibitive or even infeasible for certain information modalities when applied to certain tasks. Volume of information per transaction is one of the principle factors for establishing the level of "reality" associated with any virtual, or augmented, world. When information requirements are high, reduced presentation resolution (e.g., rendering of graphical objects), and hence reduced reality, is necessary.

2. VIRTUAL ENVIRONMENTS FOR MANUFACTURING

The value of VE technology for a given manufacturing task must be considered in terms of applicability, technological and human considerations, and potential benefits and cost considerations. Each of these three items is discussed separately before reviewing the current applications of VE technology to manufacturing.

2.1 Applicability of Virtual Environments to Manufacturing

Each of the six fundamental types of manufacturing tasks requires information support for execution, and VEs have been defined as tools for providing informational support to humans. Thus, VEs have the potential for aiding humans in executing tasks of each type in manufacturing. The choice among different VE methods to be used for different tasks depends upon the informational requirements of the task. As each of the six types of manufacturing tasks has different information requirements, the VE methods that are suitable for each will also differ. Table 54.3 shows which VE methods have been applied to each of the six task types.

Visualization can be employed for almost all types of manufacturing tasks but is particularly well suited to the design of manufacturing facilities and the execution of planning activities. One of the most common planning activities for which visualization is employed is product design. The process of designing and validating products via a real-time graphics system that allows the user to be immersed in and interact with the product is known as *virtual prototyping* (Flaig & Thrainsson, 1996). Although VE simulation can be used for various design and planning activities (see chap. 52, this volume), it holds particular promise for training operators to execute manufacturing activities. This potential is magnified by the fact that training is an essential component of all manufacturing activities. Information provision is particularly well suited for aiding in manufacturing activity execution and can lead to enhanced performance. This performance enhancement can in turn reduce operator workload and facilitate multitasking. Chung, Williges, and Shewchuk (1999), for example, show how AR can be used to provide task-related information for thickness inspection, where performance is measured by task completion time and magnitude of measurement error. As shown in Table 54.3, telerobotics is employed only in the execution of physical processing activities in manufacturing.

2.2 Considerations in Applying Virtual Environments to Manufacturing

Several considerations need to be addressed when applying VE technology to manufacturing. Dai (1998), for example, discussed the intersection of VE graphics, CAD, and telecommunications technologies as a means of supporting concurrent engineering in integrated product development. He describes the activities of a German working group using VE technology for improving primarily interactive visual prototyping and simulation in a variety of industrial applications. Likewise, Wilson et al. (1996) summarized work on the Manufacturing Operations in Virtual Environments (MOVE) program, which surveyed and provided demonstrations of VE applications to British industry. They viewed the primary role of VEs as that of providing interaction (see chap. 13, this volume) and a feeling of presence (see chap. 40, this volume) to visualization techniques used in industry. The most feasible industrial applications were related to planning and design, operations, training and communication (see chaps. 43 and 44, this volume) and integrated product development (see chap. 52, this volume).

Two aspects of human performance that must be considered in VE system development efforts are the sensory and information processing capabilities and limitations of workers. Most applications of VE technology in industry only deal with the visual representation of the virtual environment. Other sensory modalities such as auditory, vestibular, olfactory, kinesthetic, proprioceptive, locomotion, cutaneous, and gesture representations in VEs still need to be explored in manufacturing applications (see chaps. 4–11, this volume). Information processing capabilities and limitations deal with cognitive functions (see chap. 20, this volume) of the human such as spatial perception, attention sharing, memory, error analysis, decision making, workload analysis, and process control. All of these functions can affect human performance in manufacturing environments that involve VE systems.

2.3 Task Analysis

Based on our six manufacturing tasks and four VE methods for providing information (see Table 54.3), a methodology for establishing potential benefits and cost using VEs for a given manufacturing task can be developed. As shown in the Fig. 54.1 decision flow diagram, the methodology consists of three steps: evaluate overall feasibility (Step 1); determine potential benefits (Step 2); and conduct a cost–benefit analysis (Step 3).

The applicability of VEs to a given manufacturing task is evaluated in Step 1. A VE is applicable if (1) one or more information support activities are needed for task execution, and (2) at least one of these activities can be performed via one or more VE methods. Thus, the information requirements must be established and compared to the capabilities of each VE method. The result of this step will determine whether or not VEs are applicable for a given manufacturing task, and if so, the VE methods that can be used.

During Step 2, the potential benefits of VEs are determined. The objective is to use a VE to provide the necessary information for a given task in order to improve task execution (reduced time, improved quality, etc.; see chap. 35, this volume). As shown in Fig. 54.1, the potential for such improvements can be established in two ways. The first of these, analytical evaluation, consists of estimating potential benefit based on the impact of the information on overall task performance. For example, if the presentation of a high-quality, dynamic graphic image is of paramount importance to task execution, the potential benefit of using a VE for this task is high. On the other hand, the potential benefit is low if either the presentation of such an image will likely have only a minor impact on performance or a VE is not well suited to presenting such images. The second of these, experimental evaluation, consists of obtaining prototype/production VE hardware, establishing a procedure, and performing experiments to

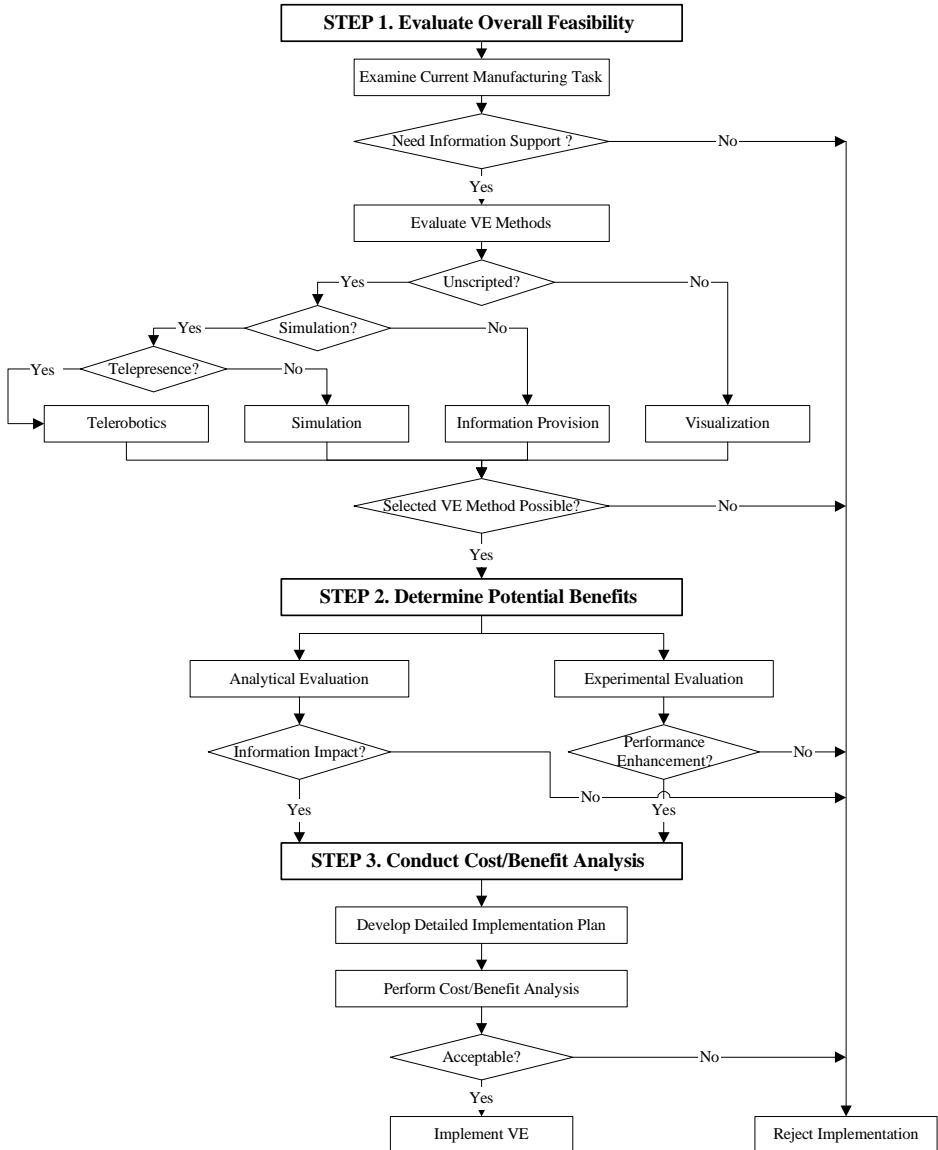

FIG. 54.1. Decision Process for Analyzing Manufacturing Tasks for Application of Virtual Environments.

establish quantitatively the performance benefit under experimental conditions. This gives an estimate of the potential benefit if the VE hardware and procedure were employed in actual production conditions. The results of Step 2 will provide quantitative and/or qualitative measures establishing the potential benefit of employing each of the applicable VE methods for the given task.

Virtual environments should actually be used, however, only if the benefits outweigh the costs (i.e., VE hardware, procedure development, training, and lost production time during implementation). Thus, a cost-benefit analysis must be performed in Step 3 (see chap. 28, this volume). This can only be done after a detailed plan of the VE implementation has been developed so that costs can be estimated. Once this has been done, the cost-benefit analysis

will be either subjective or objective depending on how the potential benefits were quantified in Step 2. Given that cost–benefit analysis provides a sufficiently positive result from an economic point of view, VE technology is a good candidate for implementation.

The main goal of the above three-step procedure is to ensure that VEs are used only if they provide concrete benefits and these benefits outweigh the costs involved. If these conditions are not met, it is better to continue using traditional methods (paper, traditional computer presentations, etc.) for supplying the required information.

3. CURRENT APPLICATIONS OF VIRTUAL ENVIRONMENTS IN MANUFACTURING

The application of VE technology to manufacturing is an emerging area, and about 50 applications appear in the scientific literature. As shown in Table 54.4, most applications exist in product design. Since the current focus of a VE is mainly on visual information, applications employing haptic feedback (see chaps. 5 and 6, this volume) to increase fidelity and presence (see chap. 40, this volume) are not well represented.

3.1 Design of Manufacturing Activities

Visualization and simulation are useful VE methods for designing and evaluating manufacturing activities. These methods are applicable for finding possible problems in a manufacturing process and for the design and redesign of the manufacturing process and activity. Evaluating current manufacturing procedures and activities via a virtual environment can determine optimal work methods and workplace design. For example, Arzi (1997) used VE technology to find the best design solution for a workstation. The results showed that VE technology allowed the designer to assess the operator's view, test the ease and the comfort of doing a task, and evaluate various critical functions for the given task.

Several applications of VEs for the design of vehicle assembly were found in the literature. Davies, Medbo, Engström, and Akselsson (1999) suggested that VE technology was applicable for an ergonomic study of the car body assembly task (see chap. 52, this volume). Volkswagen developed assembly and disassembly models that can be used for designing the assembly process (Purschke et al., 1998). They built a simplified virtual factory where robots assembled and welded the parts of a vehicle. The model showed that collisions could occur between robots and vehicle components. This application was useful to evaluate manufacturing feasibility and assembly sequence. The Virtual Reality Laboratory at the University of Michigan (1999) was used to study both the virtual modeling of ship production processes and automotive assembly robots. The results indicated that an immersive walk-through of the full-scale representation of a complex ship structure not only revealed severe design flaws but was also useful in determining the assembly sequences, welding accessibility, and movement of equipment inside the ship. The application of a VE in automotive robot assembly showed similar results to the virtual ship modeling. Modeling with animated robots permits checking of layout efficiency, correctness of robot programming, robot reach, clearances, and collision events.

3.2 Design of Manufacturing Facilities

A VE provides an ideal environment to visualize and simulate the design of a manufacturing facility. A key attribute in a VE application to facility design is the ability to maneuver around a 3-D environment in the same manner as one does in the real world. This attribute can provide

a realistic perception of the visual scene as well as the behavior of objects. Krishnamurthy, Shewchuk, and McLean (1999) describe how Virtual Reality Modeling Language (VRML) can be used to model and study manufacturing facilities in this manner.

A virtual factory is often used in the early phases of facilities layout. Users can identify problems by watching the manufacturing process during a walk-through in the virtual factory. Wilson et al. (1996) described the VE project of the Rover Powertrain Group to explore the visualization of plant layouts in Great Britain. Generic shop-floor layouts, conveyor and lift systems, cranes, storage, and distribution depots were included in a virtual factory (see chap. 46, this volume). They found that the use of VEs was a valuable aid to industrial and manufacturing engineers in facility planning and design. The virtual model showed proposed changes to building and equipment placement. Their model proved useful for communication, potential problem identification, and logistic considerations.

3.3 Training for Manufacturing Activity Execution

By working with virtual objects in a VE training simulation, users can improve their skills and knowledge just as if they were working with objects in the real world. The richer perceptual cues and feedback from a VE can facilitate positive transfer of VE-based skills to real-world tasks (see chap. 19, this volume). The VE training simulation results in more affordable, interactive,

efficient, and safer training, and provides a more comprehensive experience for the user than training under real conditions.

Motorola developed a VE for training pager assembly workers (Adams & Lang, 1995). To avoid the expense of shutting down actual production facilities, a VE was developed to replicate equipment and provide effective training. The VE included a conveyor system, three robotic work cells for pager assembly, and inspection and laser marking systems. An evaluation of training effectiveness was conducted on three groups (non-VE, desktop VE, and HMD). The HMD group resulted in the best performance for most tasks. During posttraining evaluation, the HMD trainees claimed not only an immersed feeling but also freedom from reluctance to learning in the VE system.

The Fraunhofer Institute developed a virtual generator assembly scenario that includes visual collision cues to guide workers. Their virtual assembly allows users to grab and assemble objects in a VE using a DataGlove. This system served as a training tool for maintenance and design support at BMW and Mercedes-Benz (Göbel, 1996). Recently, BMW implemented two additional application scenarios for assembly. These include the installation of door locks and window regulator components into doors (Gomes & Baacke, 1998). Their application models used sound to compensate for lack of force feedback (see *sensorial transposition*, chap. 21, this volume). These studies showed that visible collision detection (e.g., overlay of virtual objects) was very important for assembly tasks (see chap. 12, this volume). Pere, Gomez, Langrana, and Burdea (1996) studied the use of haptic information for the assembly of an engine case. A desktop VE system was integrated with a force feedback device. They suggested that this type of feedback allows the user to feel virtual tools and makes training tasks more realistic. Rolls Royce and Associates used a VE for safety training (see chap. 42, this volume). They developed a training program to enable efficient maintenance of complex machinery in hazardous operational environments. The VE system allowed maintenance engineers to familiarize themselves with location, layout, and physical restriction of equipment (Wilson, Brown, Cobb, D'Cruz, & Eastgate, 1995; Wilson et al., 1996).

The costs and benefits of flexible VE training are evident for various applications (see chap. 28, this volume). However, most of the current implementations are still somewhat restricted. The number of states and objects in VE simulation are limited, behaviors of objects are primitive (e.g., no gravity for falling objects), and only predetermined scenarios are supported. To be an effective training tool, Johnson, Rickel, Stiles, and Munro (1998) recommend that VE simulators should support delivery of information to facilitate effective learning and not just concentrate on the fidelity of the renderings and the accuracy of simulated behaviors (see also chap. 20, this volume). Integration of intelligence and behavior-oriented design into the VE simulation process is needed.

3.4 Execution of Planning Activities

Planning activities include product design, process planning, production planning, and shop-floor scheduling (see Table 54.1). Virtual environment technology can be used to visualize or simulate product design and manufacturing planning and can result in significant savings in cost and time by early detection of errors in the product design and manufacturing process. Most applications use HMDs, VE workbenches, and/or CAVE equipment to provide a perception of immersion for the user. However, some applications employ desktop computers for user comfort and convenience.

3.4.1 Product Design

Virtual prototyping is a widely used term to describe product design that is based on VE technology. Virtual prototyping provides an alternative concept for the design-test-evaluation

cycle by eliminating the fabrication of physical prototypes. It can also support product design and presentation through simulations and analysis so that designers can evaluate the product functions by manipulating and modifying the model directly (Dai & Göbel, 1994). A VE is an effective analysis tool for problems where complex spatial arrangements are dominant and humans have to interact with these arrangements. Because immersion facilitates realistic responses from users, VEs can help designers identify possible design problems and improve the usability of final products (see chap. 34, this volume). Expected benefits include improved product design, savings in cost and time, and better market response through reduced design cycles.

The automotive industry has already recognized the potential of VEs as a tool to improve the design process (see chap. 42, this volume). Virtual environment technology might provide an efficient way of prototyping automotive interiors and can be used for design analysis and human factors studies (Beier, 1994; Buck, 1998; Flanagan & Earnshaw, 1997). The Virtual Reality Laboratory at the University of Michigan (1999) is developing a virtual prototype of a concept car. A VE provides a tool for evaluating such designs in full scale without building physical prototypes. Volkswagen is also studying the virtual product clinic that is conceptually similar to the concept car approach. A vehicle concept, which includes an ergonomic mockup, is tested in the virtual product clinic (Purschke et al., 1998). In Great Britain, Kalawsky (1993) developed an interactive virtual car interior. Designers could sit inside the virtual car on a real car seat and reach out and grab objects such as the steering wheel.

Another class of applications in the automotive industry is 3-D visualization, which demands a fine granularity of visualization and interaction with the virtual scene rather than navigating through a virtual space. A VE workbench offers an efficient way to develop this type of application. The Fraunhofer Institute has developed a VE for visualization of air flow around a car (Zachmann, 1998). Wesche, Wind, and Göbel (1997) summarized a VE project at Daimler-Benz that simulates fluid dynamics. Engineers gained a much deeper insight into the structure of the velocity field inside a cylinder during the injection process. NASA has also been involved in a similar application to depict a virtual wind tunnel for visualization of air flow around an aircraft (Bryson, 1997; see chap. 53, this volume). This model allowed two users, each with independent viewpoints, to reach into the simulation and manipulate the visualization tools interactively. Some applications that do not require fully immersive VEs, such as part design (e.g., motor vehicle engine thermostat housing), can use a desktop VE system. Desktop VE has an advantage in terms of graphic quality, flexibility, user comfort and convenience, and longer work times with lower cost (Wilson et al., 1995).

Virtual prototyping has also been used to facilitate communications in distributed environments. Maxfield, Fernando, and Dew (1998) studied a distributed collaborative engineering environment system that allows members of a geographically dispersed multidisciplinary team to collaborate during product design. Lehner and DeFanti (1997) also discussed a distributed VE communication project between the National Center for Supercomputing Applications and the German National Research Center for Information Technology. They developed a collaborative virtual prototyping system for Caterpillar so that engineers in Belgium and the United States could work together on vehicle designs in a distributed virtual environment. Finger et al. (1997) studied the integration of virtual and physical prototyping technologies to support rapid design and rapid manufacturing. Their experimental system could be accessed through the Internet.

One of the major problems of virtual prototyping is the link between VE and CAD systems (Dai, 1998; Harrison, Jagues, & Strickland, 1993). The generation of a 3-D model rendered by computer graphics is an extremely elaborate and time-consuming task. Impressive VE demonstrations are frequently based on geometric models that have been developed over a long time period (Beier, 1994). Although these designs are 3-D in nature, user inputs are often restricted to two-dimensional (2-D) devices (i.e., keyboard and mouse). Several researchers are

examining new interfaces that enable interaction in an intuitive and easy way for visualizing, creating, and editing 3-D product models based on VE technology (Chu, Dani, & Gadh, 1999; Flaig & Thrainsson, 1996; Harrison, Jagues, & Strickland, 1993). In a related study, Vance (1997, 1998) studied a VE where a designer can change the shape of design by using a DataGlove. She optimized engineering design by reviewing stress distribution as the shape was changed.

3.4.2 Process Planning

Process planning can be supported by an interactive VE that merges a fully functional factory-floor process simulator with a 3-D factory model. Engineers might have a better understanding of functionality in the manufacturing process by using real-time simulation in a VE and evaluating their plans according to the simulation results. For this reason, Bickel (1998) emphasized the need to integrate VE tools with simulation software and demonstrated several simulation-based applications. One application simulated the automobile manufacturing process. A virtual factory was built to replicate real manufacturing sequences, and the improved material flow saved Audi millions of Deutsche marks.

Vance (1999) is developing a virtual factory that employs a discrete-event simulation program. The users are able to examine part flow through the factory by varying different simulation parameters. Cobb, D'Cruz, and Wilson (1995) developed a virtual factory on a desktop VE representing the manufacture of a consumer product that could be used to support process planning as well as facility layout. Various stages of the manufacturing process were featured, including design, manufacturing, and testing. The virtual factory allowed demonstrations such as factory walk-throughs, visualization of the manufacturing process, and design modification. Users could observe finished parts on conveyor lines and bottlenecks in the manufacturing process. A national survey of this application showed that respondents from 170 companies considered the walk-through to be useful. But respondents were mixed in their opinions of the usefulness of two other applications, citing that the current user interface was difficult to use and the system was not suitable for complex modeling.

3.4.3 Production Planning

No applications of VE technology to production planning were found in the literature. Production planning determines when to make the various products, in what quantity, and with which resources. It is mainly concerned with quantitative data rather than visual information. Therefore, VE applications that rely primarily on visual displays may be somewhat limited.

3.4.4 Shop-Floor Scheduling

When scheduling the assembly of a ship or airplane, a scheduler must cognitively step through the assembly sequence and visualize the changes over time. A scheduler primarily uses Gantt charts or network diagrams to represent the construction schedule and static 3-D models to represent the ship or airplane. A VE, however, allows a new way to experience complex assembly through an interactive and dynamic modeling environment. Such an application allows a scheduler to get immediate and consistent feedback by integrating a 3-D model with scheduled activities. Frölich, Fischer, Agrawala, Beers, and Hanrahan (1997) developed an application that combined 3-D modeling and scheduling for building construction on a VE workbench. The application facilitated successful interaction and collaboration between two users who were sharing the virtual environment.

3.5 Execution of Control and Monitoring Activities

Control and monitoring activities include manufacturing activity control, quality control and inspection, testing, and inventory control (see Table 54.1). Applications of VEs for visualization, simulation, and information provision are appropriate. Since users have to interact with real objects directly or indirectly, see-through HMDs or video-based AR displays may be employed for information provision while performing such activities. In addition, several simulation applications using a VE workbench for control and monitoring exist.

3.5.1 Manufacturing Activity Control

No applications of VE technology to manufacturing activity control were found in the literature. Manufacturing activity control requires constant evaluation of activities and conditions in a manufacturing facility with respect to pre-established plans. Employing VEs to provide the necessary real-time status information and relevant plans could dramatically increase the ability of humans to perform this task effectively.

3.5.2 Quality Control and Inspection

One of the few projects that has shown real benefits for the use of a VE was the application of AR for thickness inspection (Chung et al., 1999). Performance differences among manual, computer-aided, and AR-aided inspection were measured. Results indicated that while all three methods were similar in terms of accuracy, AR-aided inspection was two to three times faster than the other two methods. Additionally, although inspection time increased with part shape complexity for the manual and computer-aided inspections, it was unaffected by part shape complexity for AR-aided inspection. Purschke et al. (1998) described a surface inspection application at Volkswagen. Virtual models offered not only high-quality shape and surface rendering, but also some physical features such as shininess, contour changes, and functional features (e.g., opening and closing of doors). Their application has already been incorporated into the development process of an automobile.

3.5.3 Testing

Virtual prototyping or visualization is often used for testing during the iterative design process. These test data are used to evaluate the design of a product (see chap. 34, this volume). Kesavadas (1996) developed a virtual template that is a graphic replica of a real template to carry out various design checks. Workers can check design factors (i.e., drilled holes, bores, and slots of various diameters) by merging the prototype of a component with a set of virtual templates in an AR environment. Purschke et al. (1998) and Wesche et al. (1997) described how Daimler-Benz and Volkswagen are using a VE system for crash and airbag testing where engineers can move around the vehicle and observe the effects of crash-state computations (e.g., structure behavior for a specific time frame).

3.5.4 Inventory Control

No applications of VE technology to inventory control were found in the literature. However, VE simulation could easily be used for warehouse control.

3.6 Execution of Physical Processing Activities

Physical processing activities include fabrication, assembly and disassembly, material handling, material storage, and maintenance (see Table 54.1). Telerobotics and information

provision are appropriate VE methods for the execution of these activities. Virtual environment technology has been used to improve the perception of teleoperators or to provide information required for a given task (see chap. 48, this volume). Since users have to interact with real objects directly or indirectly, a see-through HMD or video-based AR display can be used. Some applications use multimodal displays (i.e., visual, auditory, and haptic displays) and focus on natural interfaces.

3.6.1 Fabrication

Robots have been used in fabrication for many years. Virtual environment technology is expected to provide enhanced perception and a natural interface for telerobotics and robotics. Since the current generation of teleoperated robots does not convey a sense of real presence, operators cannot obtain the necessary level of awareness about remote sites. In order to enhance the operator's perception and understanding within remote sites, improvements in depth perception of teleoperated robots through AR visual feedback have been investigated. Milgram, Zhai, Drascic, and Grodski (1993) studied an overlaid virtual stereographic display to enhance absolute depth judgment and perception when using augmented reality. Another limitation of telerobotics is that feedback to operators has not been designed to map human kinematics accurately. Operators must adapt their reflexes, dexterity, and skill to the robot. Kheddar, Tzafestas, and Coiffet (1997) and Tezuwa, Goto, Kashiwa, Yoshikawa, and Kawano (1994) studied a natural control interface and direct manipulation using a DataGlove. Rosenberg (1993) used haptic and auditory feedback to provide additional information in the form of a virtual fixture to reduce the demands on visual cues when an operator controls a robot. He conducted an experiment to evaluate peg insertion performance and demonstrated up to a 70% improvement in operator performance using haptic and auditory virtual fixtures as compared to no virtual fixtures.

Natonek, Flückiger, Zimmerman, and Baur (1994) developed a VE system in which users can determine trajectories of robots in an intuitive way. The results showed that VEs are a powerful interface for robotic system control; users without programming experience could successfully define robot trajectories using the VE system. Cannon and Thomas (1997) also introduced virtual tools with collaborative robotic control concepts that enable users with no expertise in robotics to point and direct robots and machines to complete specific tasks.

3.6.2 Assembly/Disassembly

Augmented reality can provide workers with direct information access when performing manufacturing or assembly tasks. Such information includes assembly guides, templates, drawings, parts lists, and locating marks. Workers can see real parts and augmented information together via a see-through HMD. Fabrication and assembly in the aircraft industry are usually done by hand because they are too complex for automation (Caudell & Mizell, 1992). For instance, a commercial airplane has about 1,000 wire bundles ranging from 2 feet to 120 feet in length, and each bundle can consist of hundreds of wires. A significant source of expense and delay in aircraft manufacturing is that workers must constantly refer to several complex drawings during assembly. Boeing used a see-through HMD for four such assembly applications, including wiring formboard, wiring connection assembly, composite cloth layout, and wire frame display (Caudell & Mizell, 1992; Caudell, 1994; Sims, 1994). A test in 1995 using a prototype resulted in a 20% to 50% improvement in wiring assembly performance even though the application was limited by lack of resolution accuracy and long-range head-position tracking (Nash, 1999).

Sharma and Molineros (1997) investigated an efficient information presentation scheme for augmented stimuli in assembly. Assembly of compact disks was developed on a video-based desktop VE system using computer-vision algorithms to track the position and orientation of each part. An assembly graph showed different assembly sequences to guide a person

through various stages of the assembly task. Gupta, Sheridan, and Whitney (1997) studied a multimodal VE system for assembly analysis. They developed a system that tracked collisions and contacts of parts (i.e., overlay of virtual objects) using auditory and haptic feedback. Peg-in-hole assembly (most common in metal products) was used for evaluating task performance. The results showed, however, that multimodal VE assembly required twice the time of the real assembly task. This additional time might be due to the inappropriate task application and/or the immaturity of the haptic feedback technology used in the multimodal display.

3.6.3 Material Handling

No applications of VE technology to material handling were found in the literature. Material handling is a physical activity that does not include high-level decisions; therefore, applications where realistic force feedback is not present are somewhat limited. Telerobotics might be an appropriate method for improving material handling, and some research studies related to fabrication (Cannon & Thomas, 1997; Natonek et al., 1994) are also applicable for material handling.

3.6.4 Material Storage

No applications of VE technology to material storage were found in the literature. Augmented reality could be employed, however, to help workers locate items in storage, ascertain stock rotation patterns, and perform other tasks.

3.6.5 Maintenance

One of the first applications of AR in manufacturing was maintenance assistance. Feiner, Macintyre, and Seligmann (1993) demonstrated a maintenance and repair application for a laser printer. See-through HMDs hold promise for providing data without requiring maintenance engineers to take their hands off their work. The European Computer-Industry Research Center, or ECRC (1994), used AR for automobile maintenance and repair. A mechanic was assisted by an AR system while repairing a vehicle engine. Part names, functions, and a maintenance record could be annotated by the system. Pimentel and Teixeira (1995) described a similar scenario for aircraft engine maintenance. An aircraft mechanic could use an AR system to view virtual information panels that overlaid the real image of a jet engine. By tracking hand position as compared to where parts were located inside the engine, a mechanic could “see through” the machinery to the workplace without disassembly.

Another potential application area is maintenance using telerobots in hazardous environments. Tezuka et al. (1994) developed an experimental VE system to assemble and disassemble machines for maintenance using a robot arm manipulated by a DataGlove, as well as the use of hand gesture recognition (see chap. 10, this volume). They found that the time lag between a DataGlove and robot arm was an important factor in determining the performance of this system.

Although VEs are usually considered for isolated task applications, often various VE methods can be used in several application areas simultaneously. Perhaps the greatest benefit can be achieved by integrating VE technology into manufacturing as a whole, rather than by improving one isolated manufacturing task with a specific application. For example, product design is facilitated and tested by virtual prototyping and visualization, process planning and scheduling are aided by VE visualization, and production workers are supported by training and information-provision applications of AR to enhance performance. Virtual environment technology should become just another tool that can be used to pursue continuous improvement in design and manufacturing by facilitating the communication of ideas and concepts across the entire manufacturing system and product life cycle.

4. FUTURE APPLICATIONS OF VIRTUAL ENVIRONMENTS IN MANUFACTURING

Although relatively few real applications of VEs (and even fewer empirical studies that evaluate these VEs) exist, the potential for using VEs in manufacturing is great based on current demonstrations. Most of the current technical literature deals primarily with expert opinion, industrial surveys, and isolated demonstration examples that have not received systematic evaluation. Surprisingly, only about 10% of the nearly 50 references listed in Table 54.4 provided empirical evaluations of their VE applications. As Kies, Williges, and Rosson (1998) point out, most human-computer interface applications are developed in an iterative design fashion that involves both formative and summative evaluation (see chap. 34, this volume). Formative evaluation occurs during design iteration to form the basis of redesign and uses primarily subjective methods based on user opinions and expert observations based on ethnographic methods. Summative evaluation is a formal procedure for evaluating final application efficacy and is usually based on controlled testing using experimental design methods to collect performance metrics and subjective opinions of users.

What is needed is an integrated and focused approach combining research, demonstration, and rigorous formative, as well as summative evaluation of VE applications to manufacturing. Based on our overview, the areas of facilities and product design, training, and execution of physical processing activities hold promise for significant research and applications leading to improved performance in manufacturing.

4.1 Facilities/Product Design

Interactive simulation coupled with interactive virtual prototyping can improve the design of manufacturing facilities and products. This includes all aspects of the manufacturing facility from computer, communications, and data-storage systems to processing equipment, material handling equipment, and the layout of these items in the facility. The use of VE simulation procedures with interactive visualization capabilities is a logical extension of current industrial use of 3-D CAD technology. However, Wilson et al. (1996) note an incompatibility between current CAD packages that provide high-resolution 3-D graphics and current VE software that provides interactive and immersive visualization. They also note usability difficulties of VE software, few working demonstrations of VE applications, and little evidence of added value for the use of VE in industry. Once software support is available to facilitate the importing of CAD files directly into VE software, increased value in the use of simulation should be realized in all aspects of facilities and product design.

4.2 Training

Perhaps the greatest potential for VE applications to manufacturing is in the area of training, because training is a component of all of manufacturing activities. The potential for using a VE as a training simulator has already been demonstrated (see chaps. 43 and 44, this volume). What has not been demonstrated is the effectiveness of this training technique as compared to other training procedures. Cost-effectiveness of training needs to be considered. For example, training workers to perform multitasking can be cost-prohibitive if real production systems are used. Virtual environment simulation of production systems might be quite cost-effective for training purposes, however. Likewise, the appropriate level of simulation fidelity that results in the maximum positive transfer of training to on the job performance must be established (see chap. 19, this volume). Both psychological and physical fidelity of VE simulation training must be considered and evaluated (see chap. 35, this volume).

4.3 Execution of Physical Processing Activities

The major application area of VE technology is the improvement of performance in execution of physical processing activities. Maintaining the appropriate level of operator workload is critical in advanced manufacturing systems. Insufficient workload could result in reduced attention span and reaction time, whereas excessive workload may lead to reduced performance or failure. Virtual environment technology has the potential for playing a major role in human-operator workload management applications in manufacturing.

Worker performance in executing various manufacturing activities can be improved through the judicious use of VE technology. For example, assembly workers need to be given information as to what the item looks like before and after assembly, a detailed description of how and in what order assembly tasks are to be done, a list of tools required, and disposition instructions. This information is textual and graphic in nature and requires a low-to-medium volume of transactions. Augmented reality could be employed to provide this information. The worker could wear a see-through HMD when picking up a part to examine. The next item to be assembled could appear as a phantom on the part, and the instructions could float in space beside this part. The needed tool and type of fastener could then be listed. When the worker looks at the bin of different fasteners, an arrow could appear in space pointing to the correct bin. By reducing information acquisition time, VE technology could improve both throughput and product quality. The more customized products become, the more these advantages will be realized.

5. CONCLUSIONS

Based on our review, the appropriate application of VE for information support holds great promise for manufacturing. An integrated approach is needed to realize this potential. The proposed three-step activity analysis would evaluate feasibility, determine potential benefits, and conduct a cost-benefit analysis of using VE technology. Once a VE application is considered feasible, the implementation should follow an iterative design process that incorporates formative and summative evaluation procedures. Both the appropriate level of virtuality and the allocation of functions between humans and the manufacturing process must be considered. Systematic research is needed to determine the advantages and disadvantages of differing levels of virtuality with respect to the manufacturing framework described in this chapter. This research can lead to improved function allocation between humans and mechanisms in manufacturing systems. Applications of VE technology to manufacturing activity control, inventory control, and material handling (including shipping) are particularly needed. Research is needed to develop guidelines and models of the appropriate use of VE technology to improve manufacturing performance in an integrated manner.

1. INTRODUCTION

Virtual environments (VEs) as we know them today originated in the 1970s with simple computer-based flight simulators, which continued to be developed through the 1980s and 1990s. This form of VE was overtaken by the emergence of VE video games in the entertainment market, both in amusement arcades and at home on video games consoles.

Entertainment-based VEs, however, are nothing new. At the Paris Fair in 1900, three high-tech virtual experiences were presented to the public. The Trans-Siberian Railway Panorama enlivened existing dioramas and panoramas by introducing motion and treated visitors to a 45-minute experience reenacting a 14-day rail journey between Moscow and Peking. A number of horizontal belts and painted screens driven at high speed gave the illusion of traveling while being comfortably seated in a train coach. The Mareorama added a motion platform to simulate a cruise from Nice to Constantinople, and the Cineorama Air-Balloon Panorama presented for the first time a full-surround movie shot from a balloon rising over Paris. Fifty years later, the Scopitone, Experience Theater, Sensorama Simulator, and Telesphere Mask offered remarkably visionary ways to transport people through alternative realities, either in large groups or individually (Dodsworth, 1998).

Today, virtual environments are at the core of most successful games and other entertainment platforms. This chapter does not seek to establish an exhaustive list of technologies, systems, and applications available. This area is moving much too fast for this to be realistic. Besides, most of the technologies relevant to games and entertainment applications, in general, have been covered in previous chapters. Instead, this chapter will survey the major entertainment areas in which VEs are an essential element and attempt to provide some guidance on what the future may bring.

Current VE entertainment applications include games, whether they are stand-alone or networked, and online communities created around games. They increasingly offer various services reaching much beyond pure entertainment, such as interpersonal communication forms and online electronic transactions. They also include game characters and avatars (see chap. 15, this volume), pointing the way to artificial life and populated persistent worlds. High-end systems, such as location-based entertainment (LBE) centers and digital theme parks, are also addressed, offering some of the most exciting virtual experiences to date.

The chapter also examines the strong historical links between military simulation and entertainment and important issues, such as violence and pornography in entertainment, are briefly discussed. A final section attempts to guide the reader through future prospects for entertainment applications based on virtual environments. What is the future of content? What are the trends in interactivity? How will theme parks and LBEs evolve? What about distributed games? What can research in augmented reality (AR) and telepresence offer to entertainment? When will we be able to fully immerse ourselves in highly compelling shared VEs to play, experience an impossible ride, or simply communicate with others in a completely new way?

Because they are developed in a very demanding and competitive environment, games have always been at the forefront of the technology wave. Games and entertainment systems are a major driving force for the development of VE-based systems and their applications in other sectors. This chapter aims at explaining why.

2. GAMES, ONLINE GAMES, AND VIRTUAL COMMUNITIES

Computer games are as financially successful as film, video, and pop music. They may run on arcade machines, personal computers (PCs), gaming consoles and palmtop devices. They are interactive, providing an experience of story line, time, and pacing that is entirely different from the linear content of film. Computer gaming is a hugely influential popular culture. Many games

aim just for sheer entertainment. Others may also be educational, intellectually challenging, or emotionally engaging. We are arguably still in the early days of computer gaming. Some see the move from two-dimensional (2-D) to three-dimensional (3-D) computer graphics paralleling how movies evolved from silents to talkies in the 1920s.

Early games were 2-D, and were viewed from the top or side. For years, characters jumped endlessly from one flat platform or level to another to score points—some still do! In 1980, *Battlezone* was the first true 3-D gaming world, and ever since then virtual environments have been the setting of most successful games. Games developers are working on innovative forms of computer-generated “beings,” artificial life, and intelligence (see chap. 15, this volume). Along with interface technologies such as speech recognition, these will enable more sophisticated interaction and independent behavior in gaming characters. Better imaging quality and video headsets will provide more visually realistic, immersive worlds.

The success of computer games has been due to the availability of low-cost ubiquitous machines. The Nintendo 64 platform provided the first truly interactive 3-D video game machine and used a Silicon Graphics state-of-the-art semiconductor to achieve a low-cost, high-performance, high-volume product. Because it is important to get the most out of technology, games are mostly based on proprietary technology, guaranteeing appropriate reaction speed for fighting games. The difficulty for game producers is to have one platform for several games to ensure sufficient revenues while keeping enough room for flexibility for constant innovation in order to keep games attractive. Progress is constant. As an example, recent advances are taking the visual reality of 3-D scenes to unprecedented heights with real-time special effects. Games are set to become more elaborate, engaging, cooperative, intense, and cinematic—while not forgetting their sense of fun!

2.1 Gaming Genres

Many computer games have been born, flourished for a moment and then been lost to history. Those that survive generally belong to a few popular types or genres. The genres discussed in this section demonstrate some of the visual styles, game-playing formulas, and intentions typical of contemporary games.

2.1.1 *Shoot-'em-ups and Beat-'em-ups*

A staple games diet is relentless, fast-paced combat action, backed-up by awesome arsenals of weapons and powers. Run around killing everything that moves before it kills you! Game play consists of fast eye–brain–hand reflexes focused on control-button combinations. These offer some of the most intense gaming experiences—but leave your intellect behind.

2.1.2 *Flying, Racing, and Sports*

These games range from cartoon capers offering slapstick thrills and spills, to serious simulators of military jets or F1 racers that can hardly be called games at all. Such simulations represent the pinnacle of realism in computer games—not just in image quality but also in the authenticity with which they mimic the dynamics of the vehicles and gadgets involved.

2.1.3 *Strategy and Puzzle Games*

These simulations require long-term game plans for managing resources and negotiating problems. Players build and run complex, dynamic structures, such as cities or ecosystems, with populations and maybe armies for conquest. Some require only mechanical learning of the rules, but the best present challenging scenarios akin to the real world. Puzzlers are often more restful, involving ingenuity and problem solving.

2.1.4 Adventures and Role-playing Games (RPGs)

Somewhere between shoot-'em-ups and strategies, adventures let you control characters engaged in action-based quests. They involve exploration, puzzles, obstacles and enemies to overcome. In more complex RPGs, the main character is your alter ego—a personality that evolves as you journey through a maze of plots and subplots.

2.1.5 Online Games

Online games are the latest trend and offer completely new and exciting perspectives to gaming. Popular consoles are now equipped with modems for online multiplayer gaming, and the Internet takes the game experience to new levels. There are more than a dozen online gaming services available today—Interactive Magic's shock force, Segasoft's 10six, Sony's Everquest, CyberPark, Heat.net, Engage, Battle.net, MPG Net, Dwango, TEN, Kali, Mpath, Ultima online, and others—and new entrants are around the corner (Berry, 1997).

So far, shoot-'em-ups have dominated networked gaming. Internet connections allow remote players to compete in shared multiplayer gaming worlds through avatars. Cyber wars are being organized starting at a given time, complete with battle moderators, prebattle briefing, and daily war reports.

Teams of players often interact and collaborate with each other through additional audio and text chat channels. The best games have sophisticated 3-D rendering and the ability to custom design your own worlds. Since the Internet is not yet able to provide the kind of low latency necessary to fast shooting games, online games tend to emphasize strategy and collaboration in what can be seen as a positive trend. Like for many other Internet businesses, the perfect business models for such games is still being sought and few game companies make money. Most online games offer licenses for a day or for unlimited use. Some rely on commercial sponsors.

Online, graphic RPGs are increasingly popular. Thousands of people can play simultaneously in massive, mysterious worlds full of intrigue and conflict. These environments go beyond games and offer a constantly changing world where players chart their own destiny. They choose their appearance, personality, and place in the world. They become involved in intrigues, fulfill quests, kill scores of monsters, or even other players.

Some games offer an entire world with diverse species, economic systems, alliances, and politics. One can choose from a variety of races and classes, and begin a journey in any number of cities or villages throughout virtual continents. One can learn skills, earn experience, acquire treasure and equipment, meet friends, and encounter enemies. The multiplayer online gaming community explores and extends the digital frontier, pushing new technology to its performance limit and in effect creating new opportunities for building immersive virtual communities.

In the search for killer applications appealing to a broader population base, gambling and virtual sex are hot contenders. Gambling is a very large business and cyberspace is gambling's next frontier. Transposed to the Net, gambling could be everywhere and nowhere at once. Cybercasinos offer the perfect shelter from taxes, and if ever legalized, gambling from home is likely to drive masses of people to virtual worlds. For now, online casinos simulate the excitement of gambling—without real betting. They aim to recreate the “Las Vegas experience”, with the hope of being well positioned for the day when online wagering is legalized (Virtual Vegas).

2.1.6 Interactive Virtual Worlds

New cyber settlements allow users to own 3-D virtual real estate with personal chat rooms, message boards, and clubs. Friends can be invited to come over and socialize. These “cyber towns” can have their own economy and social structure. One can become a proper citizen, take jobs in the community, and earn community “money” (community credits), which can be used

in the virtual community mall. Some cyber towns are fully functioning communities with an elected mayor and city council, city guides, and security officers. There is even a virtual reality time (VRT), suggested to be the common time zone for all virtual environments, wherever you are around the world.

These virtual worlds offer places to meet, venues for online events, message boards, and shopping malls. They overcome distances and open limitless possibilities for the development of new markets and shopping experiences opened 24 hours a day. Conducting business in an entertainment-like setting is part of the attraction. Online communities are bound to have a huge impact on e-commerce, education, health, and leisure. Ultimately, they may also change democracy, as more direct contact with government and other citizens may lessen the role of elected representatives.

Online communities are particularly interesting because they offer a radical alternative to real-life communities. They involve large numbers of geographically dispersed people. They have access to and strive on an infinite source of information. They involve people who are mostly complete strangers but yet are friendly with each other. Online communities have their roots in text-based multiuser games and communities (i.e., multiuser domains [MUDs], MUDs object-oriented [MOOs], and Web-based MOOs [WOOs]). These environments have been successful in building functioning communities. Inhabited worlds have added the rendering power developed for games such as Doom and Quake. There are many inhabited virtual worlds on the Internet, although these are still early days for some. Some of them are work in progress and still have problems with communication between avatars. Some are also very sparsely populated, and one can feel pretty lonely while exploring them (Damer, Gold, Marcelo, & Revi, 1997). But others are already fully functioning business and entertainment portals with large user communities (Blaxxun Interactive, Cybertown). They integrate with popular World Wide Web browsers and require a set of Java plug-ins, running on any platform supporting Java.

The technology involved is not necessarily very sophisticated. Some interactive worlds do not always make use of available VE features. Instead, they concentrate on a large range of consumer platforms at modem speed. Some companies specialize in the use of proprietary or industry standard "photographic" VE software to enable virtual travel around the world.

Avatars can be personalized and are able to exchange cards with any user met online. Messages can be sent, private chats opened, and voice conversation supported. An open architecture allows users to build their own world. Since the potential of user creativity in virtual worlds is huge, there has been a major change in the way content is created (see chap. 25, this volume).

But this is just the beginning. Navigation in virtual worlds can still be difficult because it is mostly based on a set of keyboard commands (see chap. 24, this volume). Lack of collision detection (see chap. 12, this volume) is often a source of confusion in Virtual Reality Modeling Language (VRML) worlds. Some worlds are still too artificial. As more worlds are built, artistic quality will improve and progress in interface technologies will ensure that navigation in online virtual worlds is as easy as in popular games such as Doom.

These new interfaces naturally appeal to the younger generation. Although most people have only recently got used to 2-D interfaces, the generation brought up on Quake, Doom, and Nintendo 64 is used to navigation through complex 3-D environments and sophisticated behaviors. They demand metaphors based on real place, and the Web is giving them what they want.

The home-based playing, chatting, socializing, and playing experience is increasingly being integrated within multipurpose infotainment appliances offering radio, TV, computing, and VE-based services. Virtual communities are also approaching convergence with traditional media programming. Some include network cameras and live 3-D broadcasts for special events. They also feature new modes of interaction, such as 3-D chat worlds, text to speech, and audio conferences with artists and personalities. The result is a new media for which the frontier

between “storytelling,” as in current broadcasting, and “communication” will progressively blur, leaving us with a continuum of image-rich and flexible “infocommunication” services somewhere between plain old television and multimodal telepresence.

3. POPULATING VIRTUAL ENVIRONMENTS FOR ENTERTAINMENT: AUTONOMOUS ELEMENTS, ARTIFICIAL LIFE, AND VIRTUAL HUMANS

Just as in real life, the characters one meets in virtual environments are often essential to the quality of the experience. Empty virtual environments would quickly lose their attractiveness. Characters are naturally central to games, but they are also moving to the forefront in other applications of VEs, whether they support new forms of human-to-human or human-to-machine communication or they are meant to increase the realism of complex environments. This section surveys a few of the most popular game stars and takes us through some of the latest research on the way to virtual humans.

3.1 Game Characters

Computer games have their own virtual superstars—leading characters that have helped sell games by the millions. Good characters can be vital to the success of a game. They can help draw players into the story line and identify with the fun and tension that game play offers. Successful characters also build brand loyalty, making sequels easier to market and supporting spin-off merchandising.

ATARI’s 1980 Pac-Man was perhaps the first true computer-game character. The middle-aged Italian plumber Mario is one of the most successful game characters of all. Mario first appeared in 1981 in the arcade game Donkey Kong and has since become as important to Nintendo as Mickey Mouse is to Disney.

Lara Croft, star of Tomb Raider, is widely credited with introducing a whole new audience to computer gaming since she first appeared in the mid-1990s. Lara’s British developers, Core Design, “manage” her like a film star. They even keep a manual on her that records her personality, dislikes, and favorite colors, music, and food.

Character modeling and movement in 2-D and 3-D are constantly improving, but it is not just looks that count. Some games go to great lengths to create believable identities and convincing personalities, even for fantasy creatures. Characters have aims, motives, desires, sadness, humor, problems, backgrounds, and relationships with other characters. Players can explore these as the story line and characters themselves evolve.

The interactive structure of games can undermine the use of some traditional storytelling techniques that help establish characters. Whether games will ever need—or could achieve—the rich characterization that traditional linear media can achieve is open to question. Perhaps this would only be needed in games in which the whole aim was to explore the nature of the characters themselves. In the end, the primary reason for any game character’s existence and success will continue to be that the game itself is fun to play.

3.2 Virtual Humans

In the games market, constant innovation is required in order to prevent sales of games from falling off. Convincing simulated humans in games have been identified by the industry as a way of giving a fresh appearance to existing games and enabling new kinds of game to be produced. The ability to embed the viewer, as an avatar (Capin, Pandzic, Magnenat, Thalmann, & Thalmann, 1999), in a dramatic situation created by the behavior of other,

simulated, digital actors will add a new dimension to existing simulation-based products for education and entertainment.

In most popular games, the level of artificial intelligence of digital creatures is still limited. Recently, however, a few games have appeared based on artificial life principles. The most well known is Creatures, from Cyberlife. Artificial life in VEs is a new promising approach, and several researchers have proposed innovative algorithms and systems (Magnenat-Thalmann & Thalmann, 1994). Sims (1994) describes a system for the evolution and coevolution of virtual creatures that compete in physically simulated 3-D worlds. Pairs of individuals enter one-on-one contests in which they contend to gain control of a common resource. The winners receive higher relative fitness scores allowing them to survive and reproduce. Realistic dynamics simulation, including gravity, collisions, and friction, restricts the actions to physically plausible behaviors. The morphology of these creatures and the neural systems for controlling their muscle forces are both genetically determined, and the morphology and behavior can adapt to each other as they evolve simultaneously. In the ALIVE system (Maes, Darrell, Blumberg, & Pentland, 1995), the virtual world is inhabited by inanimate objects as well as agents. Agents are modeled as autonomous behaving entities, which have their own sensors and goals and which can interpret the actions of participants and react to them in "interactive time." Several digital creatures have been created: autonomous fish living in a physically modeled virtual marine world (Tu & Terzopoulos, 1994); virtual actors, with seemingly emotionally responses driven by random noise functions; and autonomous dogs (Blumberg & Galyean, 1995). The system IMPROV (Goldberg, 1997) allows production of 3-D VEs in which human-directed avatars and agents interact with each other in real-time, through a combination of procedural animation and scripts.

One of the most challenging VE applications is real-time simulation and interaction with autonomous actors, especially in the area of games and cooperative work. Systems such as the Virtual Life NETwork (VLNET; Capin, Pandzic, Magnenat-Thalmann, Capin, & Thalmann, 1997; Pandzic, Magnenat-Thalmann, Capin, & Thalmann, 1997) support a networked shared VE that allows multiple users to interact with each other and their surrounding in real time. Users are represented by 3-D virtual human actors who serve as agents to interact with the environment and other agents. The agents have a similar appearance and behavior to real humans, to support the sense of presence (see chap. 40, this volume) of the users in the environment. In addition to user-guided agents, the environment can also be extended to include fully autonomous human agents used as a friendly user interface to different services, such as navigation. Virtual humans can also be used in order to represent currently unavailable partners, allowing asynchronous cooperation between distant partners.

Users should animate their virtual human representation in real-time. However, virtual human control is not straightforward; complexity of virtual human representation needs a large number of degrees of freedom to be tracked. In addition, interaction with the environment increases this difficulty even more. Therefore, virtual human control should use higher level mechanisms to animate the representation with maximal facility and minimal input. Virtual human control can be divided into three classes:

1. *Avatars*: Basic motion data of the virtual human are modified directly by providing new degrees of freedom values directly (e.g., by sensors attached to the body).
2. *User-guided virtual humans*: A user guides the virtual human by defining tasks to perform, and the virtual human uses its motor skills to perform actions by coordinated joint movements (e.g., walk, sit).
3. *Autonomous virtual humans*: The virtual human is assumed to have an internal state, which is built by its goals and sensor information from the environment, and the participant modifies this state by defining high-level motivations and state changes (e.g., turning on vision behavior).

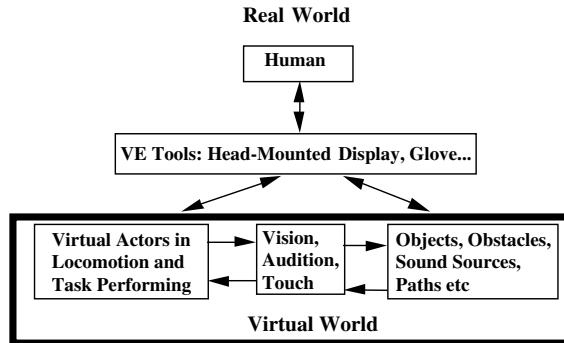

FIG. 55.1. Real and virtual sensors.

Participants are naturally aware of the actions of the virtual humans through VE tools, such as a head-mounted display (HMD), but one major problem to solve is to make virtual actors conscious of the behavior of participants. Virtual actors should sense the participants through their virtual sensors (see Fig. 55.1). For the interaction between virtual humans and real ones, gesture and facial expression recognition (see chap. 10, this volume) is a key issue for new high-end games. For example, Emering, Boulic, and Thalmann (1998) describe a project in which a real person represented by an avatar can fight against an autonomous actor. The motion of the real person is captured using a Flock of Birds. Gestures are recognized by the system, and the information is transmitted to the virtual actor, who is able to react to the gestures.

Artificial intelligence (AI) is increasingly making its way into games and other forms of entertainment. It primarily affects characters' behavior and offers radical new forms of game play. New AI-based games feature characters that can cope with complex situations and evolve, for example, moving up the social ladder throughout a game session. Others can learn gestures and movements during the course of the game. Artificial life is here and some of the first commercial successes were due to games.

4. LOCATION-BASED ENTERTAINMENT AND VIRTUAL ENVIRONMENTS IN THEME PARKS

Before making their way to the home on low-cost platforms such as consoles and personal computers, virtual environments have flourished in entertainment centers and theme parks. The following section takes a look at some of the most successful 'high-end' VEs so far.

4.1 Location-based Entertainment Centers

Location-based entertainment (LBE) blends the amusement park ride and video game. Pods or cockpits are installed in a thematic setting, and passengers discover fantasy worlds via computer-based graphics, sound, input, and various display technologies. LBE centers started in the 1990's as an outgrowth of video arcade and military simulators.

The most popular LBE games are flight and driving simulators. Two-seat flight simulators allow players to experience and perform maneuvers that replicate those of an actual fighter aircraft. A flight crew is composed of two people, a pilot and a weapons system officer. Cockpits are networked to allow teams to wage war in a simulated battle environment. The experience is complete. Cockpit controls include foot pedals, throttle, military-style joystick, and monitors. Team members cooperate to accomplish a mission and are in radio contact. Surround Sound

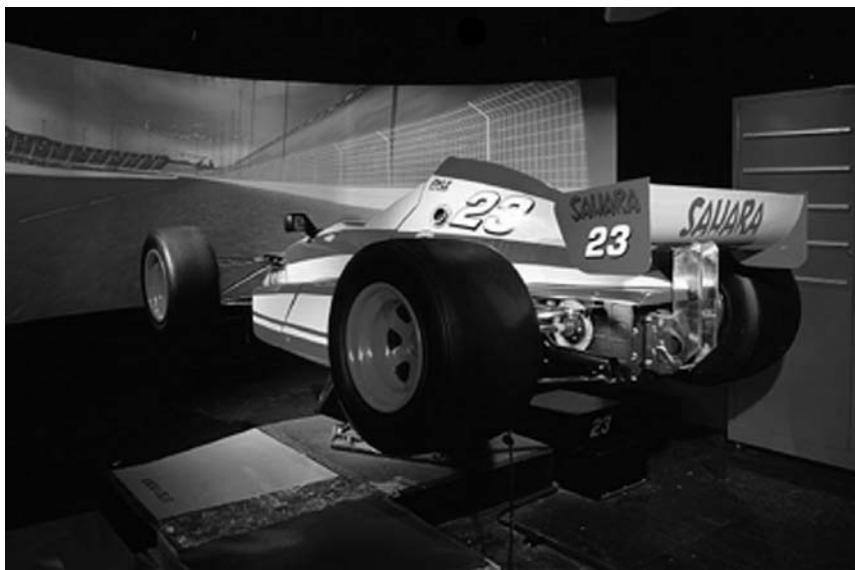

FIG. 55.2. Indy racing car. Courtesy of Illusion, Inc.

and high-resolution graphics guarantee high realism with the sound of explosions, crashes, and gunfire.

LBE provide powerful dramatic immersive experiences. An important part of their fun comes from communicating with other players and through collaboration. LBE centers are fast becoming some of the most visible applications of interactive digital graphics and visualization. In some places, LBE centers have given birth to a subculture. They provide a specific attraction, often accompanied by a cafe, bar, or restaurant. When players come out of a cockpit they have shared an experience and talk about it with newly made friends. But despite very sophisticated technology, current scenarios are usually very basic and juvenile. Players are mostly young males, and these centers capitalize on the fact that most young males enjoy seek-and-destroy games. The emphasis is on quick action and high tension. The content is mostly competition-based and most LBEs as they exist today can be seen as “boy toys.” This is changing as content evolves to address a broader user group.

4.2 Virtual Environments in Theme Parks

Theme parks offer the best of VE entertainment in the form of simulation films, interactive rides, and immersion theaters, such as the popular IMAX. Immersion theaters have been around for three decades. They are designed to immerse large audiences within a high-resolution movie, projected on a very large screen so that the image field of view completely dominates peripheral vision. Immersion theaters were long used for short documentary films or for education purposes. They are now increasingly moving to entertainment content with more commercial potential. They also often provide environmental scenography as a background for live actors, motion-based simulations, and special effects. But production costs tend to limit their use to high-end theme parks. Digital technology may provide solutions to this cost issue in the future (Dodsworth, 1998).

Simulation films usually place the audience inside a vehicle (e.g., train, plane, or car) and give them a few minutes of a sensation-rich ride. Hydraulic systems animate the entire floor of the theater, synchronized with the video image. Motion-enhanced rides are increasingly

interactive. Some rides have seamless transition between video-disk-based real imagery walk-throughs and fully interactive rides. Since such amusement park rides require waiting time, this time is generally used to create an atmosphere, define the context, and explain what visitors have to do during interactive sequences. Giving a pre-immersion background story, giving clues and concrete goals to fulfill are important elements.

There are many examples of popular games and rides experienced in LBE centers, theme restaurants, bars, family entertainment centers, or theme parks. Their number is growing by the day, only limited by people's imagination and availability of venture capital to make them happen.

Thanks to advances in interface technologies and to a positive evolution in the content of attractions, a new generation of rides is now emerging. There has been a move away from competition to an emphasis on experience or story line, as opposed to a competitive objective. Here is a snapshot of some of the best second-generation rides available today.

4.2.1 Sport

Simulators are targeting many sports, including soccer, basketball, racquetball, table tennis, ice hockey, tennis, and darts. Video-based, unencumbered interfaces allow players to measure themselves against a team of opponents by moving their body and interacting with images. These highly interactive games challenge physical coordination, tactical decision making, and cooperation between players.

Distributed sport simulation is the subject of interesting experiments. A virtual tennis game over a network (Molet et al., 1999) was shown in the opening and closing ceremonies of Telecom Interactive '97 in Geneva, Switzerland. The tennis game involved two participants and one umpire. The participants, one in Geneva, the other in Lausanne, were represented by directly controlled virtual humans wearing Flock of Birds magnetic trackers attached to their bodies. They were using immersive HMDs to visualize the scene. The autonomous umpire used her synthetic vision to watch the game and decided the state of the game and score. She updated the state of the match when she "heard" a ballcollision event (ball-ground, ball-net, ball-racket) according to what she saw and her knowledge of the tennis game. She communicated her decisions and the state of the game by "spoken words" (sound events, see Fig. 55.3).

4.2.2 Thrill Rides

Being able to fly is a universal dream. A virtual hang gliding simulator (Dreamality Technologies, Inc.) allows users to experience the thrill of hang gliding without leaving the ground. It brings a level of realism that permits virtual pilots to experience this sport without the risk or expense. The rider scores points for finding thermals and gaining altitude, the length of flying time, and for making successful landings. The scoring system also deducts points for crashes and collisions with weather phenomena and objects such as planes, jets, birds, balloons, ultralites, or buildings. When using an HMD, head tracking can be used to enable the rider to look in any direction and view that portion of the visual scene. Different high-quality sounds and various noises are also experienced while flying. The sensation of wind in the face is also provided. These simulators can be networked to other simulators, allowing each rider to see other riders and interact with them.

Directly derived from military training systems, parachuting in the safety of an indoor simulator is also possible. In one such system, JumpZone, the floor drops away, and the guest drops several inches as the ride starts. As the ride is activated, the noise of the wind and the receding airplane is heard, and wind effects start. As soon as the ripcord is pulled, the guest hears the sound of the chute unfurling and feels the harness jerk (see Fig 55.4).

FIG. 55.4. JumpZone. Courtesy of Illusion, Inc.

The ultimate thrill may be virtual skyboarding, where users interact by moving their body in real space thanks to camera-based unencumbered virtual environments. A tracking system allows a player to interact with on-screen background and foreground graphics. Images and game-play are viewed via three television monitors, and players direct a flying sky board through a futuristic landscape to earn points and progress to higher levels. Moving in front of a video camera, players see themselves on-screen, where they control their movement flying through and interacting with a computer generated landscape. The experience tests a user's agility and speed. In the future it may lead to very extreme physical experiences through the use of full 360-degree rotational interfaces such as VE gyroscopes.

4.2.3 Disney Quest

Some of the best examples of immersive entertainment are Disney Quest's indoor interactive theme parks (Disney Quest). These multiple-story centers combine Disney content with leading-edge immersive technology to create what is claimed to be a new kind of entertainment. Such centers offer various entertainment zones to explore and discover rich VEs or play games based on popular Disney characters. Guests can embark on adventures that let them actually enter the story and become a part of it.

A creation zone even allows the design of one's own roller-coaster ride before experiencing it on Cyberspace Mountain, a 360-degree pitch-and-roll simulator. Rides such as the Virtual Jungle Cruise or Aladdin's Magic Carpet are very popular. Virtual environments are used as a new medium to tell stories. Content and interactivity are the key. The shows contain a large number of synthetic characters and narrative storylines.

In Aladdin's Magic Carpet, visitors wear HMDs and pilot a flying carpet sitting on a motorcycle-style seat. The seat is mounted on a movable base, allowing it to pitch up and down following the driver's instructions. Stereo ambient sound, binaural recorded sound, and eight channels of localized sound ensure total audio immersion.

4.2.4 Experiential Rides

Building on game technology, new entertainment options are becoming available. Instead of fast reactions and strategy, they emphasize discovery and novel experiences. Some VE installations are far away from the thrill-seeking VE games found in malls and theme parks.

From water beds to gyroscopes and hydraulic units, a variety of platforms provide a new kind of travel into cyberspace and into virtual worlds, where one can experience intense sensory stimulation or where two or more players can interact with each other in challenging play/reality situations. Capitalizing on the success of "riding" games (previously discussed), virtual gliders enable you to fly into canyons with no other purpose than the observation of virtual insects or fellow gliders.

Perfectly merging auditory and visual VE, other experiences use cues extracted from recorded music to create geometry and control object behaviors within a virtual world. Virtual objects respond in sync with music, creating a rich, multisensory experience. Such tools allow directors and designers to develop visually active, immersive environments that merge 3-D models with sound, such as a music video, in which users are completely immersed and free to explore a world generated by music. In essence, these new virtual environments explore new art forms.

5. VIRTUAL ENVIRONMENTS, INTERACTIVE MOVIES, AND THE FUTURE OF STORYTELLING

Nakatsu and Tosa (1997) proposed a model in which virtual environments, movies, and video games will soon converge into a single kind of interactive media. Such a convergence of

traditional media and VE, however, raises several issues in terms of interactivity and user experience (Nakatsu & Altman, 1997). The next sections discuss required additions to current VE technologies that could assist in realizing the next generation of interactivity. After analyzing user behavior, some concepts are introduced that can support analysis of next-generation interactivity. This framework is related to the process of interactive content creation and authoring. The discussion concludes with a review of technical challenges. The present situation in interactive entertainment and storytelling will be mainly illustrated by examples from recent computer games, while state-of-the-art VE applications can be found in other chapters (see chaps. 42–55, this volume).

In future interactive media, the traditional distinction between actor, director, and spectator will tend to disappear (Benford, Greenhalgh, & Craven, 2001). Bolter and Grusin (1999) noted that in current interactive games, players are both directors and spectators. This is, for instance, announced by the way some games offer a third-person perspective on the player characters, such as Lara Croft (*Tomb Raider*) or Solid Snake (*Metal Gear Solid*). And it can be observed that the games with personified avatars have also introduced a variety of camera movements during the action itself. Another relevant paradigm consists in alternating active gaming phases and replay phases where the player is a spectator of his previous game. This has already been introduced in games in which the strain was too important for the user to fully enjoy the global action as a visual scene. The intense playing phases of some video games (e.g., *Gran Turismo* or *Ace Combat*) generate corresponding replay sequences of the same length, in which the user can still control the viewpoint and camera effects. These games offer an interesting model for interactive media in light of the current discussion on the trade-off between playing and authoring. This feature can be part of the solution to a well-known problem—that interactivity could involve the spectator far beyond his own wishes and make interactive media an exhausting rather than relaxing experience.

There are two major concepts that should be analyzed in connection with interactivity. The first one is user experience/user involvement. How can the user both interact with the scene and with the plot? How can he interact and be a spectator at the same time? The second one is adaptive storytelling, which should support interactive experience from the storytelling perspective by offering models and formalisms for content description, thereby enabling user-controlled nonlinear storytelling.

There are currently no complete theories of interactivity that would be suitable for the analysis of digital media. For the brief analysis outlined here, we propose to ground the analysis of interactivity on the concepts of causality and determinism. The notion of causality is central to many epistemological discussions and has been extensively investigated in the field of artificial intelligence. It should thus not come as a surprise that it surfaces here, as AI should be an important enabling technology for interactive media, not only through artificial actors but also through nonlinear storytelling management, natural language interfaces, user-dependent customization, and other means. What causality essentially corresponds to is that user actions should determine changes, not so much in the virtual world in which the action now takes place but in the plot itself, which can involve more complex and abstract representations. This trend would be supported by the emerging field of intelligent VEs, which brings back AI into VE systems and applications.

It can be observed that the situation in current video games only reflects a single movie category—action movies. This is largely because of the kind of actions that are made possible with current input devices, which are physical actions. Being able to interact on the plot at a more abstract level is less common, for instance by engaging in conversation with synthetic actors whose intentions and beliefs would relate actions to the narrative structure of the plot. The current situation in interactive entertainment is largely that of full determinism. The same actions produce the same effects, as initial conditions are repeated through various stages of the game. The representation behind the plot is still a treelike representation, with

branching nodes being associated with key events. Interactivity thus takes place only at these key events.

In order to implement more sophisticated forms of causality, an appropriate level of modeling has to be found to make it possible to dynamically propagate the consequences of user actions in terms of the plot itself. When considering the simplest computer games, such as driving simulators or shoot-'em-ups, there is no autonomous storytelling. The interaction loop is a simple one in which the player is constantly solicited to interact and in which there are direct consequences of those actions. It thus appears that there is a trade-off between storytelling and full real-time plot generation. Let us examine the benefits and drawbacks of both extremes in terms of game-play and user acceptance. A full dynamic computation would allow an infinite number of stories and endings to be generated (provided this would be technically feasible on the basis of physical simulation, which is unlikely) but would on the other hand demand permanent user involvement. The main advantage of operating within an interaction framework is that users can decide when to be involved. It is indeed a property of storytelling itself that some key events largely decide the further unfolding of the plot, and this is reflected by the specific meaning that some actions take for the spectator. In other words, some properties of the content itself could facilitate its formalization in an interactive computer system.

Therefore some causality in storytelling should exist to support user involvement, just like (a simplified) physical causality supports game-play in first generation computer games. At this stage, one realizes the delicate balance between determinism and creativity. This important concept deserves a more detailed discussion. Several arguments can minimize the drawbacks of determinism. The first one is simply to say that entertainment is just emerging from non-interactive movies and that any way of choosing alternate plots, even if deterministic, would represent some progress in terms of spectator's experience (for a receptive audience). The second argument is that predictability, not determinism, is the actual problem. In the real world, system complexity and the inaccessibility of some initial conditions can make deterministic systems nonpredictable. In virtual worlds, this arises from the fact that users have no access to the underlying principles that control event generation. The final paradox is that some form of determinism is required for the story to be understandable and that narratology is, to some extent, based on the determinism of narrative functions. The novelty of interactive storytelling should thus take place in the framework of such a deterministic formalism. That is to say, interactive storytelling will be a matter of substituting some narrative functions to others, under the supervision of the spectator.

Let us consider, as an example, the unfolding of a James Bond movie. This has been the object of narrative analysis since Barthes (1966). Barthes, analyzing some phases of the James Bond movie *Goldfinger*, described a subset of narrative functions and gave an example of how alternative actions might have resulted in a different course of action, still compatible with the storytelling formalism. Following traditional concepts in narratology established by Propp (1968), Barthes introduced the notion of *sequence* as the basic unit of storytelling. A sequence is an elementary ordered set of actions. For instance, offering a cigarette involves the following elementary actions: offering, accepting, lighting, and smoking. Schank and Abelson (1977) developed similar concepts in the field of AI for story understanding, which were termed *scripts*. However, while Schank and Abelson put emphasis on the script as a normal course of action that enables recognition of a classic situation from the occurrence of its basic elements, Barthes considers that elementary actions within a sequence act as *dispatchers*, serving as a basis for story variability. This can be reinterpreted in terms of interactive storytelling. The main problem is to be able to authorize interactions at crucial stages of the plot and to confer an implicit meaning to user intervention. This implicit meaning is often accessible to the user through the common knowledge of narrative structures that popular culture has assembled. Note that, through this knowledge, the user will have some awareness of the nature of his

intervention, yet this will not be a deterministic process, as he might miss many elements of the plot. So the spectator can look like he is acting perfectly as he tries to “help the hero,” although in reality his actions will be highly detrimental.

The forms of interaction and user involvement that can be conceived in the perspective of VE and storytelling convergence can now be summarized:

- *Physical interaction with the world.* As VE systems are strongly based on physical worlds, one might think that their support of interactivity should be through actual physical simulation. But, apart from being largely out of reach in terms of generalized physical modeling, this would simply miss the main point of storytelling, which is to allow characters to be the main source of determinism. Designers should thus not restrict themselves to physical interaction, but also consider interactivity as involving information exchange with artificial actors (see chap. 15, this volume), which in turn influences their beliefs and plans, hence the story as a whole. In this case, it is more AI techniques than rendering and simulation that are going to support interactivity.

- *Conversational interaction with one of the characters.* This would appear to be the most natural and acceptable way of interacting with characters. The user would give instructions or advice to the main characters (e.g., “do not open that door”), thus changing the course of the plot. Apart from the well-known difficulties of speech recognition and natural language understanding, the main technical problem would be to control the phases at which such interaction would take place.

- *High-level plot alteration.* This is actually the degree zero of interaction. For example, early interactive movies allowed the choice of different paths on a tree-structured story, based on a given action being chosen by the audience from a list. That such a primitive approach should be used for next generation systems can only be justified by the desire of some spectators to actually control future events or impose constraints on the scenario (such as “Character X should not die”).

The convergence of VE and storytelling also brings an important consequence that it is possible to navigate in the virtual world outside of the main scene. This is a dramatic extension from just being able to change viewpoints and perspective on the scene itself, as it disrupts the traditional conception of storytelling being based on a visible set. It thus allows altering the future course of action by interacting with world objects outside the main focus of the story at the expense of the user’s spectator role. Such deferred interaction, however, would consist in the user altering the course of action, not through interfering with the action itself, but by changing the structure of the physical world in which the action will take place.

The convergence of VE and storytelling could represent a major transformation of both media and entertainment technologies. However, many technical challenges that go far beyond the development of new VE or interface technologies can be identified. It appears that new theories of storytelling should be developed in order to describe computer formalisms that can support interactivity while still accommodating traditional narrative content.

6. MILITARY SIMULATION AND GAMES

Many computer games find their inspiration in military simulation, whether these are flight simulators or war games. In both cases, they replicate, in a reduced and more accessible form, actual military systems, not only flight simulators but also control and command systems. The latter also belong to VE technology, as they eventually implement user-centered interaction with 3-D world models (Cavazza, Bonne, Pernel, Pouteau, & Prunet, 1995).

While it has been reported that defense organizations have shown interest in using gaming software for training purposes (one famous example being the use of the Doom engine, adapted for simple infantry training), the main rationale for the use of gaming technology has been its performance–cost ratio. However, in most cases, the technology transfer is still more likely to take place from military systems toward entertainment applications, though recently technological convergence between military and entertainment systems has been addressed (Zyda & Sheehan, 1997).

Military simulation is the most relevant technology for entertainment systems. One of the major endeavors of modern military simulation is the achievement of realistic large-scale distributed battlefield simulations (see chap. 43, this volume). Many R&D programs are part of this long-term effort, such as the Synthetic Theatre of War (STOW) and Command FORces (CFOR) initiatives.

These include several technologies that are relevant to distributed gaming as well, including efficient distributed simulation using minimal bandwidth and population by both human actors and computer-generated forces, which demand the development of credible synthetic opponents. The simulation of intelligent behavior has certainly been one of the main achievements of military simulation programs. Furthermore, this research has addressed both individual and intelligent collective behavior, such as the coordination of synthetic forces towards a common goal (see chap. 44, this volume). One such example of intelligent behavior modeling for synthetic forces has been the use of the SOAR system. Recently, a simplified version of SOAR has been adapted to the popular Quake video game to control behavior of nonplayer characters by a research group at the University of Michigan (van Lent & Laird, 1999).

Another recent example of the convergence between games and distributed simulation has been the development of the DIS-lite protocol, a simple version of the Distributed Interactive Simulation (DIS) protocol. This has been adopted by a commercial video game offering distributed realistic tank combat simulation over the Internet (Spearhead from Zombie/Interactive Magic).

The main characteristic of military simulation is its total realism, whereas games are governed by a trade-off between game-play and realism. Some simplifications occurring in current games derive from technical choices, and others are required to make the game accessible. A fully accurate simulator would require the same skills, hence the same amount of training as a professional, which might put off a significant fraction of players. Simplification in games finds its origin in the need to get the whole process accessible to a single player on a reasonable time scale. It thus tends to reduce complexity and time scales simultaneously. This in turn enables a single player, not only to control many different entities, but also to perform situation assessment on his own, whereas in the real world this is achieved by specialized teams whose efforts are supported by complex information systems. Computer games usually ignore some essential components of modern warfare, such as electronic warfare, communications, intelligence, and detection, which would appear less spectacular than actual phases of air or ground combat.

Technically speaking, realism is supported by a set of computing techniques, which can be briefly summarized as real-time distribution protocols and architectures, realistic physical modeling (also based on real-world data), terrain modeling (with large-scale geographical data), and, most important, intelligent behavior modeling for synthetic forces. One example familiar to gamers is path planning on a simulated terrain. While simple algorithms like A* can compute a path on the sole basis of geometrical constraints, important additional constraints exist on the battlefield, such as line of sight and direction from which a tank platoon can approach an enemy position (Hepplewhite & Baxter, 1998). These techniques can be straightforwardly ported to computer games to increase realism, credibility of synthetic opponents, and game play. The whole set of behavioral techniques that have been developed for tactical simulation and synthetic forces could be transferred to computer games to improve their realism and make them more challenging.

However, the advent of large-scale distributed gaming can potentially make realistic simulations a viable option, as players would tend to specialize, very much like in the real world. The fact that the frontier between actual military simulation and large-scale gaming may eventually disappear could probably have significant implications for military doctrines, but at this stage this still remains a science-fiction scenario. Distribution (see chap. 16, this volume) can thus have a major impact on game play, depending on the availability of large-scale distribution techniques. The same applies to intelligent behavior of synthetic opponents (see chap. 15, this volume). Synthetic actors were originally designed to populate distributed VEs that could not accommodate a large number of users, whether because of limited distribution capabilities or 24 hours availability of such human players. With the advent of large-scale distributed simulation, the population of human users will increase dramatically, thereby creating a need to redefine the role of synthetic actors towards more specialized assistants.

Apart from having inspired a significant number of computer games, military applications have paved the way for important technical developments, like distributed systems, synthetic opponents, and a large set of AI techniques, which will play a major role in next generation entertainment systems. The possible convergence of gaming and military simulations is attracting growing attention—the actual data on which these systems will be used would eventually constitute the main difference between the two applications. The U.S. Army is already working on a “holodeck,” a super simulator that will leverage virtual cinematography and video game technology to create realistic 3-D scenes of actual inhabited locations worldwide (Verton & Caterinicchia, 2000).

7. POLITICS OF GAMES

Film, television, and video have long lived with the politics of regulation and censorship. Contentious matters such as violence, sex, and stereotyping are becoming bigger issues for computer gaming too, particularly as it moves toward more intense, graphic realism.

Like early rock’n’roll, gaming is often seen as a potentially subversive popular culture. Some think that because gaming involves active participation, rather than passive viewing as in film, it can have more damaging and addictive psychological effects (see chap. 33, this volume). Others feel that game play is mainly physical activity, and less dangerous than cinema’s ability to arouse powerful emotions.

The computer games industry is largely self-regulating (see ESRB), and games companies such as Sega, Sony, and Nintendo voluntarily publish guidelines on what they deem acceptable. Such policies have caused games to be cut or dropped entirely. For example, Sensible Software’s game *Sex and Drugs and Rock’n’Roll*, based on the theme of a rising rock star that falls for every imaginable vice on the road to stardom, was shelved because it could not find a publisher.

Games publishers frequently tailor content to differing sensibilities among global markets. The Japanese games *Samurai Spirits 3* and *Resident Evil*, for example, reduced their bloodletting for release into the U.S. and U.K. markets. Computer gaming can also be affected by legislation. In the U.K. game titles can come under the scope of the Video Recordings Act, which deals with gross violence or sexual activity. The British Board of Film Classification can ban games it finds unacceptable.

Yet such policing of computer games can be tricky. In the mid-1990s, the game *Carmageddon* invited players to drive cars recklessly and score points by mowing down innocent bystanders. The game was banned, and could only be released after zombies replaced human pedestrians. But the resulting publicity helped elevate *Carmageddon* to cult status. Shortly after its release, software patches that restored it to its original status could be found on the Internet.

Pornography has not tended to be a major issue for games, as it has for the Internet. However, games are notorious for gender stereotyping. A late-1990s U.K. television advertisement for

the game *Zelda* symbolized gaming's virtual world of muscle-bound male leads and story lines by asking Wilt thou get the girl, or play like one? Traditionally, the vast majority of computer games players have been adolescent males. Precisely why is the subject of much debate, maybe it is simply to do with different male and female attitudes to popular culture, technology, and computers. In any case, games developers have long drawn upon male stereotypes and fantasies to appeal to this audience.

One of the key games icons of the 1990s, Lara Croft, star of *Tomb Raider*, bears many of the hallmarks of gender stereotyping. Her curvaceous female form is pure fantasy. Some see the way players watch and control her from above or behind as "voyeuristic." Yet she has also been hailed as one of the first strong female games characters, a model of 1990s "girl-power"—intelligent, tough, independent, and in control.

As games companies seek to expand their markets, games are likely to be carefully designed to appeal to specific target groups. To attract a wider female audience, characters may be used that females are more likely to identify with. The success of *Barbie* games has already shown the potential of that market. Some games are designed to appeal to girls and boys. The cute and quirky *Pac-Man* was a massive hit with both sexes. The game play in Sega's *Sonic the Hedgehog* involves rescuing and protecting creatures rather than terminating their virtual lives.

There is even a two-player version of *Sonic*, where players wait for each other to catch up and collaborate in solving problems. This social and cooperative "female" gaming model may well appeal to girls more than the competitive and combative "male" gaming model that seems to appeal to boys. Perhaps the ideal gender-neutral game would combine the two ideas, pitting the "female" and the "male" models against each other in the same arena—one called real life!

8. VIRTUAL ENVIRONMENTS "FUTURES"

What is the future of entertainment? How pervasive will VEs, be? In the following section, some of the trends in new forms of content and interactivity are reviewed. Prospects for future LBEs and high-end rides in theme parks are discussed. Research in AR and telepresence are examined, which point to some exciting possibilities for future entertainment. The section concludes with a peek inside the living (and playing) room of the future.

8.1 Content

Whether in arcade games, LBEs, or high-end theme park rides, the prime element of interactive experiences is content and not technology. An attractive background story is a prerequisite. Good games and rides are able to bring users to the point where the interface becomes transparent and where they focus only on task performance. Sound is a key element for complete immersion but the need for high-fidelity multimodal cues can be reduced by engaging the user in a complex series of real-time tasks.

The future may belong to goal-oriented entertainment, which emphasizes the journey rather than the objective. Rides will become more experiential, allowing us to explore or unwrap a story hidden beneath a rich environment. The main question for content creators is what is in guests' heads during the experience; finding the answer requires part science, part art, and part sociology.

As the new language of interactive entertainment is being developed, edutainment content will become more important. Museums, science centers, zoos, and aquariums have a need for novel information delivery systems and will want to capitalize on new digital entertainment techniques. The potential for growth is enormous.

Thanks to online virtual communities, we are about to see an explosion of decentralized competition for content creation. This is already noticeable in the musical area and when extended to 3-D and video content will lead to a complete revolution in the way content is produced and distributed (see chap. 25, this volume). Content will also evolve to appeal to a wider population. Interactive entertainment or edutainment, if aimed at culture, health, or well-being could appeal to everyone, including senior citizens.

8.2 Interactivity

Beyond the navigation level, interactivity is still essentially an open field. Attempts at interactive plots have not always been successful (Benford, Greenhalgh, & Craven, 2001). There is clearly still a lot of room for passive media, as most people still want to be told stories. This may change as the new “Nintendo generation” grows up. Today’s children are used to navigating complex 3-D spaces and interacting with content. They expect more than static displays and television monitors. They want immersion and interaction. They want to explore and discover, and simulation is the dynamic medium that will satisfy them.

Group interactivity in immersive theaters and simulation films is even more of a challenge (e.g., Avatar Farm, an inhabited television event, collaboratively performed over the Web). But it is attracting a lot of interest since people want shared, social experiences when they go for out-of-home entertainment. People usually come in a group to enjoy themselves, to have fun together, to share an experience that draws them closer to each other. Beyond the ride itself, the experience should help people enjoy the company of each other. Games should either be true group games or single interaction activities that others are encouraged to share. People should laugh and talk and bump and touch and never lose track of the other people they came with, no matter how absorbing the activity. This type of multiuser interactivity is now being rolled out in large reality-center simulators for up to 100 participants. Each player controls the action through individual controls and decisions are taken on a majority basis (DePinxi Interactive Experiences).

8.3 LBE Centers and Theme Parks

Future LBE centers will introduce new kinds of immersive technologies, higher quality texture mapping, and improved motion platforms. New interfaces, such as voice (see chap. 4, this volume), touch (see chaps. 5 and 6, this volume), position (see chap. 8, this volume), gaze (see chap. 9, this volume), and gesture (see chap. 10, this volume) will be introduced. They will also be networked (see chap. 16, this volume), so that players from around the world can challenge each other in the same virtual world. LBEs are starting to use large-scale networked systems based on DIS. LBE experiences will also be personalized. Transponder badges will give player preferences to the system and help track performance improvements.

But LBE games are also likely to evolve from the fighting and driving thematic to exploration and discovery. LBEs offer a chance to develop new kinds of collaboration-focused activities supported by advanced technology (Dodsworth, 1998). New centers may create a legitimate entertainment format, interesting to adults, with a story to escape into; perhaps similar to Internet-based RPGs but improved with high-end audiovisual and haptic interfaces still out of reach of home users for some time.

As they spread in more accessible locations, take advantage of advanced networking infrastructure, and leverage better content targeted to a broader audience, LBEs will create opportunities for new frameworks, scenarios, and situations. Social multiplayer network experiences may recreate the entertainment format of our ancestors; collectively told, locally created interactive storytelling with Technicolor fidelity (Dodsworth, 1998).

The future may belong to combinations of real, brick-and-mortar theme parks, with online, broadband virtual worlds. Online players will build a character in the virtual world and when they come to the park, they can literally log into it. As they roam the park, transponders pick them up and they can interact with virtual characters through large, high-resolution screens. Such a real-virtual amusement park is currently being developed around the *Wizard of Oz* story. The real park will be built in Kansas and in addition to thousands of real virtual it hopes to help attract hundreds of millions of people in the virtual world as soon as broadband Internet allows for it (see Oz). This demonstrates how real and virtual worlds are likely to be intertwined in the future.

8.4 Players and Spectators

An important aspect of group entertainment is the spectator's role. Today's audience wants more direct participation even if not everyone wants to be a direct participant. People also enjoy being active spectators, which offers a less threatening forum to express themselves than direct participation. The best examples are sports such as football, in which only a few participants play although tens of thousands share an exciting experience. There is an important potential market to be developed for providing a substantial and rewarding spectator "experience" in the digital entertainment area (Zyda & Sheehan, 1997).

8.5 Augmented Reality for Entertainment

Augmented reality is a relatively new field of research by which a user's view of the real world is augmented with additional information from a computer model (Azuma, 1997; Ohta & Tamura, 1999; see chap. 48, this volume). Users can work with and examine real 3-D objects while receiving additional information about those objects or the task at hand. By bridging the gap between VE and the real world, it occupies a central position in the reality–virtuality continuum (Milgram & Colquhoun, 1999), exploiting technologies and methods developed in the VE and sensing domains.

Augmented reality, although currently still in its infancy, is maturing rapidly. Since its inception as a new, distinct, research area (Caudell & Mizell, 1992), it has seen an impressive rate of growth. Depending on many information technologies, such as mobile wearable computing, wireless networking, computer graphics/VE, and sensing that are all showing rapid maturations as well, AR is likely to quickly become a commodity in the next millennium. Demonstrations and systems presented in this handbook are still prototypical. But they should be seen as early indicators of a new user interface paradigm yet to fully emerge. Entertainment applications of AR are no exception. Most of them are yet to be invented.

Augmented reality can provide a set of rather sophisticated approaches focusing on "digital workbenches" (Krueger et al., 1995; MacKay, Velay, Carter, Ma, & Pagani, 1993; Ullmer & Ishii, 1997; Wellner, 1993). Such approaches require special setups, typically consisting of a back-projected near-horizontal screen serving as a table plus several tracking devices, such as magnetic trackers and cameras. Digital workbenches, especially in combination with physical objects facilitating new user interaction schemes, can be very suitable for educational purposes in museums and schools. One demonstration concerned a map of the MIT campus, identifying and marking various landmarks by physical replicas and computing distances between them.

Similar concepts have been explored using a less specialized computing environment (Klinker, Stricker, & Reiners, 1999a). On a regular table, users can combine real and virtual objects to create elaborate "mixed mock-up" scenes. Real and virtual objects are each identified by a special marker (like a bar code) and can be moved about by users. A computer with a video camera tracks object motions and augments the scene with virtual objects.

Applications in museums and schools can thereby enact “what-if” scenarios, using dollhouses, small physical replicas of historical battle scenes, or construction kits. Such systems will certainly be used for entertainment once content creators discover them and let free their imagination.

Other scenarios involve outdoor tourist applications. A prototypical system has demonstrated how users can walk about in an area, such as a campus, and gain background information about buildings they are looking at (Feiner, MacIntyre, & Höllerer, 1999). In this system, a PC in a backpack tracks the user’s current position and viewing direction with a differential GPS antenna and a magnetometer/inclinometer. It accesses information pertaining to buildings in view wirelessly from the Intranet of Columbia University and presents information both on a head-worn display and, in more detail, on a small handheld monitor via which the user can also request more specialized information. Such prototypical applications can be extended toward scenarios in which tourists roam historical sites of ancient cities, requesting information about buildings, seeing them “virtually” reconstructed or repainted, as well as finding out what the opening hours for special shows are and when the next bus will be at a nearby bus stop to take them to a different site.

Relatively inexpensive game applications of AR technology have been demonstrated. In their simple setup involving a small workstation equipped with a video camera and a monitor or (optionally) a \$500 HMD, they allow users to play board games like Tangram and tic-tac-toe with a computer. In contrast to conventional computer games, these AR-based versions allow users to play games on a real game board, laid out on a table in front of them. They place real stones on the board. Via the video camera, the computer keeps track of what the user is doing. On the monitor or inserted into the HMD, the video picture is augmented with additional information and comments, thereby indicating to the user its own next move in a tic-tac-toe game or hints where to place the next Tangram piece (Klinker et al., 1999a,b).

An AR AiR Hockey (AR^2 Hockey) system has been developed as a case study of real-time collaborative AR for human communication. In demonstrations at several occasions, such as Siggraph ’98, this system was tested by thousands of visitors. Air hockey is a game in which two players hit a puck with mallets on a table. In AR^2 Hockey, the puck is virtual, whereas the two mallets are real. Users use the mallets to shoot a virtual puck into the opponent’s goal. The game is played on a real table. Each player wears an optical see-through HMD to see the puck superimposed on the table. Users’ heads are tracked both by magnetic sensors and by cameras on the HMDs (Tamura, Yamamoto, & Katayama, 1999).

The Kids Room at the MIT Media Lab (Bobick et al., 1999) was set up as a one-time experiment for a 6-week period in 1996. It was a fully automated, interactive narrative play-space for children. Using images, lighting, sound, and computer vision action recognition technology, a child’s bedroom was transformed into an unusual world for fantasy play. Objects in the room became characters in an adventure, and the room itself actively participated in the story, guiding and reacting to the children’s choices and actions. Through voice, sound, and image the Kids Room entertained and stimulated the minds of the children.

8.6 Telepresence for Entertainment

There is no doubt that a highly immersive system would be extremely attractive to theme parks and other entertainment centers. Being able to go into a booth and vicariously visit exotic locations throughout the world using sensor platforms (surrogate heads) located at remote sites would be immensely attractive. Sites should be chosen that provide the maximum stimulus to visual and aural senses (i.e., activities need to be happening, such as people moving about and talking). Examples of fitting locations might be the Grand Canyon, Great Wall of China, Great Barrier Reef, Times Square, Niagara Falls, or even just busy city centers or beaches.

One could use an intelligent avatar that could be available to every individual user. The avatar would provide all necessary information to the user about the remote site and could be interrogated for further information. Other computer generated text and graphics could be integrated with live video (e.g., an external view of an Egyptian pyramid could be augmented with computer generated internal views).

Sports and entertainment events, such as the Olympics and music concerts, could all be visited using telepresence. The user would be able to experience the live atmosphere and have control over the viewing by zooming, panning, and tilting cameras. Although this might seem akin to digital interactive television, the “immersive” element would make the experience unique.

Combining telepresence experiences with educational themes would also be possible. For example, a famous battle site could be visited by telepresence as it is today. However, the user would then be able to overlay the actual battle and its development on the live image, considerable content creation would obviously be necessary (e.g., a prerecorded film using actors or a VE animation).

A commercial use, bordering on edutainment, would be the use of telepresence by travel agents to allow potential customers to view holiday resorts live and overlay, where necessary, temperature charts, flight times, and enhancing QuicktimeVR or other 360-degree still and video images.

For reasonable immersion, stereoscopic full color vision with a wide field of view and full binaural or environmental sound effects may be necessary (see chap. 40, this volume). For telepresence utilizing telecommunications systems this obviously creates bandwidth problems, especially where interactivity is necessary. If a motorized camera platform is being used at the remote site this also means that every simultaneous visitor to the site requires exclusive use of their own platform for the duration of the visit. Good quality stereo viewing systems are still expensive, but binaural or surround systems are reasonable. Another factor that will influence cost is whether the home site will be designed for single or multiple users.

Telepresence for entertainment is certainly possible today but probably still too expensive to be commercially attractive. Improvements in bandwidth availability, cost, home site visual and aural display technology, and remote site sensor platform design are all necessary before the adoption of telepresence for entertainment becomes commercially attractive.

8.7 A Holodeck at Home?

The ultimate VE would be a computer interface that allows users to perform tasks as easily as they do in the real world. This would require building interfaces that effectively add natural manipulation (see chap. 13, this volume) and locomotion (see chap. 11, this volume) to visual immersion. Science fiction has given us attractive visions of this superinterface, of which the Star Trek holodeck is probably the most popular. The holodeck is envisioned as a next-generation VE simulation system that would allow people to experience multisensorial virtual worlds including sight, hearing, touch, and even smell. The holodeck would allow virtual travel anywhere, anytime. In the movie Star Trek, crew members used the holodeck to play, exercise, travel, and even discover historical sites that disappeared centuries ago. One of the essential features of the holodeck is the presence of characters with whom the user can interact in a natural way.

We are still far from being able to realize this vision. Building a holodeck will require breakthroughs in sensors, robotics, and mechanical interfaces, not to mention significant progress in graphical interfaces and computational simulations. The key will be to attain latency levels far more stringent than anything available today. It will also mean adapting movie making and storytelling skills to create realistic simulations.

Not only would it be the ultimate interface to experience telepresence, learn, or communicate, a holodeck would also be the perfect entertainment platform and one could argue that some games are the closest venue to a holodeck available today. But when the dream becomes reality, players will be able to fully immerse themselves in virtual worlds to experience rich, multisensory adventures. These very compelling experiences will make current motion platform rides feel like black-and-white silent cinema does today. We will finally be able to fly.

9. ACKNOWLEDGMENTS

We thank the following individuals for their contributions and support: Fiona Allan (European Commission), Lia Brosseau (Illusion, Inc.), Philippe Chiwy (DePinxi), Karen Drasler (Disney Quest), Richard Gallery (Philips/S3), Anne Hohenberger (SGI), Steve Hunter (Dreamality Technologies, Inc.), Thierry Nabeth (INSEAD), Randy Pausch (Carnegie Mellon University), Frank van Reeth (Limburg University Center, Belgium), Peter Schickel (Blaxxun), Kay Stanney (University of Central Florida) and the four anonymous reviewers whose constructive comments were much appreciated.

1. INTRODUCTION

Although this handbook largely focuses on the current status and future vision of virtual environments (VE) technology, it would be unjust to develop such a work without providing acknowledgement to the pioneers whose vision and innovativeness laid the groundwork for the science, technology, and applications described here. This chapter provides a very brief historical overview of some of the key people and major milestones that led to the current state of the art. In addition, readers of this handbook may be left wondering where they can gain more information about the VE profession. This chapter provides a number of such references, including major application Web links, associated periodicals, major conferences and trade shows, major organizational players, and general and historical references.

2. A BRIEF HISTORY OF VIRTUAL ENVIRONMENTS

Not surprisingly, the science fiction literature envisioned the generation of artificial or illusory environments before there was any idea of the technology to accomplish such a feat. For example, a famous 1950 science fiction story by Ray Bradbury (Bradbury, 1976) called *The Veldt* depicted a playroom where children experienced an African landscape. The animals ultimately ate the parents. The first attempts at developing such a technology used electronics, but not computers, which at that time were much too primitive. In 1956, Morton Heilig, a filmmaker, developed *Sensorama* (U.S. Patent No. 3,050,870), a mechanical virtual display device (see Fig. 56.1). Perhaps the first head-mounted display (HMD) was developed by Philco in 1961, which permitted remote viewing via a video camera (Kalawsky, 1993).

In the early 1960s computer graphic technology was beginning to be developed. The technology for computer-generated VEs probably began in 1963, when Dr. Ivan Sutherland developed the first interactive computer graphics system, called *Sketchpad*, while a graduate student at the Massachusetts Institute of Technology (MIT; Sutherland, 1965). Sketchpad created highly precise engineering drawings that could be manipulated, duplicated, and stored. In 1968, Sutherland joined with David Evans to build an HMD at the University of Utah (Sutherland, 1970). Shortly thereafter, Thomas Furness, working at Wright-Patterson Air Force Base, developed an HMD that he called a "visually coupled system" (Furness, 1969). Furness went on to develop a virtual cockpit flight simulator in 1981 (Furness, 1988). Since the early developments of Sutherland and Furness, there has been continual evolution in HMD design by various government organizations and private companies, including Honeywell and Hughes.

While Sutherland and Furness were working on the technical aspects, Myron Krueger was studying the artistic and psychological aspects of VEs at the University of Wisconsin. Krueger first concocted *Glowflow* in 1969, a kind of artistic light and sound show that was controlled by a computer but involved no computer graphics (Krueger, 1977). In *Glowflow*, audiences actively participated in the show by moving around on pressure-sensitive plates embedded in the floor, though most were unaware of the controlling mechanism. The following year Krueger developed the much more elaborate *Metaplay* with a grant from the National Science Foundation and the university's computer science department. This system involved 800 pressure-sensitive switches and an 8 × 10-foot rear projection screen on which people

viewed video images of themselves from a video camera, superimposed on computer graphics generated by a minicomputer. During the next several years Krueger developed ever more elaborate artistic works that provided interactive experiences to audiences, such as *Videoplace*, which immerses an individual into a computer-generated world inhabited by other human and virtual participants, in which the laws of cause and effect can be composed from moment to moment (Krueger, 1985). Krueger is credited with coining the term *artificial reality* in 1973 (Krueger, 1985).

In 1974 personal computers were introduced, and in 1977 the first glove device for controlling a computer was developed. One of the first commercial gloves, was VPL Research's *DataGlove*, which was invented by Thomas Zimmerman (U.S. Patent No. 4,542,291) and operated by a programming language developed by Jaron Lanier (Jones, Rheingold, 1991). Also in 1977, Kit Galloway and Sherri Rabinowitz created virtual space with the Satellite Arts Project, implementing the vision of Arthur C. Clark and Marshall McLuhan's global village, interconnecting the people of the world via electronic communication. In what Galloway and Rabinowitz called *Hole in Space*, they set up a large video screen and camera in public spaces in New York City and Los Angeles to effectively videoconference in a group setting. A decade later they went on to found the *Electronic Café* (<http://www.ecafe.com/>) in Santa Monica, California, allowing videoconferencing on an individual basis.

By 1979 researchers at MIT began developing spatial data management systems, and in the early 1980s educators began interactive control of video playback with Apple II computers for use in computer-aided instruction (CAI). One of the group, Scott Fisher, developed the technology of stereographic displays using an HMD. In 1981 those researchers, including Fisher, produced the *Aspen Movie Map*, in which a person could navigate, using a touch-sensitive display screen, along 20 miles of streets in Aspen, Colorado (Fisher, 1982). This did not use an HMD; rather, it was an elaborate 'CAVE'-type (Cave Automatic Virtual Environment; see chap. 11, this volume) system that projected scenes on the surrounding walls of a room.

Also in the early 1980s the Defense Advanced Research Projects Agency (DARPA) funded a global war game simulator called "simulation networking," or *SIMNET*, that broke new ground in large-scale networks. Using *SIMNET* and its later upgrade, Distributed Interactive Simulation (DIS), hundreds of soldiers all over the world then—and now—can sit in tank, helicopter, and fighter bomber simulators, testing their combat skills against one another in real time, much like a video game, but very realistic. The cost savings and safety of such simulators will undoubtedly continue to drive the development of military battle simulators ever more in the future (see chap. 43, this volume).

In 1984 the movie *The Last Starfighter*, written by Jonathan R. Betuel and produced by Edward Denault and Gary Edelson, merged live action with computer graphics to save millions of dollars in production costs. Also in 1984, William Gibson wrote a science fiction novel, *Neuromancer*, in which he introduced the now-ubiquitous term *cyberspace*. In 1986 Lucasfilm, a firm founded from the revenues of the 1976 *Star Wars* movie series, began developing computer movies. Since that time the movie industry has steadily increased its use of computer graphics to reduce costs and create astounding visual effects.

In 1985 Jaron Lanier and Jean-Jacques Grimaud founded VPL Research, Inc., to produce state-of-the-art human interface devices (Kalawsky, 1993). Lanier, who coined the term *virtual reality*, was an interesting, creative, and eccentric character that the public came to identify so closely with the technology that many incorrectly viewed him as the founder of virtual environments. In the middle and late 1980s VPL Research became famous for making what was intended to be the first consumer grade VE hardware: the DataGlove and the *EyePhone*. Unfortunately, in a few years VPL Research came on hard financial times and Lanier, the company, and the products essentially disappeared.

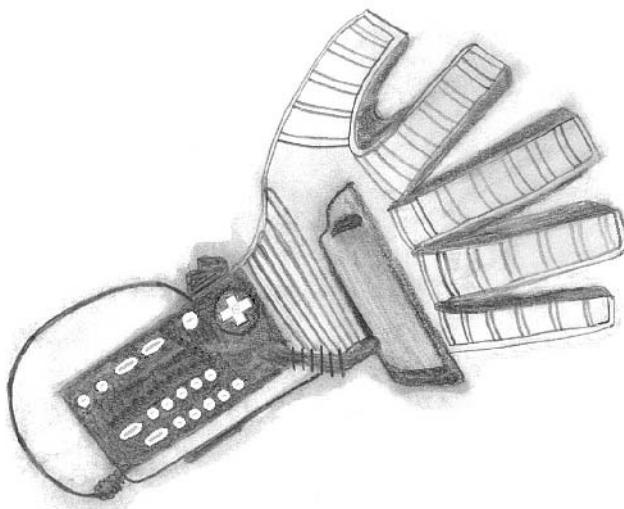

FIG. 56.2. Mattel's PowerGlove. Drawing Courtesy of Kay Stanney.

Also in 1985 a team under Dr. Frederick P. Brooks, Jr., began experimenting with three-dimensional (3-D) perception of molecules at the University of North Carolina. In the next decade that project developed into the *Nanomanipulator*, where a person wearing an HMD can manipulate single atoms or small groups of atoms by a force-feedback arm electronically connected to a scanning tunneling electron microscope (Taylor et al., 1993; see chap. 42, this volume).

In 1988 Chris Gentile, of Abrams/Gentile Entertainment, developed the *PowerGlove* for Nintendo Home Entertainment System (see Fig. 56.2; Gardner, 1989). Licensed and marketed by Mattel, the PowerGlove became a best-selling toy in 1989 and 1990, but was discontinued at the end of 1991 because it failed to produce expected revenues. That was probably the first truly consumer-grade VE hardware. Since that time, the PowerGlove has remained a prized item for VE professionals and amateur enthusiasts alike.

In 1989 and the early 1990s the general public became aware of the concept of VEs and their potential, and enough people began working in the field that the first professional VE conferences were held. Fakespace developed the *BOOM*¹ (Binocular Omni Orientation Monitor), an HMD mounted on a boom for tracking position (see Fig. 56.3). Sense8 Corporation and the Human Interface Technology Laboratory (HIT Lab) were formed. AutoDesk demonstrated their PC-based VE CAD system at SIGGRAPH. W. Industries in the United Kingdom began to sell *Virtuality*, a complete VE system for interactive, interpersonal gaming, and Division Industries began to sell VE systems.

In 1993 SGI announced their *Reality Engine*, a computer capable of running significant VE applications, beginning the current era of rapidly multiplying applications as significant computer power has developed on relatively inexpensive personal computers. In 1996 VE was ported to the Internet (see chap. 16, this volume), with the creation of Virtual Reality Modeling Language (VRML), and today there exists a plethora of hardware and software that permits easy development of VE applications. Finally, in a well-publicized application of VE, astronauts were trained to do repairs on the Hubble space telescope using a full scale VE simulator constructed at Goddard Space Flight Center (see chap. 42, this volume).

¹BOOM is a registered trademark of Fakespace Labs, Inc.

FIG. 56.3. Fakespace's Boom HMD. Photo Courtesy of Fakespace Labs, Inc., Mountain View, California.

Today, applications of VE technology include architectural design with walk-throughs, VE fantasy games, VE flight simulations, and educational materials, including human anatomy walk-throughs and map fly-arounds (see chap. 42, this volume). NASA plans virtual exploration of the solar system. The entertainment industry not only creates many movie effects with computer graphics, but provide VEs in the form of passive and interactive movie rides that include motion simulation (see chap. 55, this volume). The military continues to develop simulators for all aspects of training and is working on telerobotics for battlefield medical treatment (see chap. 43, this volume). The medical industry trains surgeons using virtual patients and “telesurgery” is expected to be prevalent some time in the future (see chap. 47, this volume). Psychologists use VEs to desensitize against phobias (see chap. 51, this volume). Disabled persons use VEs to train wheelchair operation as well as a host of other rehabilitative applications (see chaps. 49 and 50, this volume). Financial professionals use VEs to visualize stock market and other financial trends.

There are major challenges, however. Most researchers in the field express disappointment in the current state of specialized hardware necessary to support VE applications. True consumer grade HMDs still do not exist, and even the expensive ones used by researchers are sadly lacking. Tracking methods and force feedback devices are still primitive, and more sophisticated means of getting information from the body to the electronics need to be developed, such as signal processing of electrical signals emanating directly from the nervous system. Clearly, though, no one questions the potential and ultimate development of VE, including applications not yet conceived.

3. MAJOR APPLICATION AREAS

Many VE applications have developed over the past decade (see chaps. 42–55, this volume). Provided below is a short list of some of the main applications and associated reference sites. Links to Web sites for most can be found at the Virtual Reality Resources Web site: <http://ils.unc.edu/houseman/applications.html/>:

Medicine

- Medical Telepresence, Department of Computer Science, University of North Carolina at Chapel Hill, <http://www.cs.unc.edu/~mcmillan/telep.html>.
- Medical Telepresence Interfaces, Human Interface Technology Lab, University of Washington, [http://www.hitl.washington.edu/projects/medicine/telemedicine.html/](http://www.hitl.washington.edu/projects/medicine/telemedicine.html).
- Minimally Invasive Surgery, Fraunhofer Institute (IAO), Germany, <http://www.iao.fhg.de/>.
- Treatment of Acrophobia, Graphics Visualization Center, Georgia Tech, <http://www.cc.gatech.edu/gvu/virtual/Phobia/>.
- Treatment of Parkinson's disease, Human Interface Technology Lab, University of Washington, <http://www.hitl.washington.edu/research/parkinsons/>.
- Ultrasound Examination, Department of Computer Science, University of North Carolina at Chapel Hill, <http://www.cs.unc.edu/Research/ProjectSummaries/ultrasou.pdf>.

4. PERIODICALS FOR PROFESSIONALS

There are a handful of journals and other publications that focus on VE science, technology, and applications. Provided below is a list of the main publications and associated reference sites:

- *Human–Computer Interaction*, published quarterly by Lawrence Erlbaum Associates, Inc. This academic journal publishes theoretical, empirical, and methodological articles on user psychology and computer system design as it affects the user; <http://www.erlbaum.com/Journals/Journals/HCI/hci.htm>.

- *The International Journal of Human–Computer Interaction*, published quarterly by Lawrence Erlbaum Associates, Inc. This academic journal addresses the cognitive, social, health, and ergonomics aspects of work with computers and emphasizes both the human and computer science aspects of the effective design and use of computer interactive systems; <http://ijhci.engr.ucf.edu>.
- *The International Journal of Virtual Reality*, a multimedia (CDROM with each issue) journal of research and applications, published irregularly but nominally four times per year. Though published in English, the journal emphasizes international involvement and cooperation; <http://www.ijvr.com>.
- *Presence: Teleoperators and Virtual Environments*, published by MIT Press, an academic journal published bimonthly, provides a scientific forum for current research and advanced ideas on teleoperators and virtual environments; <http://mimsy.mit.edu/presence/>.
- *RealTime Graphics*, published by CGSD Corporation in Mountain View, California, a newsletter published ten times a year, providing in-depth information on the technology of real time imaging and providing coverage of industry news; <http://www.realtimegraphics.com>.
- *VR News*, a monthly newsletter published digitally in the United Kingdom by Cydata Ltd., emphasizing developments in the virtual reality industry; <http://www.vrnews.com>.

5. MAJOR CONFERENCES AND TRADE SHOWS

There are a number of conferences and trade shows that focus on VE science, technology, and applications. Provided below is a list of many of these forums:

- A/E/C SYSTEMS: computer and management show for design construction, utilities, and manufacturing industries; <http://www.aecsystems.com>.
- ACM Conference on Human Factors in Computing Systems (CHI); <http://www.acm.org/sigchi>.
- ACM Multimedia Conference; <http://www.acm.org/sigmm>.
- Advances in Automotive and Transportation Technologies and Practice for the 21st Century (ISATA); <http://www.isata.com>.
- Amusement Trades Exhibition International (ATEI): a trade show for the entertainment industry; <http://www.atei.co.uk>.
- Annual IASTED International Conference on Computer Graphics and Imaging (CGIM); <http://www.iasted.com>.
- ASME CEI: organized by the ASME Virtual Environments and Systems Technical Committee; <http://www.asme.org>. <http://www.asme.org/divisions/cie>
- Autonomous Agents Conference (AGENTS); <http://www.cs.washington.edu/research/agents99>.
- Games Developers Conference (CGDC); <http://www.gdconf.com> or <http://www.gamasutra.com>.
- Conference on Computer Animation; <http://www.miralab.unige.ch>.
- Conference on Computer Generated Forces and Behavioral Representation (CGF&BR); <http://www.sisostds.org/cgf-br/index.htm>.
- Defense Modeling and Simulation Office Industry Days (DMSO); <http://www.dmso.mil>.
- Electronic Entertainment Expo (E3 EXPO): a trade show for new multimedia, entertainment, and educational products; <http://www.e3expo.com>.
- Eurographics Workshop on Virtual Environments (EGVE): focusing on augmented reality; <http://www.cg.tuwien.ac.at/conferences/egve99>.

- Human–Computer Interaction (HCI) International; <http://hcii2001.engr.wisc.edu/>.
- ICAT: the oldest international conference on virtual environments, sponsored by the Virtual Reality Society of Japan and the University of Tokyo; <http://www2.vsl.gifu-u.ac.jp/vrsje/>.
- *IEEE Real Time Technologies and Applications Symposium (RTAS)*; <http://cs-www.bu.edu/pub/ieee-rts/Home.html>.
- IEEE Virtual Reality Conference (IEEE VR); <http://www.ieee-vr.org>.
- Industrial Virtual Reality Symposium; <http://www.mae.buffalo.edu/symposiums/ASME/imece99.html>.
- International Conference in Central Europe on Computer Graphics and Visualization (WSCG); <http://wscg.zcu.cz/>.
- International Conference on Disability, Virtual Reality and Associated Technologies (ICDVRAT); <http://www.cyber.reading.ac.uk/P.Sharkey/WWW/ecdvrat>.
- International Conference on Virtual Reality Modeling Language and Web 3D Technologies (VRML); <http://www.c-lab.de/web3d2001/>.
- International Conference on Visual Computing Interaction, Modeling, Rendering, Animation, and 3-D Environments (ICVC); <http://www.ncst.ernet.in/icvc99>.
- International Immersive Projection Technology Workshop (IPTW '99), Stuttgart, Germany; <http://vr.iao.fhg.de/index.en.html>.
- International Workshop on Presence; <http://www.presence-research.org/presence2000.html>.
- Interservice/Industry Training, Simulation, and Education Conference (I/ITSEC), Orlando, Florida; <http://www.iitsec.org>.
- ITEC: a major conference on equipment and simulation for education and training; <http://www.itec.co.uk/>.
- IVR: a comprehensive VR exhibition in Japan; <http://www.reedexpo.co.jp/ivr/>.
- Medicine Meets Virtual Reality (MMVR): the foremost conference on virtual reality and health care; <http://www.amainc.com/index.html>.
- Modeling and Simulation (MS); <http://www.iasted.com>.
- Modeling and Simulation Crosstalk Conference, sponsored by the International Test and Evaluation Association; www.itea.org.
- SIGGRAPH: a very large exhibition and conference on all aspects of computer graphics, <http://www.siggraph.org/conferences>.
- Society for Information Display Symposium (SID); <http://www.sid.org>.
- SPIE Annual Meeting and Exhibition, <http://www.spie.org>.
- Symposium on Augmented and Virtual Reality (AVR); <http://www.graphicslink.demon.co.uk/IV2001/AVR.htm>.
- Symposium on Virtual Reality Software and Technology (VRST); <http://www.cs.ucl.ac.uk/staff/m.slater/VRST99>. See also <http://www.siggraph.org/calendar/calendar.html>.
- Symposium on Visualization (VisSym), sponsored jointly by EUROGRAPHICS and the IEEE; <http://www.cg.tuwien.ac.at/conferences/VisSym99/cfp.html>.
- Technology and Persons With Disabilities; <http://www.csun.edu/cod>.
- Trade Show of the International Association of Amusement Parks and Attractions (IAAPA): the latest VE and simulation rides, <http://www.iaapa.org>. International Association of Amusement Parks and Attractions, 1448 Duke Street, Alexandria, VA 22314.
- Trends in Leisure and Entertainment (TiLE 1999); <http://www.andrich.com/tile>.
- United Kingdom Virtual Reality Special Interest Group Conference (UKVRSIG): includes preconference on intelligent agents; <http://www.crg.cs.nott.ac.uk/groups/ukvrsig>.
- Virtual Systems and Multimedia (VSMM); <http://www.vsmm.org>. International Society on Virtual Systems and MultiMedia Virtual System Laboratory, Gifu University, 1-1 Yanagido, Gifu 501-1193 JAPAN.

6. MAJOR ORGANIZATIONS

There are a number of professional organizations that focus on VE science, technology, and applications. Provided below is a list of some of the primary endeavors:

- Advanced Interfaces Group, University of Manchester Department of Computer Science, England; <http://aig.cs.man.ac.uk/>.
- Army Research Institute; <http://www-ari.army.mil/>.
- Computer Graphics and User Interfaces Lab, Columbia University; <http://www.cs.columbia.edu/graphics/>.
- Computer Graphics Lab, Ecole Polytechnique Federale de Lausanne (Swiss Federal Institute of Technology), Switzerland; <http://ligwww.epfl.ch/>.
- Department of Computer Science, University of North Carolina at Chapel Hill; <http://www.cs.unc.edu/>.
- Electronic Systems Technology Office of the Advanced Research Projects Agency (ARPA). Although not a research lab, this agency provides information on research it funds at several institutions in the United States; <http://www.arpa.mil/>.
- Electronic Visualization Lab, University of Illinois at Chicago; <http://evlweb.eecs.uic.edu/>.
- Graphics Visualization Center, Georgia Institute of Technology; <http://www.gvu.gatech.edu/>.
- Human Interface Technology Lab, University of Washington; <http://www.hitl.washington.edu/>.
- I-CARVE Lab (Laboratory for Integrated Computer Aided Research in Concurrent and Virtual Design), University of Wisconsin Department of Mechanical Engineering; <http://www.engr.wisc.edu/me/>.
- Information Systems Department, Technical University of Delft, the Netherlands; <http://www.its.tudelft.nl/>.
- Institute for Simulation and Training Visual Systems Lab, University of Central Florida, <http://www.vsl.ist.ucf.edu/>.
- Iwata Lab, University of Tsukuba, Japan; <http://intron.kz.tsukuba.ac.jp/>.
- Korean Advance Institute for Science and Technology; <http://dangun.kaist.ac.kr/>.
- Navigating and Acting in Virtual Environments (NAVE) Research Group, Department of Computer Science and Institute of Cognitive Science, University of Colorado at Boulder; <http://psych-www.colorado.edu/ics/home.html>.
- NPSNET Research Group, Naval Postgraduate School; <http://www.nps.navy.mil/>.
- Mobile Aeronautics Education Lab Virtual Reality Station, NASA; <http://www.grc.nasa.gov/WWW/MAELVRSTATION/>.
- Graphics Research and Analysis Facility (GRAF), NASA Lyndon B. Johnson Space Center; http://jsc-web-pub.jsc.nasa.gov/fpd/SHFB/GRAF/GRAF_Home.html.
- Studio for Creative Inquiry, Carnegie Mellon University; <http://www.cmu.edu/studio/index.html>.
- User Interface Group, University of Virginia Computer Science Department; <http://www.cs.virginia.edu/> or <http://www.cs.cmu.edu/~stage3/>.
- Virtual Reality Lab, National Center for Supercomputing Applications; <http://www.ncsa.uiuc.edu/>.
- Vision and Autonomous System Center (VASC), Carnegie Mellon University, <http://www.vasc.ri.cmu.edu/>.

Subject Index

Note: (fig) denotes a figure; (tab) denotes a table

A

abdominal simulator, 947 (fig)
above real-time training (ARTT), 383
absolute positional device, 286
academic learning tool, VE as, 893
 NICE project, 902–904
 prebuilt world/discovery learning/constructivism
 gorilla exhibit, 899–900
 Science/Space project, 897–899
 role-playing/situated learning, 904–905
 AutoLand, 908
 DinoLand, 908
 ExploreNet, 906–909
 Round-Earth Project, 905–906
 Zora's world, 907–908
use of VE in education, 893, 895–896
 constructivism, 896
 obstacle to, 894–895
 reason for using, 894
 situated learning, 896–897
VRRV project, 901–902. *See also* education;
 education, development of VLE for;
 education, evaluation of VLE for
acceleration, aftereffect of, 591. *See also* accelerator
 perception; body acceleration
accelerator perception
 eliciting, 140–141

involving user acceleration, 138–139
not involving user acceleration, 139–140
accelerometer/gravimetric tilt sensing, 177
accident, from VE aftereffect, 544, 598
accommodation, 17, 37, 50, 57, 722–723, 726, 736–737
accuracy, 282
ACE. *See* ADAPTIVE Communication Environment
acoustic, physical, 68–69
acoustical rearrangement, 625
acoustic head shadow, 73
acrophobia, 1068
action sequence knowledge, 420
active virtual guide. *See* virtual fixture
Active Worlds, 350
activity design, 1129
activity execution
 control/monitoring, 1135
 planning, 1132–1134
 training for, 1131–1132
acupressure, 655
adaptation, 774
adaptation, to VE, 619
controlling/facilitating variable
 by active interaction, 626–627
 by distributed practice, 629
 by error-corrective feedback, 627
 by immediate sensory feedback, 628
 by incremental exposure, 629
 by stable rearrangement, 626
deficiency in VE, 621
depth/distance distortion, 622–623

- adaptation, to VE (*cont.*)
 form/size distortion, 623–624
 intersensory conflict, 621–622
 sensory “disarrangement,” 624–625
 sensory feedback delay, 624
 drawback to maximal adaptation
 eliminating aftereffect, 631–633
 negative aftereffect/negative transfer, 630–631
 individual difference, role of, 633
 measuring, 621
 need for research on, 59
 optimal adaptation training
 deliberate intersensory discordance, 630
 procedure for, 629–630
 response to user complaint, 620–621
 user complaint, 620 (tab)
- ADAPTIVE Communication Environment (ACE), 349
- ADD. *See* attention deficit disorder
- addiction, to computer interaction, 676–677
- adoption, of technology, 534–535
- adverse effect, 724–726
- aerial perspective, 36
- aero engineering, 831–833 (fig), 832 (fig)
- affective facial expression, 318
- affordances, 283, 284
- After Action Review (AAR) System, 865
- aftereffect, 10–11, 12, 631–633, 774
 defined, 17
 eliminating, 631–634
 flight simulator, 545, 546
 following product usage, 544–546
 head-mounted display (HMD), 545
 negative, 630–631, 774–775, 1002
 physiological, 10–11
 and product liability, 544–546
 psychological, 10. *See also* human syndrome,
 sign/symptom of; proprioceptive adaptation,
 and aftereffect; visual aftereffect, of binocular
 VE
- age, user, 387–389
- agency, 523
- agent
 autonomous, 7
 belief, desire, intention (BDI), 324
 defined, 313–314
 practical reasoning, 324
 Steve (intelligent agent), 432, 433 (fig), 883. *See also*
 embodied autonomous agent
- agent-based algorithm, 441
- aggressive behavior, 11
- aggressive interaction, 671–672
- agoraphobia, 1067–1068
- AI. *See* artificial intelligence
- aircraft design, 1086–1089, 1087 (fig)
- aircraft simulator, 621–622
- airforce avionics training, 837–838 (fig)
- alcohol, 726
- altered lens, 545
- amblyopia, 738
- American National Standards Institution (ANSI), 16, 26, 701–702
- Americans with Disabilities Act, 95
- anaglyphic glasses, 55–56
- anaglyphic technique, for stereo vision, 51, 52, 56
- Anastomosis Simulator, 950–951 (fig)
- anechoic distance cue, 74
- anechoic environment, 74
- animation, 520
- aniso-accommodation, 737
- ANSI. *See* American National Standards Institution
- anthropometrics, 808 (tab), 812–813 (tab), 814 (tab)
- antisocial behavior, 11
- application, overview of, 827–828
 aero engineering, 831–833 (fig), 832 (fig)
 airforce avionics training, 837–838 (fig)
 close-range weaponry simulation, 838–839 (fig)
 database/scientific visualization, 852–854 (fig), 853 (fig)
 defense, 837–842
 education, 849–852, 851 (fig)
 engineering, 828–830, 829 (fig)
 ergonomic/human factor, 836 (fig)–837 (fig)
 land mine detection training, 842 (fig)
 medicine/surgery, 94, 842–844 (fig), 939, 1173
 micro-/nano-technology, 830 (fig)–831
 retail, 848–849 (fig), 850 (fig)
 Royal Navy submarine qualification, 839–840 (fig)
 space engineering, 833–835 (fig), 834 (fig)
 submarine training, 840–842, 841 (fig)
 virtual heritage, 844–847 (fig), 845 (fig), 846 (fig)
- application design, individual difference and, 379–381
- performance and, 381–382
- personality traits/virtual collaboration, 392–393
- presence experience, 391–392, 394
- remote v proximate access, 394
 behavioral cybernetics, 394–396
 design effect of, 396–397
 perturbation source, 395–396
- user experience and, 382–385
 disability accommodation, 389
 personality trait, 390
 reasoning aptitude, 387
 sense of reality, 390–391
 spatial aptitude, 386
 team experience, 385
 technical aptitude, 386
 user age and, 387–389
- application task analysis, 359 (fig)
- AR. *See* augmented reality
- archetype, 17
- architectural design, 499, 522–523, 1089 (fig)–1093, 1090 (fig), 1091 (fig), 1172
- architecture
 deliberative, 323
 human-centered, in CAT, 973–976, 975 (fig), 977 (fig)
 hybrid, 323
 multimodal input, 438–439

- reactive, 323
 tutor architecture, 420–422 (fig), 421 (fig)
- arm-extension technique, 291
 arm gesture, 232–233
 arousal theory, 668, 669 (tab)
 Arthroscopy simulator, 951–952 (fig)
 artificial intelligence (AI), 1149–1150
 artificial life, 1149
 artistic design, 1098
ARTT. *See* above real-time training
 assembly/disassembly, 1136–1137
 assisted teleoperation. *See* computer assisted teleoperation (CAT)
 associated heterophoria, 744
 astigmatic, 732
 asynchrony, 610
 ATR locomotion interface, 246–247
 attentional inertia, 17
 attention deficit disorder (ADD), 1030, 1034–1036, 1071–1072
 attitudes, 17
 attractors, 525–526, 527–528
 Aubert effect/phenomenon, 17
 audification, 17. *See also* sonification
 audiogyril illusion, 68
 audio-visual cross modality, 455–456
 audio-visual sensory interaction
 in auditory scene analysis, 459
 cross-modal matching, 459–460
 in entertainment industry, 459
 visual dominance, 460–463
 intersensory research perspective
 neurological, 458
 theoretical, 456–458
 suprathreshold perception experiment, 464–467, 466 (tab)
 threshold perception experiment, 463
 audiovisual media, music and, 464–465
 auditory collision cue, 67
 auditory cue, 65
 auditory display, 68
 auditory masking, 71
 auditory meatus, 87
 auditory scene analysis, 77–78, 459
 auditory sensitivity
 auditory scene analysis, 77–78
 frequency analysis, 70
 intensity perception, 70–71
 masking effect, 71
 pitch, 71–72
 spatial hearing, 72–77
 speech perception, 78
 temporal resolution, 72
 timbre, 72. *See also* virtual audio
- auditory system, direct effect of VE on, 585–586 (tab)
 auditory-visual compellingness, 460–461
 augmented reality (AR), 17, 1124, 1162–1163
 AuSim Acoustetron, 87
 AuSim GoldServer, 86
- autism, 1072
 autogenic feedback, 654–655
 autokinetic effect, 45
 AutoLand, 339 (fig)
 automatic teller machine (ATM), 373, 374 (tab)
 autonomic nervous system (ANS), 637, 638, 640–642
 autonomous agent, 7
 use in national defense training, 862–863
 virtual team member as, 875–876. *See also* embodied autonomous agent
 autonomous behavior. *See* embodied autonomous agent
 autostereoscopic system, 55, 56
 avatar, 17, 94, 172–173, 524, 666–667, 675, 937–938, 1147, 1148, 1149, 1155, 1160
 aviation enhancement, 148–149
